scikit-learn user guide

Release 0.22.2

scikit-learn developers

Mar 04, 2020

CONTENTS

CHAPTER

ONE

WELCOME TO SCIKIT-LEARN

1.1 Installing scikit-learn

There are different ways to install scikit-learn:

- *Install the latest official release*. This is the best approach for most users. It will provide a stable version and pre-built packages are available for most platforms.
- Install the version of scikit-learn provided by your *operating system or Python distribution*. This is a quick option for those who have operating systems or Python distributions that distribute scikit-learn. It might not provide the latest release version.
- *Building the package from source*. This is best for users who want the latest-and-greatest features and aren't afraid of running brand-new code. This is also needed for users who wish to contribute to the project.

1.1.1 Installing the latest release

Then run:

In order to check your installation you can use

Note that in order to avoid potential conflicts with other packages it is strongly recommended to use a virtual environment, e.g. python3 `virtualenv` (see python3 virtualenv documentation) or conda environments.

Using an isolated environment makes possible to install a specific version of scikit-learn and its dependencies independently of any previously installed Python packages. In particular under Linux is it discouraged to install pip packages alongside the packages managed by the package manager of the distribution (apt, dnf, pacman...).

Note that you should always remember to activate the environment of your choice prior to running any Python command whenever you start a new terminal session.

If you have not installed NumPy or SciPy yet, you can also install these using conda or pip. When using pip, please ensure that *binary wheels* are used, and NumPy and SciPy are not recompiled from source, which can happen when using particular configurations of operating system and hardware (such as Linux on a Raspberry Pi).

If you must install scikit-learn and its dependencies with pip, you can install it as `scikit-learn[alldeps]`.

Scikit-learn plotting capabilities (i.e., functions start with "plot_" and classes end with "Display") require Matplotlib (>= 1.5.1). For running the examples Matplotlib >= 1.5.1 is required. A few examples require scikit-image >= 0.12.3, a few examples require pandas >= 0.18.0.

Warning: Scikit-learn 0.20 was the last version to support Python 2.7 and Python 3.4. Scikit-learn now requires Python 3.5 or newer.

Note: For installing on PyPy, PyPy3-v5.10+, Numpy 1.14.0+, and scipy 1.1.0+ are required.

1.1.2 Third party distributions of scikit-learn

Some third-party distributions provide versions of scikit-learn integrated with their package-management systems.

These can make installation and upgrading much easier for users since the integration includes the ability to automatically install dependencies (numpy, scipy) that scikit-learn requires.

The following is an incomplete list of OS and python distributions that provide their own version of scikit-learn.

Arch Linux

Arch Linux's package is provided through the official repositories as `python-scikit-learn` for Python. It can be installed by typing the following command:

```
$ sudo pacman -S python-scikit-learn
```

Debian/Ubuntu

The Debian/Ubuntu package is splitted in three different packages called `python3-sklearn` (python modules), `python3-sklearn-lib` (low-level implementations and bindings), `python3-sklearn-doc` (documentation). Only the Python 3 version is available in the Debian Buster (the more recent Debian distribution). Packages can be installed using `apt-get`:

```
$ sudo apt-get install python3-sklearn python3-sklearn-lib python3-sklearn-doc
```

Fedora

The Fedora package is called `python3-scikit-learn` for the python 3 version, the only one available in Fedora30. It can be installed using `dnf`:

```
$ sudo dnf install python3-scikit-learn
```

NetBSD

scikit-learn is available via pkgsrc-wip:

http://pkgsrc.se/math/py-scikit-learn

MacPorts for Mac OSX

The MacPorts package is named `py<XY>-scikits-learn`, where `XY` denotes the Python version. It can be installed by typing the following command:

```
$ sudo port install py36-scikit-learn
```

Canopy and Anaconda for all supported platforms

Canopy and Anaconda both ship a recent version of scikit-learn, in addition to a large set of scientific python library for Windows, Mac OSX and Linux.

Anaconda offers scikit-learn as part of its free distribution.

Intel conda channel

Intel maintains a dedicated conda channel that ships scikit-learn:

```
$ conda install -c intel scikit-learn
```

This version of scikit-learn comes with alternative solvers for some common estimators. Those solvers come from the DAAL C++ library and are optimized for multi-core Intel CPUs.

Note that those solvers are not enabled by default, please refer to the daal4py documentation for more details.

Compatibility with the standard scikit-learn solvers is checked by running the full scikit-learn test suite via automated continuous integration as reported on https://github.com/IntelPython/daal4py.

WinPython for Windows

The WinPython project distributes scikit-learn as an additional plugin.

1.1.3 Troubleshooting

Error caused by file path length limit on Windows

It can happen that pip fails to install packages when reaching the default path size limit of Windows if Python is installed in a nested location such as the `AppData` folder structure under the user home directory, for instance:

```
C:\Users\username>C:\Users\username\AppData\Local\Microsoft\WindowsApps\python.exe -m␣
↪pip install scikit-learn
Collecting scikit-learn
...
Installing collected packages: scikit-learn
ERROR: Could not install packages due to an EnvironmentError: [Errno 2] No such file␣
↪or directory:
↪'C:\\Users\\username\\AppData\\Local\\Packages\\PythonSoftwareFoundation.Python.3.7_
↪qbz5n2kfra8p0\\LocalCache\\local-packages\\Python37\\site-
↪packages\\sklearn\\datasets\\tests\\data\\openml\\292\\api-v1-json-data-list-data_
↪name-australian-limit-2-data_version-1-status-deactivated.json.gz'
```

In this case it is possible to lift that limit in the Windows registry by using the `regedit` tool:

1. Type "regedit" in the Windows start menu to launch `regedit`.

2. Go to the `Computer\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem` key.
3. Edit the value of the `LongPathsEnabled` property of that key and set it to 1.
4. Reinstall scikit-learn (ignoring the previous broken installation):

```
pip install --exists-action=i scikit-learn
```

1.2 Frequently Asked Questions

Here we try to give some answers to questions that regularly pop up on the mailing list.

1.2.1 What is the project name (a lot of people get it wrong)?

scikit-learn, but not scikit or SciKit nor sci-kit learn. Also not scikits.learn or scikits-learn, which were previously used.

1.2.2 How do you pronounce the project name?

sy-kit learn. sci stands for science!

1.2.3 Why scikit?

There are multiple scikits, which are scientific toolboxes built around SciPy. You can find a list at https://scikits.appspot.com/scikits. Apart from scikit-learn, another popular one is scikit-image.

1.2.4 How can I contribute to scikit-learn?

See *Contributing*. Before wanting to add a new algorithm, which is usually a major and lengthy undertaking, it is recommended to start with *known issues*. Please do not contact the contributors of scikit-learn directly regarding contributing to scikit-learn.

1.2.5 What's the best way to get help on scikit-learn usage?

For general machine learning questions, please use Cross Validated with the `[machine-learning]` tag.

For scikit-learn usage questions, please use Stack Overflow with the `[scikit-learn]` and `[python]` tags. You can alternatively use the mailing list.

Please make sure to include a minimal reproduction code snippet (ideally shorter than 10 lines) that highlights your problem on a toy dataset (for instance from `sklearn.datasets` or randomly generated with functions of `numpy.random` with a fixed random seed). Please remove any line of code that is not necessary to reproduce your problem.

The problem should be reproducible by simply copy-pasting your code snippet in a Python shell with scikit-learn installed. Do not forget to include the import statements.

More guidance to write good reproduction code snippets can be found at:

https://stackoverflow.com/help/mcve

If your problem raises an exception that you do not understand (even after googling it), please make sure to include the full traceback that you obtain when running the reproduction script.

For bug reports or feature requests, please make use of the issue tracker on GitHub.

There is also a scikit-learn Gitter channel where some users and developers might be found.

Please do not email any authors directly to ask for assistance, report bugs, or for any other issue related to scikit-learn.

1.2.6 How should I save, export or deploy estimators for production?

See *Model persistence*.

1.2.7 How can I create a bunch object?

Don't make a bunch object! They are not part of the scikit-learn API. Bunch objects are just a way to package some numpy arrays. As a scikit-learn user you only ever need numpy arrays to feed your model with data.

For instance to train a classifier, all you need is a 2D array `X` for the input variables and a 1D array `y` for the target variables. The array `X` holds the features as columns and samples as rows . The array `y` contains integer values to encode the class membership of each sample in `X`.

1.2.8 How can I load my own datasets into a format usable by scikit-learn?

Generally, scikit-learn works on any numeric data stored as numpy arrays or scipy sparse matrices. Other types that are convertible to numeric arrays such as pandas DataFrame are also acceptable.

For more information on loading your data files into these usable data structures, please refer to *loading external datasets*.

1.2.9 What are the inclusion criteria for new algorithms ?

We only consider well-established algorithms for inclusion. A rule of thumb is at least 3 years since publication, 200+ citations and wide use and usefulness. A technique that provides a clear-cut improvement (e.g. an enhanced data structure or a more efficient approximation technique) on a widely-used method will also be considered for inclusion.

From the algorithms or techniques that meet the above criteria, only those which fit well within the current API of scikit-learn, that is a `fit`, `predict/transform` interface and ordinarily having input/output that is a numpy array or sparse matrix, are accepted.

The contributor should support the importance of the proposed addition with research papers and/or implementations in other similar packages, demonstrate its usefulness via common use-cases/applications and corroborate performance improvements, if any, with benchmarks and/or plots. It is expected that the proposed algorithm should outperform the methods that are already implemented in scikit-learn at least in some areas.

Inclusion of a new algorithm speeding up an existing model is easier if:

- it does not introduce new hyper-parameters (as it makes the library more future-proof),
- it is easy to document clearly when the contribution improves the speed and when it does not, for instance "when n_features >> n_samples",
- benchmarks clearly show a speed up.

Also note that your implementation need not be in scikit-learn to be used together with scikit-learn tools. You can implement your favorite algorithm in a scikit-learn compatible way, upload it to GitHub and let us know. We will be happy to list it under *Related Projects*. If you already have a package on GitHub following the scikit-learn API, you may also be interested to look at scikit-learn-contrib.

1.2.10 Why are you so selective on what algorithms you include in scikit-learn?

Code is maintenance cost, and we need to balance the amount of code we have with the size of the team (and add to this the fact that complexity scales non linearly with the number of features). The package relies on core developers using their free time to fix bugs, maintain code and review contributions. Any algorithm that is added needs future attention by the developers, at which point the original author might long have lost interest. See also *What are the inclusion criteria for new algorithms ?*. For a great read about long-term maintenance issues in open-source software, look at the Executive Summary of Roads and Bridges

1.2.11 Why did you remove HMMs from scikit-learn?

See *Will you add graphical models or sequence prediction to scikit-learn?*.

1.2.12 Will you add graphical models or sequence prediction to scikit-learn?

Not in the foreseeable future. scikit-learn tries to provide a unified API for the basic tasks in machine learning, with pipelines and meta-algorithms like grid search to tie everything together. The required concepts, APIs, algorithms and expertise required for structured learning are different from what scikit-learn has to offer. If we started doing arbitrary structured learning, we'd need to redesign the whole package and the project would likely collapse under its own weight.

There are two project with API similar to scikit-learn that do structured prediction:

- pystruct handles general structured learning (focuses on SSVMs on arbitrary graph structures with approximate inference; defines the notion of sample as an instance of the graph structure)
- seqlearn handles sequences only (focuses on exact inference; has HMMs, but mostly for the sake of completeness; treats a feature vector as a sample and uses an offset encoding for the dependencies between feature vectors)

1.2.13 Will you add GPU support?

No, or at least not in the near future. The main reason is that GPU support will introduce many software dependencies and introduce platform specific issues. scikit-learn is designed to be easy to install on a wide variety of platforms. Outside of neural networks, GPUs don't play a large role in machine learning today, and much larger gains in speed can often be achieved by a careful choice of algorithms.

1.2.14 Do you support PyPy?

In case you didn't know, PyPy is an alternative Python implementation with a built-in just-in-time compiler. Experimental support for PyPy3-v5.10+ has been added, which requires Numpy 1.14.0+, and scipy 1.1.0+.

1.2.15 How do I deal with string data (or trees, graphs...)?

scikit-learn estimators assume you'll feed them real-valued feature vectors. This assumption is hard-coded in pretty much all of the library. However, you can feed non-numerical inputs to estimators in several ways.

If you have text documents, you can use a term frequency features; see *Text feature extraction* for the built-in *text vectorizers*. For more general feature extraction from any kind of data, see *Loading features from dicts* and *Feature hashing*.

Another common case is when you have non-numerical data and a custom distance (or similarity) metric on these data. Examples include strings with edit distance (aka. Levenshtein distance; e.g., DNA or RNA sequences). These can be encoded as numbers, but doing so is painful and error-prone. Working with distance metrics on arbitrary data can be done in two ways.

Firstly, many estimators take precomputed distance/similarity matrices, so if the dataset is not too large, you can compute distances for all pairs of inputs. If the dataset is large, you can use feature vectors with only one "feature", which is an index into a separate data structure, and supply a custom metric function that looks up the actual data in this data structure. E.g., to use DBSCAN with Levenshtein distances:

```
>>> from leven import levenshtein
>>> import numpy as np
>>> from sklearn.cluster import dbscan
>>> data = ["ACCTCCTAGAAG", "ACCTACTAGAAGTT", "GAATATTAGGCCGA"]
>>> def lev_metric(x, y):
...     i, j = int(x[0]), int(y[0])     # extract indices
...     return levenshtein(data[i], data[j])
...
>>> X = np.arange(len(data)).reshape(-1, 1)
>>> X
array([[0],
       [1],
       [2]])
>>> # We need to specify algoritum='brute' as the default assumes
>>> # a continuous feature space.
>>> dbscan(X, metric=lev_metric, eps=5, min_samples=2, algorithm='brute')
...
([0, 1], array([ 0,  0, -1]))
```

(This uses the third-party edit distance package `leven`.)

Similar tricks can be used, with some care, for tree kernels, graph kernels, etc.

1.2.16 Why do I sometime get a crash/freeze with n_jobs > 1 under OSX or Linux?

Several scikit-learn tools such as `GridSearchCV` and `cross_val_score` rely internally on Python's `multiprocessing` module to parallelize execution onto several Python processes by passing `n_jobs > 1` as argument.

The problem is that Python `multiprocessing` does a `fork` system call without following it with an `exec` system call for performance reasons. Many libraries like (some versions of) Accelerate / vecLib under OSX, (some versions of) MKL, the OpenMP runtime of GCC, nvidia's Cuda (and probably many others), manage their own internal thread pool. Upon a call to `fork`, the thread pool state in the child process is corrupted: the thread pool believes it has many threads while only the main thread state has been forked. It is possible to change the libraries to make them detect when a fork happens and reinitialize the thread pool in that case: we did that for OpenBLAS (merged upstream in master since 0.2.10) and we contributed a patch to GCC's OpenMP runtime (not yet reviewed).

But in the end the real culprit is Python's `multiprocessing` that does `fork` without `exec` to reduce the overhead of starting and using new Python processes for parallel computing. Unfortunately this is a violation of the POSIX

standard and therefore some software editors like Apple refuse to consider the lack of fork-safety in Accelerate / vecLib as a bug.

In Python 3.4+ it is now possible to configure `multiprocessing` to use the 'forkserver' or 'spawn' start methods (instead of the default 'fork') to manage the process pools. To work around this issue when using scikit-learn, you can set the `JOBLIB_START_METHOD` environment variable to 'forkserver'. However the user should be aware that using the 'forkserver' method prevents joblib.Parallel to call function interactively defined in a shell session.

If you have custom code that uses `multiprocessing` directly instead of using it via joblib you can enable the 'forkserver' mode globally for your program: Insert the following instructions in your main script:

```
import multiprocessing

# other imports, custom code, load data, define model...

if __name__ == '__main__':
    multiprocessing.set_start_method('forkserver')

    # call scikit-learn utils with n_jobs > 1 here
```

You can find more default on the new start methods in the multiprocessing documentation.

1.2.17 Why does my job use more cores than specified with n_jobs?

This is because `n_jobs` only controls the number of jobs for routines that are parallelized with `joblib`, but parallel code can come from other sources:

- some routines may be parallelized with OpenMP (for code written in C or Cython).
- scikit-learn relies a lot on numpy, which in turn may rely on numerical libraries like MKL, OpenBLAS or BLIS which can provide parallel implementations.

For more details, please refer to our *Parallelism notes*.

1.2.18 Why is there no support for deep or reinforcement learning / Will there be support for deep or reinforcement learning in scikit-learn?

Deep learning and reinforcement learning both require a rich vocabulary to define an architecture, with deep learning additionally requiring GPUs for efficient computing. However, neither of these fit within the design constraints of scikit-learn; as a result, deep learning and reinforcement learning are currently out of scope for what scikit-learn seeks to achieve.

You can find more information about addition of gpu support at *Will you add GPU support?*.

1.2.19 Why is my pull request not getting any attention?

The scikit-learn review process takes a significant amount of time, and contributors should not be discouraged by a lack of activity or review on their pull request. We care a lot about getting things right the first time, as maintenance and later change comes at a high cost. We rarely release any "experimental" code, so all of our contributions will be subject to high use immediately and should be of the highest quality possible initially.

Beyond that, scikit-learn is limited in its reviewing bandwidth; many of the reviewers and core developers are working on scikit-learn on their own time. If a review of your pull request comes slowly, it is likely because the reviewers are busy. We ask for your understanding and request that you not close your pull request or discontinue your work solely because of this reason.

1.2.20 How do I set a `random_state` for an entire execution?

For testing and replicability, it is often important to have the entire execution controlled by a single seed for the pseudo-random number generator used in algorithms that have a randomized component. Scikit-learn does not use its own global random state; whenever a RandomState instance or an integer random seed is not provided as an argument, it relies on the numpy global random state, which can be set using `numpy.random.seed`. For example, to set an execution's numpy global random state to 42, one could execute the following in his or her script:

```
import numpy as np
np.random.seed(42)
```

However, a global random state is prone to modification by other code during execution. Thus, the only way to ensure replicability is to pass `RandomState` instances everywhere and ensure that both estimators and cross-validation splitters have their `random_state` parameter set.

1.2.21 Why do categorical variables need preprocessing in scikit-learn, compared to other tools?

Most of scikit-learn assumes data is in NumPy arrays or SciPy sparse matrices of a single numeric dtype. These do not explicitly represent categorical variables at present. Thus, unlike R's data.frames or pandas.DataFrame, we require explicit conversion of categorical features to numeric values, as discussed in *Encoding categorical features*. See also *Column Transformer with Mixed Types* for an example of working with heterogeneous (e.g. categorical and numeric) data.

1.2.22 Why does Scikit-learn not directly work with, for example, pandas.DataFrame?

The homogeneous NumPy and SciPy data objects currently expected are most efficient to process for most operations. Extensive work would also be needed to support Pandas categorical types. Restricting input to homogeneous types therefore reduces maintenance cost and encourages usage of efficient data structures.

1.2.23 Do you plan to implement transform for target y in a pipeline?

Currently transform only works for features X in a pipeline. There's a long-standing discussion about not being able to transform y in a pipeline. Follow on github issue #4143. Meanwhile check out *`sklearn.compose.TransformedTargetRegressor`*, pipegraph, imbalanced-learn. Note that Scikit-learn solved for the case where y has an invertible transformation applied before training and inverted after prediction. Scikit-learn intends to solve for use cases where y should be transformed at training time and not at test time, for resampling and similar uses, like at imbalanced learn. In general, these use cases can be solved with a custom meta estimator rather than a Pipeline

1.3 Support

There are several ways to get in touch with the developers.

1.3.1 Mailing List

- The main mailing list is scikit-learn.
- There is also a commit list scikit-learn-commits, where updates to the main repository and test failures get notified.

1.3.2 User questions

- Some scikit-learn developers support users on StackOverflow using the [scikit-learn] tag.
- For general theoretical or methodological Machine Learning questions stack exchange is probably a more suitable venue.

In both cases please use a descriptive question in the title field (e.g. no "Please help with scikit-learn!" as this is not a question) and put details on what you tried to achieve, what were the expected results and what you observed instead in the details field.

Code and data snippets are welcome. Minimalistic (up to ~20 lines long) reproduction script very helpful.

Please describe the nature of your data and the how you preprocessed it: what is the number of samples, what is the number and type of features (i.d. categorical or numerical) and for supervised learning tasks, what target are your trying to predict: binary, multiclass (1 out of `n_classes`) or multilabel (`k` out of `n_classes`) classification or continuous variable regression.

1.3.3 Bug tracker

If you think you've encountered a bug, please report it to the issue tracker:

https://github.com/scikit-learn/scikit-learn/issues

Don't forget to include:

- steps (or better script) to reproduce,
- expected outcome,
- observed outcome or python (or gdb) tracebacks

To help developers fix your bug faster, please link to a https://gist.github.com holding a standalone minimalistic python script that reproduces your bug and optionally a minimalistic subsample of your dataset (for instance exported as CSV files using `numpy.savetxt`).

Note: gists are git cloneable repositories and thus you can use git to push datafiles to them.

1.3.4 IRC

Some developers like to hang out on channel `#scikit-learn` on `irc.freenode.net`.

If you do not have an IRC client or are behind a firewall this web client works fine: https://webchat.freenode.net

1.3.5 Documentation resources

This documentation is relative to 0.22.2. Documentation for other versions can be found here.

Printable pdf documentation for old versions can be found here.

1.4 Related Projects

Projects implementing the scikit-learn estimator API are encouraged to use the scikit-learn-contrib template which facilitates best practices for testing and documenting estimators. The scikit-learn-contrib GitHub organisation also accepts high-quality contributions of repositories conforming to this template.

Below is a list of sister-projects, extensions and domain specific packages.

1.4.1 Interoperability and framework enhancements

These tools adapt scikit-learn for use with other technologies or otherwise enhance the functionality of scikit-learn's estimators.

Data formats

- sklearn_pandas bridge for scikit-learn pipelines and pandas data frame with dedicated transformers.
- sklearn_xarray provides compatibility of scikit-learn estimators with xarray data structures.

Auto-ML

- auto_ml Automated machine learning for production and analytics, built on scikit-learn and related projects. Trains a pipeline wth all the standard machine learning steps. Tuned for prediction speed and ease of transfer to production environments.
- auto-sklearn An automated machine learning toolkit and a drop-in replacement for a scikit-learn estimator
- TPOT An automated machine learning toolkit that optimizes a series of scikit-learn operators to design a machine learning pipeline, including data and feature preprocessors as well as the estimators. Works as a drop-in replacement for a scikit-learn estimator.
- scikit-optimize A library to minimize (very) expensive and noisy black-box functions. It implements several methods for sequential model-based optimization, and includes a replacement for `GridSearchCV` or `RandomizedSearchCV` to do cross-validated parameter search using any of these strategies.

Experimentation frameworks

- REP Environment for conducting data-driven research in a consistent and reproducible way
- ML Frontend provides dataset management and SVM fitting/prediction through web-based and programmatic interfaces.
- Scikit-Learn Laboratory A command-line wrapper around scikit-learn that makes it easy to run machine learning experiments with multiple learners and large feature sets.
- Xcessiv is a notebook-like application for quick, scalable, and automated hyperparameter tuning and stacked ensembling. Provides a framework for keeping track of model-hyperparameter combinations.

Model inspection and visualisation

- eli5 A library for debugging/inspecting machine learning models and explaining their predictions.
- mlxtend Includes model visualization utilities.
- scikit-plot A visualization library for quick and easy generation of common plots in data analysis and machine learning.
- yellowbrick A suite of custom matplotlib visualizers for scikit-learn estimators to support visual feature analysis, model selection, evaluation, and diagnostics.

Model export for production

- onnxmltools Serializes many Scikit-learn pipelines to ONNX for interchange and prediction.
- sklearn2pmml Serialization of a wide variety of scikit-learn estimators and transformers into PMML with the help of JPMML-SkLearn library.
- sklearn-porter Transpile trained scikit-learn models to C, Java, Javascript and others.
- sklearn-compiledtrees Generate a C++ implementation of the predict function for decision trees (and ensembles) trained by sklearn. Useful for latency-sensitive production environments.

1.4.2 Other estimators and tasks

Not everything belongs or is mature enough for the central scikit-learn project. The following are projects providing interfaces similar to scikit-learn for additional learning algorithms, infrastructures and tasks.

Structured learning

- sktime A scikit-learn compatible toolbox for machine learning with time series including time series classification/regression and (supervised/panel) forecasting.
- Seqlearn Sequence classification using HMMs or structured perceptron.
- HMMLearn Implementation of hidden markov models that was previously part of scikit-learn.
- PyStruct General conditional random fields and structured prediction.
- pomegranate Probabilistic modelling for Python, with an emphasis on hidden Markov models.
- sklearn-crfsuite Linear-chain conditional random fields (CRFsuite wrapper with sklearn-like API).

Deep neural networks etc.

- pylearn2 A deep learning and neural network library build on theano with scikit-learn like interface.
- sklearn_theano scikit-learn compatible estimators, transformers, and datasets which use Theano internally
- nolearn A number of wrappers and abstractions around existing neural network libraries
- keras Deep Learning library capable of running on top of either TensorFlow or Theano.
- lasagne A lightweight library to build and train neural networks in Theano.
- skorch A scikit-learn compatible neural network library that wraps PyTorch.

Broad scope

- mlxtend Includes a number of additional estimators as well as model visualization utilities.
- sparkit-learn Scikit-learn API and functionality for PySpark's distributed modelling.

Other regression and classification

- xgboost Optimised gradient boosted decision tree library.
- ML-Ensemble Generalized ensemble learning (stacking, blending, subsemble, deep ensembles, etc.).
- lightning Fast state-of-the-art linear model solvers (SDCA, AdaGrad, SVRG, SAG, etc...).
- py-earth Multivariate adaptive regression splines
- Kernel Regression Implementation of Nadaraya-Watson kernel regression with automatic bandwidth selection
- gplearn Genetic Programming for symbolic regression tasks.
- multiisotonic Isotonic regression on multidimensional features.
- scikit-multilearn Multi-label classification with focus on label space manipulation.
- seglearn Time series and sequence learning using sliding window segmentation.

Decomposition and clustering

- lda: Fast implementation of latent Dirichlet allocation in Cython which uses Gibbs sampling to sample from the true posterior distribution. (scikit-learn's `sklearn.decomposition.LatentDirichletAllocation` implementation uses variational inference to sample from a tractable approximation of a topic model's posterior distribution.)
- Sparse Filtering Unsupervised feature learning based on sparse-filtering

- kmodes k-modes clustering algorithm for categorical data, and several of its variations.
- hdbscan HDBSCAN and Robust Single Linkage clustering algorithms for robust variable density clustering.
- spherecluster Spherical K-means and mixture of von Mises Fisher clustering routines for data on the unit hypersphere.

Pre-processing

- categorical-encoding A library of sklearn compatible categorical variable encoders.
- imbalanced-learn Various methods to under- and over-sample datasets.

1.4.3 Statistical learning with Python

Other packages useful for data analysis and machine learning.

- Pandas Tools for working with heterogeneous and columnar data, relational queries, time series and basic statistics.
- theano A CPU/GPU array processing framework geared towards deep learning research.
- statsmodels Estimating and analysing statistical models. More focused on statistical tests and less on prediction than scikit-learn.
- PyMC Bayesian statistical models and fitting algorithms.
- Sacred Tool to help you configure, organize, log and reproduce experiments
- Seaborn Visualization library based on matplotlib. It provides a high-level interface for drawing attractive statistical graphics.
- Deep Learning A curated list of deep learning software libraries.

Recommendation Engine packages

- GraphLab Implementation of classical recommendation techniques (in C++, with Python bindings).
- implicit, Library for implicit feedback datasets.
- lightfm A Python/Cython implementation of a hybrid recommender system.
- OpenRec TensorFlow-based neural-network inspired recommendation algorithms.
- Spotlight Pytorch-based implementation of deep recommender models.
- Surprise Lib Library for explicit feedback datasets.

Domain specific packages

- scikit-image Image processing and computer vision in python.
- Natural language toolkit (nltk) Natural language processing and some machine learning.
- gensim A library for topic modelling, document indexing and similarity retrieval
- NiLearn Machine learning for neuro-imaging.
- AstroML Machine learning for astronomy.
- MSMBuilder Machine learning for protein conformational dynamics time series.
- scikit-surprise A scikit for building and evaluating recommender systems.

1.4.4 Snippets and tidbits

The wiki has more!

1.5 About us

1.5.1 History

This project was started in 2007 as a Google Summer of Code project by David Cournapeau. Later that year, Matthieu Brucher started work on this project as part of his thesis.

In 2010 Fabian Pedregosa, Gael Varoquaux, Alexandre Gramfort and Vincent Michel of INRIA took leadership of the project and made the first public release, February the 1st 2010. Since then, several releases have appeared following a ~3 month cycle, and a thriving international community has been leading the development.

1.5.2 Governance

The decision making process and governance structure of scikit-learn is laid out in the *governance document*.

1.5.3 Authors

The following people are currently core contributors to scikit-learn's development and maintenance:

Please do not email the authors directly to ask for assistance or report issues. Instead, please see What's the best way to ask questions about scikit-learn in the FAQ.

See also:

How you can contribute to the project

1.5.4 Emeritus Core Developers

The following people have been active contributors in the past, but are no longer active in the project:

- Mathieu Blondel
- Matthieu Brucher
- Lars Buitinck
- David Cournapeau
- Noel Dawe
- Shiqiao Du
- Vincent Dubourg
- Edouard Duchesnay
- Alexander Fabisch
- Virgile Fritsch
- Satrajit Ghosh
- Angel Soler Gollonet

- Chris Gorgolewski
- Jaques Grobler
- Brian Holt
- Arnaud Joly
- Thouis (Ray) Jones
- Kyle Kastner
- manoj kumar
- Robert Layton
- Wei Li
- Paolo Losi
- Gilles Louppe
- Vincent Michel
- Jarrod Millman
- Alexandre Passos
- Fabian Pedregosa
- Peter Prettenhofer
- (Venkat) Raghav, Rajagopalan
- Jacob Schreiber
- Jake Vanderplas
- David Warde-Farley
- Ron Weiss

1.5.5 Citing scikit-learn

If you use scikit-learn in a scientific publication, we would appreciate citations to the following paper:

> Scikit-learn: Machine Learning in Python, Pedregosa *et al.*, JMLR 12, pp. 2825-2830, 2011.
>
> Bibtex entry:

```
@article{scikit-learn,
 title={Scikit-learn: Machine Learning in {P}ython},

1.5.6 Artwork

High quality PNG and SVG logos are available in the doc/logos/ source directory.

1.5.7 Funding

Scikit-Learn is a community driven project, however institutional and private grants help to assure its sustainability.

The project would like to thank the following funders.

The Members of the Scikit-Learn Consortium at Inria Foundation fund Olivier Grisel, Guillaume Lemaitre, Jérémie du Boisberranger and Chiara Marmo.

Columbia University funds Andreas Müller since 2016

Andreas Müller received a grant to improve scikit-learn from the Alfred P. Sloan Foundation . This grant supports the position of Nicolas Hug and Thomas J. Fan.

The University of Sydney funds Joel Nothman since July 2017.

Anaconda, Inc funds Adrin Jalali since 2019.

Past Sponsors

INRIA actively supports this project. It has provided funding for Fabian Pedregosa (2010-2012), Jaques Grobler (2012-2013) and Olivier Grisel (2013-2017) to work on this project full-time. It also hosts coding sprints and other events.

Paris-Saclay Center for Data Science funded one year for a developer to work on the project full-time (2014-2015), 50% of the time of Guillaume Lemaitre (2016-2017) and 50% of the time of Joris van den Bossche (2017-2018).

NYU Moore-Sloan Data Science Environment funded Andreas Mueller (2014-2016) to work on this project. The Moore-Sloan Data Science Environment also funds several students to work on the project part-time.

Télécom Paristech funded Manoj Kumar (2014), Tom Dupré la Tour (2015), Raghav RV (2015-2017), Thierry Guillemot (2016-2017) and Albert Thomas (2017) to work on scikit-learn.

The Labex DigiCosme funded Nicolas Goix (2015-2016), Tom Dupré la Tour (2015-2016 and 2017-2018), Mathurin Massias (2018-2019) to work part time on scikit-learn during their PhDs. It also funded a scikit-learn coding sprint in 2015.

The following students were sponsored by Google to work on scikit-learn through the Google Summer of Code program.

- 2007 - David Cournapeau
- 2011 - Vlad Niculae
- 2012 - Vlad Niculae, Immanuel Bayer.
- 2013 - Kemal Eren, Nicolas Trésegnie
- 2014 - Hamzeh Alsalhi, Issam Laradji, Maheshakya Wijewardena, Manoj Kumar.
- 2015 - Raghav RV, Wei Xue

- 2016 - Nelson Liu, YenChen Lin

The NeuroDebian project providing Debian packaging and contributions is supported by Dr. James V. Haxby (Dartmouth College).

1.5.8 Sprints

The International 2019 Paris sprint was kindly hosted by AXA. Also some participants could attend thanks to the support of the Alfred P. Sloan Foundation, the Python Software Foundation (PSF) and the DATAIA Institute.

The 2013 International Paris Sprint was made possible thanks to the support of Télécom Paristech, tinyclues, the French Python Association and the Fonds de la Recherche Scientifique.

The 2011 International Granada sprint was made possible thanks to the support of the PSF and tinyclues.

Donating to the project

If you are interested in donating to the project or to one of our code-sprints, you can use the *Paypal* button below or the NumFOCUS Donations Page (if you use the latter, please indicate that you are donating for the scikit-learn project).

All donations will be handled by NumFOCUS, a non-profit-organization which is managed by a board of Scipy community members. NumFOCUS's mission is to foster scientific computing software, in particular in Python. As a fiscal home of scikit-learn, it ensures that money is available when needed to keep the project funded and available while in compliance with tax regulations.

The received donations for the scikit-learn project mostly will go towards covering travel-expenses for code sprints, as well as towards the organization budget of the project[1].

Notes

1.5.9 Infrastructure support

- We would like to thank Rackspace for providing us with a free Rackspace Cloud account to automatically build the documentation and the example gallery from for the development version of scikit-learn using this tool.
- We would also like to thank Microsoft Azure, Travis Cl, CircleCl for free CPU time on their Continuous Integration servers.

1.6 Who is using scikit-learn?

1.6.1 J.P.Morgan

Scikit-learn is an indispensable part of the Python machine learning toolkit at JPMorgan. It is very widely used across all parts of the bank for classification, predictive analytics, and very many other machine learning tasks. Its

[1] Regarding the organization budget in particular, we might use some of the donated funds to pay for other project expenses such as DNS, hosting or continuous integration services.

straightforward API, its breadth of algorithms, and the quality of its documentation combine to make scikit-learn simultaneously very approachable and very powerful.

Stephen Simmons, VP, Athena Research, JPMorgan

J.P.Morgan

1.6.2 Spotify

Scikit-learn provides a toolbox with solid implementations of a bunch of state-of-the-art models and makes it easy to plug them into existing applications. We've been using it quite a lot for music recommendations at Spotify and I think it's the most well-designed ML package I've seen so far.

Erik Bernhardsson, Engineering Manager Music Discovery & Machine Learning, Spotify

1.6.3 Inria

At INRIA, we use scikit-learn to support leading-edge basic research in many teams: Parietal for neuroimaging, Lear for computer vision, Visages for medical image analysis, Privatics for security. The project is a fantastic tool to address difficult applications of machine learning in an academic environment as it is performant and versatile, but all easy-to-use and well documented, which makes it well suited to grad students.

Gaël Varoquaux, research at Parietal

1.6.4 betaworks

Betaworks is a NYC-based startup studio that builds new products, grows companies, and invests in others. Over the past 8 years we've launched a handful of social data analytics-driven services, such as Bitly, Chartbeat, digg and Scale Model. Consistently the betaworks data science team uses Scikit-learn for a variety of tasks. From exploratory analysis, to product development, it is an essential part of our toolkit. Recent uses are included in digg's new video recommender system, and Poncho's dynamic heuristic subspace clustering.

Gilad Lotan, Chief Data Scientist

1.6.5 Hugging Face

At Hugging Face we're using NLP and probabilistic models to generate conversational Artificial intelligences that are fun to chat with. Despite using deep neural nets for a few of our NLP tasks, scikit-learn is still the bread-and-butter of our daily machine learning routine. The ease of use and predictability of the interface, as well as the straightforward mathematical explanations that are here when you need them, is the killer feature. We use a variety of scikit-learn models in production and they are also operationally very pleasant to work with.

Julien Chaumond, Chief Technology Officer

1.6.6 Evernote

Building a classifier is typically an iterative process of exploring the data, selecting the features (the attributes of the data believed to be predictive in some way), training the models, and finally evaluating them. For many of these tasks, we relied on the excellent scikit-learn package for Python.

Read more

Mark Ayzenshtat, VP, Augmented Intelligence

1.6.7 Télécom ParisTech

At Telecom ParisTech, scikit-learn is used for hands-on sessions and home assignments in introductory and advanced machine learning courses. The classes are for undergrads and masters students. The great benefit of scikit-learn is its fast learning curve that allows students to quickly start working on interesting and motivating problems.

Alexandre Gramfort, Assistant Professor

1.6.8 Booking.com

At Booking.com, we use machine learning algorithms for many different applications, such as recommending hotels and destinations to our customers, detecting fraudulent reservations, or scheduling our customer service agents. Scikit-learn is one of the tools we use when implementing standard algorithms for prediction tasks. Its API and documentations are excellent and make it easy to use. The scikit-learn developers do a great job of incorporating state of the art implementations and new algorithms into the package. Thus, scikit-learn provides convenient access to a wide spectrum of algorithms, and allows us to readily find the right tool for the right job.

Melanie Mueller, Data Scientist

1.6.9 AWeber

The scikit-learn toolkit is indispensable for the Data Analysis and Management team at AWeber. It allows us to do AWesome stuff we would not otherwise have the time or resources to accomplish. The documentation is excellent, allowing new engineers to quickly evaluate and apply many different algorithms to our data. The text feature extraction utilities are useful when working with the large volume of email content we have at AWeber. The RandomizedPCA implementation, along with Pipelining and FeatureUnions, allows us to develop complex machine learning algorithms efficiently and reliably.

Anyone interested in learning more about how AWeber deploys scikit-learn in a production environment should check out talks from PyData Boston by AWeber's Michael Becker available at https://github.com/mdbecker/pydata_2013

Michael Becker, Software Engineer, Data Analysis and Management Ninjas

1.6.10 Yhat

The combination of consistent APIs, thorough documentation, and top notch implementation make scikit-learn our favorite machine learning package in Python. scikit-learn makes doing advanced analysis in Python accessible to anyone. At Yhat, we make it easy to integrate these models into your production applications. Thus eliminating the unnecessary dev time encountered productionizing analytical work.

Greg Lamp, Co-founder Yhat

1.6.11 Rangespan

The Python scikit-learn toolkit is a core tool in the data science group at Rangespan. Its large collection of well documented models and algorithms allow our team of data scientists to prototype fast and quickly iterate to find the right solution to our learning problems. We find that scikit-learn is not only the right tool for prototyping, but its careful and well tested implementation give us the confidence to run scikit-learn models in production.

Jurgen Van Gael, Data Science Director at Rangespan Ltd

1.6.12 Birchbox

At Birchbox, we face a range of machine learning problems typical to E-commerce: product recommendation, user clustering, inventory prediction, trends detection, etc. Scikit-learn lets us experiment with many models, especially in the exploration phase of a new project: the data can be passed around in a consistent way; models are easy to save and reuse; updates keep us informed of new developments from the pattern discovery research community. Scikit-learn is an important tool for our team, built the right way in the right language.

Thierry Bertin-Mahieux, Birchbox, Data Scientist

1.6.13 Bestofmedia Group

Scikit-learn is our #1 toolkit for all things machine learning at Bestofmedia. We use it for a variety of tasks (e.g. spam fighting, ad click prediction, various ranking models) thanks to the varied, state-of-the-art algorithm implementations packaged into it. In the lab it accelerates prototyping of complex pipelines. In production I can say it has proven to be robust and efficient enough to be deployed for business critical components.

Eustache Diemert, Lead Scientist Bestofmedia Group

1.6.14 Change.org

At change.org we automate the use of scikit-learn's RandomForestClassifier in our production systems to drive email targeting that reaches millions of users across the world each week. In the lab, scikit-learn's ease-of-use, performance, and overall variety of algorithms implemented has proved invaluable in giving us a single reliable source to turn to for our machine-learning needs.

Vijay Ramesh, Software Engineer in Data/science at Change.org

1.6.15 PHIMECA Engineering

At PHIMECA Engineering, we use scikit-learn estimators as surrogates for expensive-to-evaluate numerical models (mostly but not exclusively finite-element mechanical models) for speeding up the intensive post-processing operations involved in our simulation-based decision making framework. Scikit-learn's fit/predict API together with its efficient cross-validation tools considerably eases the task of selecting the best-fit estimator. We are also using scikit-learn for illustrating concepts in our training sessions. Trainees are always impressed by the ease-of-use of scikit-learn despite the apparent theoretical complexity of machine learning.

Vincent Dubourg, PHIMECA Engineering, PhD Engineer

1.6.16 HowAboutWe

At HowAboutWe, scikit-learn lets us implement a wide array of machine learning techniques in analysis and in production, despite having a small team. We use scikit-learn's classification algorithms to predict user behavior, enabling us to (for example) estimate the value of leads from a given traffic source early in the lead's tenure on our site. Also, our users' profiles consist of primarily unstructured data (answers to open-ended questions), so we use scikit-learn's feature extraction and dimensionality reduction tools to translate these unstructured data into inputs for our matchmaking system.

Daniel Weitzenfeld, Senior Data Scientist at HowAboutWe

1.6.17 PeerIndex

At PeerIndex we use scientific methodology to build the Influence Graph - a unique dataset that allows us to identify who's really influential and in which context. To do this, we have to tackle a range of machine learning and predictive modeling problems. Scikit-learn has emerged as our primary tool for developing prototypes and making quick progress. From predicting missing data and classifying tweets to clustering communities of social media users, scikit-learn proved useful in a variety of applications. Its very intuitive interface and excellent compatibility with other python tools makes it and indispensable tool in our daily research efforts.

Ferenc Huszar - Senior Data Scientist at Peerindex

1.6.18 DataRobot

DataRobot is building next generation predictive analytics software to make data scientists more productive, and scikit-learn is an integral part of our system. The variety of machine learning techniques in combination with the solid implementations that scikit-learn offers makes it a one-stop-shopping library for machine learning in Python. Moreover, its consistent API, well-tested code and permissive licensing allow us to use it in a production environment. Scikit-learn has literally saved us years of work we would have had to do ourselves to bring our product to market.

Jeremy Achin, CEO & Co-founder DataRobot Inc.

1.6.19 OkCupid

We're using scikit-learn at OkCupid to evaluate and improve our matchmaking system. The range of features it has, especially preprocessing utilities, means we can use it for a wide variety of projects, and it's performant enough to handle the volume of data that we need to sort through. The documentation is really thorough, as well, which makes the library quite easy to use.

David Koh - Senior Data Scientist at OkCupid

1.6.20 Lovely

At Lovely, we strive to deliver the best apartment marketplace, with respect to our users and our listings. From understanding user behavior, improving data quality, and detecting fraud, scikit-learn is a regular tool for gathering insights, predictive modeling and improving our product. The easy-to-read documentation and intuitive architecture of the API makes machine learning both explorable and accessible to a wide range of python developers. I'm constantly recommending that more developers and scientists try scikit-learn.

Simon Frid - Data Scientist, Lead at Lovely

1.6.21 Data Publica

Data Publica builds a new predictive sales tool for commercial and marketing teams called C-Radar. We extensively use scikit-learn to build segmentations of customers through clustering, and to predict future customers based on past partnerships success or failure. We also categorize companies using their website communication thanks to scikit-learn and its machine learning algorithm implementations. Eventually, machine learning makes it possible to detect weak signals that traditional tools cannot see. All these complex tasks are performed in an easy and straightforward way thanks to the great quality of the scikit-learn framework.

Guillaume Lebourgeois & Samuel Charron - Data Scientists at Data Publica

1.6.22 Machinalis

Scikit-learn is the cornerstone of all the machine learning projects carried at Machinalis. It has a consistent API, a wide selection of algorithms and lots of auxiliary tools to deal with the boilerplate. We have used it in production environments on a variety of projects including click-through rate prediction, information extraction, and even counting sheep!

In fact, we use it so much that we've started to freeze our common use cases into Python packages, some of them open-sourced, like FeatureForge . Scikit-learn in one word: Awesome.

Rafael Carrascosa, Lead developer

1.6.23 solido

Scikit-learn is helping to drive Moore's Law, via Solido. Solido creates computer-aided design tools used by the majority of top-20 semiconductor companies and fabs, to design the bleeding-edge chips inside smartphones, automobiles, and more. Scikit-learn helps to power Solido's algorithms for rare-event estimation, worst-case verification, optimization, and more. At Solido, we are particularly fond of scikit-learn's libraries for Gaussian Process models, large-scale regularized linear regression, and classification. Scikit-learn has increased our productivity, because for many ML problems we no longer need to "roll our own" code. This PyData 2014 talk has details.

Trent McConaghy, founder, Solido Design Automation Inc.

1.6.24 INFONEA

We employ scikit-learn for rapid prototyping and custom-made Data Science solutions within our in-memory based Business Intelligence Software INFONEA®. As a well-documented and comprehensive collection of state-of-the-art algorithms and pipelining methods, scikit-learn enables us to provide flexible and scalable scientific analysis solutions. Thus, scikit-learn is immensely valuable in realizing a powerful integration of Data Science technology within self-service business analytics.

Thorsten Kranz, Data Scientist, Coma Soft AG.

1.6.25 Dataiku

Our software, Data Science Studio (DSS), enables users to create data services that combine ETL with Machine Learning. Our Machine Learning module integrates many scikit-learn algorithms. The scikit-learn library is a perfect integration with DSS because it offers algorithms for virtually all business cases. Our goal is to offer a transparent and flexible tool that makes it easier to optimize time consuming aspects of building a data service, preparing data, and training machine learning algorithms on all types of data.

Florian Douetteau, CEO, Dataiku

1.6.26 Otto Group

Here at Otto Group, one of global Big Five B2C online retailers, we are using scikit-learn in all aspects of our daily work from data exploration to development of machine learning application to the productive deployment of those services. It helps us to tackle machine learning problems ranging from e-commerce to logistics. It consistent APIs enabled us to build the Palladium REST-API framework around it and continuously deliver scikit-learn based services.

Christian Rammig, Head of Data Science, Otto Group

1.6.27 Zopa

At Zopa, the first ever Peer-to-Peer lending platform, we extensively use scikit-learn to run the business and optimize our users' experience. It powers our Machine Learning models involved in credit risk, fraud risk, marketing, and pricing, and has been used for originating at least 1 billion GBP worth of Zopa loans. It is very well documented, powerful, and simple to use. We are grateful for the capabilities it has provided, and for allowing us to deliver on our mission of making money simple and fair.

Vlasios Vasileiou, Head of Data Science, Zopa

1.6.28 MARS

Scikit-Learn is integral to the Machine Learning Ecosystem at Mars. Whether we're designing better recipes for petfood or closely analysing our cocoa supply chain, Scikit-Learn is used as a tool for rapidly prototyping ideas and taking them to production. This allows us to better understand and meet the needs of our consumers worldwide. Scikit-Learn's feature-rich toolset is easy to use and equips our associates with the capabilities they need to solve the business challenges they face every day.

Michael Fitzke Next Generation Technologies Sr Leader, Mars Inc.

1.7 Release History

Release notes for all scikit-learn releases are linked in this this page.

Tip: Subscribe to scikit-learn releases on libraries.io to be notified when new versions are released.

1.7.1 Version 0.22.2.post1

March 3 2020

The 0.22.2.post1 release includes a packaging fix for the source distribution but the content of the packages is otherwise identical to the content of the wheels with the 0.22.2 version (without the .post1 suffix). Both contain the following changes.

Changelog

sklearn.impute

- [Efficiency] Reduce *impute.KNNImputer* asymptotic memory usage by chunking pairwise distance computation. #16397 by Joel Nothman.

sklearn.metrics

- [Fix] Fixed a bug in *metrics.plot_roc_curve* where the name of the estimator was passed in the *metrics.RocCurveDisplay* instead of the parameter `name`. It results in a different plot when calling *metrics.RocCurveDisplay.plot* for the subsequent times. #16500 by Guillaume Lemaitre.
- [Fix] Fixed a bug in *metrics.plot_precision_recall_curve* where the name of the estimator was passed in the *metrics.PrecisionRecallDisplay* instead of the parameter `name`. It results in a different plot when calling *metrics.PrecisionRecallDisplay.plot* for the subsequent times. #16505 by Guillaume Lemaitre.

sklearn.neighbors

- [Fix] Fix a bug which converted a list of arrays into a 2-D object array instead of a 1-D array containing NumPy arrays. This bug was affecting *neighbors.NearestNeighbors.radius_neighbors*. #16076 by Guillaume Lemaitre and Alex Shacked.

1.7.2 Version 0.22.1

January 2 2020

This is a bug-fix release to primarily resolve some packaging issues in version 0.22.0. It also includes minor documentation improvements and some bug fixes.

Changelog

sklearn.cluster

- [Fix] *cluster.KMeans* with `algorithm="elkan"` now uses the same stopping criterion as with the default `algorithm="full"`. #15930 by @inder128.

sklearn.inspection

- [Fix] *inspection.permutation_importance* will return the same `importances` when a `random_state` is given for both `n_jobs=1` or `n_jobs>1` both with shared memory backends (thread-safety) and isolated memory, process-based backends. Also avoid casting the data as object dtype and avoid read-only error on large dataframes with `n_jobs>1` as reported in #15810. Follow-up of #15898 by Shivam Gargsya. #15933 by Guillaume Lemaitre and Olivier Grisel.

- [FIX] *inspection.plot_partial_dependence* and *inspection.PartialDependenceDisplay.plot* now consistently checks the number of axes passed in. #15760 by Thomas Fan.

sklearn.metrics

- [FIX] *metrics.plot_confusion_matrix* now raises error when `normalize` is invalid. Previously, it runs fine with no normalization. #15888 by Hanmin Qin.
- [FIX] *metrics.plot_confusion_matrix* now colors the label color correctly to maximize contrast with its background. #15936 by Thomas Fan and @DizietAsahi.
- [FIX] *metrics.classification_report* does no longer ignore the value of the `zero_division` keyword argument. #15879 by Bibhash Chandra Mitra.
- [FIX] Fixed a bug in *metrics.plot_confusion_matrix* to correctly pass the `values_format` parameter to the `ConfusionMatrixDisplay` plot() call. #15937 by Stephen Blystone.

sklearn.model_selection

- [FIX] *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV* accept scalar values provided in `fit_params`. Change in 0.22 was breaking backward compatibility. #15863 by Adrin Jalali and Guillaume Lemaitre.

sklearn.naive_bayes

- [FIX] Removed `abstractmethod` decorator for the method `_check_X` in `naive_bayes.BaseNB` that could break downstream projects inheriting from this deprecated public base class. #15996 by Brigitta Sipőcz.

sklearn.preprocessing

- [FIX] *preprocessing.QuantileTransformer* now guarantees the `quantiles_` attribute to be completely sorted in non-decreasing manner. #15751 by Tirth Patel.

sklearn.semi_supervised

- [FIX] *semi_supervised.LabelPropagation* and *semi_supervised.LabelSpreading* now allow callable kernel function to return sparse weight matrix. #15868 by Niklas Smedemark-Margulies.

sklearn.utils

- [FIX] *utils.check_array* now correctly converts pandas DataFrame with boolean columns to floats. #15797 by Thomas Fan.
- [FIX] `utils.check_is_fitted` accepts back an explicit `attributes` argument to check for specific attributes as explicit markers of a fitted estimator. When no explicit `attributes` are provided, only the attributes that end with a underscore and do not start with double underscore are used as "fitted" markers. The `all_or_any` argument is also no longer deprecated. This change is made to restore some backward compatibility with the behavior of this utility in version 0.21. #15947 by Thomas Fan.

1.7.3 Version 0.22.0

December 3 2019

For a short description of the main highlights of the release, please refer to *Release Highlights for scikit-learn 0.22*.

Legend for changelogs

- [MAJOR FEATURE]: something big that you couldn't do before.
- [FEATURE]: something that you couldn't do before.
- [EFFICIENCY]: an existing feature now may not require as much computation or memory.
- [ENHANCEMENT]: a miscellaneous minor improvement.
- [FIX]: something that previously didn't work as documentated – or according to reasonable expectations – should now work.
- [API CHANGE]: you will need to change your code to have the same effect in the future; or a feature will be removed in the future.

Website update

Our website was revamped and given a fresh new look. #14849 by Thomas Fan.

Clear definition of the public API

Scikit-learn has a public API, and a private API.

We do our best not to break the public API, and to only introduce backward-compatible changes that do not require any user action. However, in cases where that's not possible, any change to the public API is subject to a deprecation cycle of two minor versions. The private API isn't publicly documented and isn't subject to any deprecation cycle, so users should not rely on its stability.

A function or object is public if it is documented in the API Reference and if it can be imported with an import path without leading underscores. For example `sklearn.pipeline.make_pipeline` is public, while `sklearn.pipeline._name_estimators` is private. `sklearn.ensemble._gb.BaseEnsemble` is private too because the whole `_gb` module is private.

Up to 0.22, some tools were de-facto public (no leading underscore), while they should have been private in the first place. In version 0.22, these tools have been made properly private, and the public API space has been cleaned. In addition, importing from most sub-modules is now deprecated: you should for example use `from sklearn.cluster import Birch` instead of `from sklearn.cluster.birch import Birch` (in practice, `birch.py` has been moved to `_birch.py`).

Note: All the tools in the public API should be documented in the API Reference. If you find a public tool (without leading underscore) that isn't in the API reference, that means it should either be private or documented. Please let us know by opening an issue!

This work was tracked in issue 9250 and issue 12927.

Deprecations: using `FutureWarning` from now on

When deprecating a feature, previous versions of scikit-learn used to raise a `DeprecationWarning`. Since the `DeprecationWarnings` aren't shown by default by Python, scikit-learn needed to resort to a custom warning filter to always show the warnings. That filter would sometimes interfere with users custom warning filters.

Starting from version 0.22, scikit-learn will show `FutureWarnings` for deprecations, as recommended by the Python documentation. `FutureWarnings` are always shown by default by Python, so the custom filter has been removed and scikit-learn no longer hinders with user filters. #15080 by Nicolas Hug.

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- *cluster.KMeans* when `n_jobs=1`. [FIX]
- *decomposition.SparseCoder*, *decomposition.DictionaryLearning*, and *decomposition.MiniBatchDictionaryLearning* [FIX]
- *decomposition.SparseCoder* with `algorithm='lasso_lars'` [FIX]
- *decomposition.SparsePCA* where `normalize_components` has no effect due to deprecation.
- *ensemble.HistGradientBoostingClassifier* and *ensemble.HistGradientBoostingRegressor* [FIX], [FEATURE], [ENHANCEMENT].
- *impute.IterativeImputer* when `X` has features with no missing values. [FEATURE]
- *linear_model.Ridge* when `X` is sparse. [FIX]
- *model_selection.StratifiedKFold* and any use of `cv=int` with a classifier. [FIX]
- *cross_decomposition.CCA* when using scipy >= 1.3 [FIX]

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

Changelog

`sklearn.base`

- [API CHANGE] From version 0.24 *base.BaseEstimator.get_params* will raise an AttributeError rather than return None for parameters that are in the estimator's constructor but not stored as attributes on the instance. #14464 by Joel Nothman.

`sklearn.calibration`

- [FIX] Fixed a bug that made *calibration.CalibratedClassifierCV* fail when given a `sample_weight` parameter of type `list` (in the case where `sample_weights` are not supported by the wrapped estimator). #13575 by William de Vazelhes.

sklearn.cluster

- [FEATURE] *cluster.SpectralClustering* now accepts precomputed sparse neighbors graph as input. #10482 by Tom Dupre la Tour and Kumar Ashutosh.
- [ENHANCEMENT] *cluster.SpectralClustering* now accepts a `n_components` parameter. This parameter extends `SpectralClustering` class functionality to match *cluster.spectral_clustering*. #13726 by Shuzhe Xiao.
- [FIX] Fixed a bug where *cluster.KMeans* produced inconsistent results between `n_jobs=1` and `n_jobs>1` due to the handling of the random state. #9288 by Bryan Yang.
- [FIX] Fixed a bug where `elkan` algorithm in *cluster.KMeans* was producing Segmentation Fault on large arrays due to integer index overflow. #15057 by Vladimir Korolev.
- [FIX] *MeanShift* now accepts a *max_iter* with a default value of 300 instead of always using the default 300. It also now exposes an `n_iter_` indicating the maximum number of iterations performed on each seed. #15120 by Adrin Jalali.
- [FIX] *cluster.AgglomerativeClustering* and *cluster.FeatureAgglomeration* now raise an error if `affinity='cosine'` and `X` has samples that are all-zeros. #7943 by @mthorrell.

sklearn.compose

- [FEATURE] Adds *compose.make_column_selector* which is used with *compose.ColumnTransformer* to select DataFrame columns on the basis of name and dtype. #12303 by Thomas Fan.
- [FIX] Fixed a bug in *compose.ColumnTransformer* which failed to select the proper columns when using a boolean list, with NumPy older than 1.12. #14510 by Guillaume Lemaitre.
- [FIX] Fixed a bug in *compose.TransformedTargetRegressor* which did not pass `**fit_params` to the underlying regressor. #14890 by Miguel Cabrera.
- [FIX] The *compose.ColumnTransformer* now requires the number of features to be consistent between `fit` and `transform`. A `FutureWarning` is raised now, and this will raise an error in 0.24. If the number of features isn't consistent and negative indexing is used, an error is raised. #14544 by Adrin Jalali.

sklearn.cross_decomposition

- [FEATURE] *cross_decomposition.PLSCanonical* and *cross_decomposition.PLSRegression* have a new function `inverse_transform` to transform data to the original space. #15304 by Jaime Ferrando Huertas.
- [ENHANCEMENT] *decomposition.KernelPCA* now properly checks the eigenvalues found by the solver for numerical or conditioning issues. This ensures consistency of results across solvers (different choices for `eigen_solver`), including approximate solvers such as `'randomized'` and `'lobpcg'` (see #12068). #12145 by Sylvain Marié
- [FIX] Fixed a bug where *cross_decomposition.PLSCanonical* and *cross_decomposition.PLSRegression* were raising an error when fitted with a target matrix `Y` in which the first column was constant. #13609 by Camila Williamson.
- [FIX] *cross_decomposition.CCA* now produces the same results with scipy 1.3 and previous scipy versions. #15661 by Thomas Fan.

sklearn.datasets

- [FEATURE] *datasets.fetch_openml* now supports heterogeneous data using pandas by setting `as_frame=True`. #13902 by Thomas Fan.
- [FEATURE] *datasets.fetch_openml* now includes the `target_names` in the returned Bunch. #15160 by Thomas Fan.
- [ENHANCEMENT] The parameter `return_X_y` was added to *datasets.fetch_20newsgroups* and *datasets.fetch_olivetti_faces*. #14259 by Sourav Singh.
- [ENHANCEMENT] *datasets.make_classification* now accepts array-like `weights` parameter, i.e. list or numpy.array, instead of list only. #14764 by Cat Chenal.
- [ENHANCEMENT] **The parameter `normalize` was added to** *datasets.fetch_20newsgroups_vectorized*. #14740 by Stéphan Tulkens
- [FIX] Fixed a bug in *datasets.fetch_openml*, which failed to load an OpenML dataset that contains an ignored feature. #14623 by Sarra Habchi.

sklearn.decomposition

- [EFFICIENCY] `decomposition.NMF(solver='mu')` fitted on sparse input matrices now uses batching to avoid briefly allocating an array with size (#non-zero elements, n_components). #15257 by Mart Willocx.
- [ENHANCEMENT] *decomposition.dict_learning* and *decomposition.dict_learning_online* now accept `method_max_iter` and pass it to *decomposition.sparse_encode*. #12650 by Adrin Jalali.
- [ENHANCEMENT] *decomposition.SparseCoder*, *decomposition.DictionaryLearning*, and *decomposition.MiniBatchDictionaryLearning* now take a `transform_max_iter` parameter and pass it to either *decomposition.dict_learning* or *decomposition.sparse_encode*. #12650 by Adrin Jalali.
- [ENHANCEMENT] *decomposition.IncrementalPCA* now accepts sparse matrices as input, converting them to dense in batches thereby avoiding the need to store the entire dense matrix at once. #13960 by Scott Gigante.
- [FIX] *decomposition.sparse_encode* now passes the `max_iter` to the underlying *linear_model.LassoLars* when `algorithm='lasso_lars'`. #12650 by Adrin Jalali.

sklearn.dummy

- [FIX] *dummy.DummyClassifier* now handles checking the existence of the provided constant in multiouput cases. #14908 by Martina G. Vilas.
- [API CHANGE] The default value of the `strategy` parameter in *dummy.DummyClassifier* will change from `'stratified'` in version 0.22 to `'prior'` in 0.24. A FutureWarning is raised when the default value is used. #15382 by Thomas Fan.
- [API CHANGE] The `outputs_2d_` attribute is deprecated in *dummy.DummyClassifier* and *dummy.DummyRegressor*. It is equivalent to `n_outputs > 1`. #14933 by Nicolas Hug

sklearn.ensemble

- [Major Feature] Added *ensemble.StackingClassifier* and *ensemble.StackingRegressor* to stack predictors using a final classifier or regressor. #11047 by Guillaume Lemaitre and Caio Oliveira and #15138 by Jon Cusick..
- Many improvements were made to *ensemble.HistGradientBoostingClassifier* and *ensemble.HistGradientBoostingRegressor*:
  - [Major Feature] Estimators now natively support dense data with missing values both for training and predicting. They also support infinite values. #13911 and #14406 by Nicolas Hug, Adrin Jalali and Olivier Grisel.
  - [Feature] Estimators now have an additional `warm_start` parameter that enables warm starting. #14012 by Johann Faouzi.
  - [Feature] *inspection.partial_dependence* and *inspection.plot_partial_dependence* now support the fast 'recursion' method for both estimators. #13769 by Nicolas Hug.
  - [Enhancement] for *ensemble.HistGradientBoostingClassifier* the training loss or score is now monitored on a class-wise stratified subsample to preserve the class balance of the original training set. #14194 by Johann Faouzi.
  - [Enhancement] *ensemble.HistGradientBoostingRegressor* now supports the 'least_absolute_deviation' loss. #13896 by Nicolas Hug.
  - [Fix] Estimators now bin the training and validation data separately to avoid any data leak. #13933 by Nicolas Hug.
  - [Fix] Fixed a bug where early stopping would break with string targets. #14710 by Guillaume Lemaitre.
  - [Fix] *ensemble.HistGradientBoostingClassifier* now raises an error if `categorical_crossentropy` loss is given for a binary classification problem. #14869 by Adrin Jalali.

  Note that pickles from 0.21 will not work in 0.22.
- [Enhancement] Addition of `max_samples` argument allows limiting size of bootstrap samples to be less than size of dataset. Added to *ensemble.RandomForestClassifier*, *ensemble.RandomForestRegressor*, *ensemble.ExtraTreesClassifier*, *ensemble.ExtraTreesRegressor*. #14682 by Matt Hancock and #5963 by Pablo Duboue.
- [Fix] *ensemble.VotingClassifier.predict_proba* will no longer be present when `voting='hard'`. #14287 by Thomas Fan.
- [Fix] The `named_estimators_` attribute in *ensemble.VotingClassifier* and *ensemble.VotingRegressor* now correctly maps to dropped estimators. Previously, the `named_estimators_` mapping was incorrect whenever one of the estimators was dropped. #15375 by Thomas Fan.
- [Fix] Run by default *utils.estimator_checks.check_estimator* on both *ensemble.VotingClassifier* and *ensemble.VotingRegressor*. It leads to solve issues regarding shape consistency during `predict` which was failing when the underlying estimators were not outputting consistent array dimensions. Note that it should be replaced by refactoring the common tests in the future. #14305 by Guillaume Lemaitre.
- [Fix] *ensemble.AdaBoostClassifier* computes probabilities based on the decision function as in the literature. Thus, `predict` and `predict_proba` give consistent results. #14114 by Guillaume Lemaitre.
- [Fix] Stacking and Voting estimators now ensure that their underlying estimators are either all classifiers or all regressors. *ensemble.StackingClassifier*, *ensemble.StackingRegressor*, and *ensemble.*

VotingClassifier and VotingRegressor now raise consistent error messages. #15084 by Guillaume Lemaitre.

- [FIX] *ensemble.AdaBoostRegressor* where the loss should be normalized by the max of the samples with non-null weights only. #14294 by Guillaume Lemaitre.
- [API CHANGE] presort is now deprecated in *ensemble.GradientBoostingClassifier* and *ensemble.GradientBoostingRegressor*, and the parameter has no effect. Users are recommended to use *ensemble.HistGradientBoostingClassifier* and *ensemble.HistGradientBoostingRegressor* instead. #14907 by Adrin Jalali.

sklearn.feature_extraction

- [ENHANCEMENT] A warning will now be raised if a parameter choice means that another parameter will be unused on calling the fit() method for *feature_extraction.text.HashingVectorizer*, *feature_extraction.text.CountVectorizer* and *feature_extraction.text.TfidfVectorizer*. #14602 by Gaurav Chawla.
- [FIX] Functions created by build_preprocessor and build_analyzer of feature_extraction.text.VectorizerMixin can now be pickled. #14430 by Dillon Niederhut.
- [FIX] feature_extraction.text.strip_accents_unicode now correctly removes accents from strings that are in NFKD normalized form. #15100 by Daniel Grady.
- [FIX] Fixed a bug that caused *feature_extraction.DictVectorizer* to raise an OverflowError during the transform operation when producing a scipy.sparse matrix on large input data. #15463 by Norvan Sahiner.
- [API CHANGE] Deprecated unused copy param for *feature_extraction.text.TfidfVectorizer.transform* it will be removed in v0.24. #14520 by Guillem G. Subies.

sklearn.feature_selection

- [ENHANCEMENT] Updated the following feature_selection estimators to allow NaN/Inf values in transform and fit: *feature_selection.RFE*, *feature_selection.RFECV*, *feature_selection.SelectFromModel*, and *feature_selection.VarianceThreshold*. Note that if the underlying estimator of the feature selector does not allow NaN/Inf then it will still error, but the feature selectors themselves no longer enforce this restriction unnecessarily. #11635 by Alec Peters.
- [FIX] Fixed a bug where *feature_selection.VarianceThreshold* with threshold=0 did not remove constant features due to numerical instability, by using range rather than variance in this case. #13704 by Roddy MacSween.

sklearn.gaussian_process

- [FEATURE] Gaussian process models on structured data: *gaussian_process.GaussianProcessRegressor* and *gaussian_process.GaussianProcessClassifier* can now accept a list of generic objects (e.g. strings, trees, graphs, etc.) as the X argument to their training/prediction methods. A user-defined kernel should be provided for computing the kernel matrix among the generic objects, and should inherit from gaussian_process.kernels.GenericKernelMixin to notify the GPR/GPC model that it handles non-vectorial samples. #15557 by Yu-Hang Tang.
- [EFFICIENCY] *gaussian_process.GaussianProcessClassifier.log_marginal_likelihood* and *gaussian_process.GaussianProcessRegressor.log_marginal_likelihood* now accept a clone_kernel=True keyword argument. When set

to `False`, the kernel attribute is modified, but may result in a performance improvement. #14378 by Masashi Shibata.

- [API CHANGE] From version 0.24 *gaussian_process.kernels.Kernel.get_params* will raise an `AttributeError` rather than return `None` for parameters that are in the estimator's constructor but not stored as attributes on the instance. #14464 by Joel Nothman.

sklearn.impute

- [MAJOR FEATURE] Added *impute.KNNImputer*, to impute missing values using k-Nearest Neighbors. #12852 by Ashim Bhattarai and Thomas Fan and #15010 by Guillaume Lemaitre.
- [FEATURE] *impute.IterativeImputer* has new `skip_compute` flag that is False by default, which, when True, will skip computation on features that have no missing values during the fit phase. #13773 by Sergey Feldman.
- [EFFICIENCY] *impute.MissingIndicator.fit_transform* avoid repeated computation of the masked matrix. #14356 by Harsh Soni.
- [FIX] *impute.IterativeImputer* now works when there is only one feature. By Sergey Feldman.
- [FIX] Fixed a bug in *impute.IterativeImputer* where features where imputed in the reverse desired order with `imputation_order` either `"ascending"` or `"descending"`. #15393 by Venkatachalam N.

sklearn.inspection

- [MAJOR FEATURE] *inspection.permutation_importance* has been added to measure the importance of each feature in an arbitrary trained model with respect to a given scoring function. #13146 by Thomas Fan.
- [FEATURE] *inspection.partial_dependence* and *inspection.plot_partial_dependence* now support the fast 'recursion' method for *ensemble.HistGradientBoostingClassifier* and *ensemble.HistGradientBoostingRegressor*. #13769 by Nicolas Hug.
- [ENHANCEMENT] *inspection.plot_partial_dependence* has been extended to now support the new visualization API described in the *User Guide*. #14646 by Thomas Fan.
- [ENHANCEMENT] *inspection.partial_dependence* accepts pandas DataFrame and *pipeline.Pipeline* containing *compose.ColumnTransformer*. In addition *inspection.plot_partial_dependence* will use the column names by default when a dataframe is passed. #14028 and #15429 by Guillaume Lemaitre.

sklearn.kernel_approximation

- [FIX] Fixed a bug where *kernel_approximation.Nystroem* raised a `KeyError` when using `kernel="precomputed"`. #14706 by Venkatachalam N.

sklearn.linear_model

- [EFFICIENCY] The 'liblinear' logistic regression solver is now faster and requires less memory. #14108, #14170, #14296 by Alex Henrie.
- [ENHANCEMENT] *linear_model.BayesianRidge* now accepts hyperparameters `alpha_init` and `lambda_init` which can be used to set the initial value of the maximization procedure in *fit*. #13618 by Yoshihiro Uchida.

- [Fix] *linear_model.Ridge* now correctly fits an intercept when `X` is sparse, `solver="auto"` and `fit_intercept=True`, because the default solver in this configuration has changed to `sparse_cg`, which can fit an intercept with sparse data. #13995 by Jérôme Dockès.
- [Fix] *linear_model.Ridge* with `solver='sag'` now accepts F-ordered and non-contiguous arrays and makes a conversion instead of failing. #14458 by Guillaume Lemaitre.
- [Fix] *linear_model.LassoCV* no longer forces `precompute=False` when fitting the final model. #14591 by Andreas Müller.
- [Fix] *linear_model.RidgeCV* and *linear_model.RidgeClassifierCV* now correctly scores when `cv=None`. #14864 by Venkatachalam N.
- [Fix] Fixed a bug in *linear_model.LogisticRegressionCV* where the `scores_`, `n_iter_` and `coefs_paths_` attribute would have a wrong ordering with `penalty='elastic-net'`. #15044 by Nicolas Hug
- [Fix] *linear_model.MultiTaskLassoCV* and *linear_model.MultiTaskElasticNetCV* with X of dtype int and `fit_intercept=True`. #15086 by Alex Gramfort.
- [Fix] The liblinear solver now supports `sample_weight`. #15038 by Guillaume Lemaitre.

sklearn.manifold

- [Feature] *manifold.Isomap*, *manifold.TSNE*, and *manifold.SpectralEmbedding* now accept precomputed sparse neighbors graph as input. #10482 by Tom Dupre la Tour and Kumar Ashutosh.
- [Feature] Exposed the `n_jobs` parameter in *manifold.TSNE* for multi-core calculation of the neighbors graph. This parameter has no impact when `metric="precomputed"` or (`metric="euclidean"` and `method="exact"`). #15082 by Roman Yurchak.
- [Efficiency] Improved efficiency of *manifold.TSNE* when `method="barnes-hut"` by computing the gradient in parallel. #13213 by Thomas Moreau
- [Fix] Fixed a bug where *manifold.spectral_embedding* (and therefore *manifold.SpectralEmbedding* and *cluster.SpectralClustering*) computed wrong eigenvalues with `eigen_solver='amg'` when `n_samples < 5 * n_components`. #14647 by Andreas Müller.
- [Fix] Fixed a bug in *manifold.spectral_embedding* used in *manifold.SpectralEmbedding* and *cluster.SpectralClustering* where `eigen_solver="amg"` would sometimes result in a LinAlgError. #13393 by Andrew Knyazev #13707 by Scott White
- [API Change] Deprecate `training_data_` unused attribute in *manifold.Isomap*. #10482 by Tom Dupre la Tour.

sklearn.metrics

- [Major Feature] *metrics.plot_roc_curve* has been added to plot roc curves. This function introduces the visualization API described in the *User Guide*. #14357 by Thomas Fan.
- [Feature] Added a new parameter `zero_division` to multiple classification metrics: `precision_score`, `recall_score`, `f1_score`, `fbeta_score`, `precision_recall_fscore_support`, `classification_report`. This allows to set returned value for ill-defined metrics. #14900 by Marc Torrellas Socastro.
- [Feature] Added the *metrics.pairwise.nan_euclidean_distances* metric, which calculates euclidean distances in the presence of missing values. #12852 by Ashim Bhattarai and Thomas Fan.

- [FEATURE] New ranking metrics *metrics.ndcg_score* and *metrics.dcg_score* have been added to compute Discounted Cumulative Gain and Normalized Discounted Cumulative Gain. #9951 by Jérôme Dockès.
- [FEATURE] *metrics.plot_precision_recall_curve* has been added to plot precision recall curves. #14936 by Thomas Fan.
- [FEATURE] *metrics.plot_confusion_matrix* has been added to plot confusion matrices. #15083 by Thomas Fan.
- [FEATURE] Added multiclass support to *metrics.roc_auc_score* with corresponding scorers `'roc_auc_ovr'`, `'roc_auc_ovo'`, `'roc_auc_ovr_weighted'`, and `'roc_auc_ovo_weighted'`. #12789 and #15274 by Kathy Chen, Mohamed Maskani, and Thomas Fan.
- [FEATURE] Add *metrics.mean_tweedie_deviance* measuring the Tweedie deviance for a given `power` parameter. Also add mean Poisson deviance *metrics.mean_poisson_deviance* and mean Gamma deviance *metrics.mean_gamma_deviance* that are special cases of the Tweedie deviance for `power=1` and `power=2` respectively. #13938 by Christian Lorentzen and Roman Yurchak.
- [EFFICIENCY] Improved performance of *metrics.pairwise.manhattan_distances* in the case of sparse matrices. #15049 by `Paolo Toccaceli <ptocca>`.
- [ENHANCEMENT] The parameter `beta` in *metrics.fbeta_score* is updated to accept the zero and `float('+inf')` value. #13231 by Dong-hee Na.
- [ENHANCEMENT] Added parameter `squared` in *metrics.mean_squared_error* to return root mean squared error. #13467 by Urvang Patel.
- [ENHANCEMENT] Allow computing averaged metrics in the case of no true positives. #14595 by Andreas Müller.
- [ENHANCEMENT] Multilabel metrics now supports list of lists as input. #14865 Srivatsan Ramesh, Herilalaina Rakotoarison, Léonard Binet.
- [ENHANCEMENT] *metrics.median_absolute_error* now supports `multioutput` parameter. #14732 by Agamemnon Krasoulis.
- [ENHANCEMENT] 'roc_auc_ovr_weighted' and 'roc_auc_ovo_weighted' can now be used as the *scoring* parameter of model-selection tools. #14417 by Thomas Fan.
- [ENHANCEMENT] *metrics.confusion_matrix* accepts a parameters `normalize` allowing to normalize the confusion matrix by column, rows, or overall. #15625 by `Guillaume Lemaitre <glemaitre>`.
- [FIX] Raise a ValueError in *metrics.silhouette_score* when a precomputed distance matrix contains non-zero diagonal entries. #12258 by Stephen Tierney.
- [API CHANGE] `scoring="neg_brier_score"` should be used instead of `scoring="brier_score_loss"` which is now deprecated. #14898 by Stefan Matcovici.

sklearn.model_selection

- [EFFICIENCY] Improved performance of multimetric scoring in *model_selection.cross_validate*, *model_selection.GridSearchCV*, and *model_selection.RandomizedSearchCV*. #14593 by Thomas Fan.
- [ENHANCEMENT] *model_selection.learning_curve* now accepts parameter `return_times` which can be used to retrieve computation times in order to plot model scalability (see learning_curve example). #13938 by Hadrien Reboul.
- [ENHANCEMENT] *model_selection.RandomizedSearchCV* now accepts lists of parameter distributions. #14549 by Andreas Müller.

- [FIX] Reimplemented *model_selection.StratifiedKFold* to fix an issue where one test set could be `n_classes` larger than another. Test sets should now be near-equally sized. #14704 by Joel Nothman.
- [FIX] The `cv_results_` attribute of *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV* now only contains unfitted estimators. This potentially saves a lot of memory since the state of the estimators isn't stored. ##15096 by Andreas Müller.
- [API CHANGE] *model_selection.KFold* and *model_selection.StratifiedKFold* now raise a warning if `random_state` is set but `shuffle` is False. This will raise an error in 0.24.

sklearn.multioutput

- [FIX] *multioutput.MultiOutputClassifier* now has attribute `classes_`. #14629 by Agamemnon Krasoulis.
- [FIX] *multioutput.MultiOutputClassifier* now has `predict_proba` as property and can be checked with `hasattr`. #15488 #15490 by Rebekah Kim

sklearn.naive_bayes

- [MAJOR FEATURE] Added *naive_bayes.CategoricalNB* that implements the Categorical Naive Bayes classifier. #12569 by Tim Bicker and Florian Wilhelm.

sklearn.neighbors

- [MAJOR FEATURE] Added *neighbors.KNeighborsTransformer* and *neighbors.RadiusNeighborsTransformer*, which transform input dataset into a sparse neighbors graph. They give finer control on nearest neighbors computations and enable easy pipeline caching for multiple use. #10482 by Tom Dupre la Tour.
- [FEATURE] *neighbors.KNeighborsClassifier*, *neighbors.KNeighborsRegressor*, *neighbors.RadiusNeighborsClassifier*, *neighbors.RadiusNeighborsRegressor*, and *neighbors.LocalOutlierFactor* now accept precomputed sparse neighbors graph as input. #10482 by Tom Dupre la Tour and Kumar Ashutosh.
- [FEATURE] *neighbors.RadiusNeighborsClassifier* now supports predicting probabilities by using `predict_proba` and supports more outlier_label options: 'most_frequent', or different outlier_labels for multi-outputs. #9597 by Wenbo Zhao.
- [EFFICIENCY] Efficiency improvements for *neighbors.RadiusNeighborsClassifier.predict*. #9597 by Wenbo Zhao.
- [FIX] *neighbors.KNeighborsRegressor* now throws error when `metric='precomputed'` and fit on non-square data. #14336 by Gregory Dexter.

sklearn.neural_network

- [FEATURE] Add `max_fun` parameter in `neural_network.BaseMultilayerPerceptron`, *neural_network.MLPRegressor*, and *neural_network.MLPClassifier* to give control over maximum number of function evaluation to not meet `tol` improvement. #9274 by Daniel Perry.

sklearn.pipeline

- [ENHANCEMENT] *pipeline.Pipeline* now supports *score_samples* if the final estimator does. #13806 by Anaël Beaugnon.
- [FIX] The `fit` in *FeatureUnion* now accepts `fit_params` to pass to the underlying transformers. #15119 by Adrin Jalali.
- [API CHANGE] `None` as a transformer is now deprecated in *pipeline.FeatureUnion*. Please use `'drop'` instead. #15053 by Thomas Fan.

sklearn.preprocessing

- [EFFICIENCY] *preprocessing.PolynomialFeatures* is now faster when the input data is dense. #13290 by Xavier Dupré.
- [ENHANCEMENT] Avoid unnecessary data copy when fitting preprocessors *preprocessing.StandardScaler*, *preprocessing.MinMaxScaler*, *preprocessing.MaxAbsScaler*, *preprocessing.RobustScaler* and *preprocessing.QuantileTransformer* which results in a slight performance improvement. #13987 by Roman Yurchak.
- [FIX] KernelCenterer now throws error when fit on non-square *preprocessing.KernelCenterer* #14336 by Gregory Dexter.

sklearn.model_selection

- [FIX] *model_selection.GridSearchCV* and `model_selection.RandomizedSearchCV` now supports the *_pairwise* property, which prevents an error during cross-validation for estimators with pairwise inputs (such as *neighbors.KNeighborsClassifier* when *metric* is set to 'precomputed'). #13925 by Isaac S. Robson and #15524 by Xun Tang.

sklearn.svm

- [ENHANCEMENT] *svm.SVC* and *svm.NuSVC* now accept a `break_ties` parameter. This parameter results in *predict* breaking the ties according to the confidence values of *decision_function*, if `decision_function_shape='ovr'`, and the number of target classes > 2. #12557 by Adrin Jalali.
- [ENHANCEMENT] SVM estimators now throw a more specific error when `kernel='precomputed'` and fit on non-square data. #14336 by Gregory Dexter.
- [FIX] *svm.SVC*, *svm.SVR*, *svm.NuSVR* and *svm.OneClassSVM* when received values negative or zero for parameter `sample_weight` in method fit(), generated an invalid model. This behavior occurred only in some border scenarios. Now in these cases, fit() will fail with an Exception. #14286 by Alex Shacked.
- [FIX] The `n_support_` attribute of *svm.SVR* and *svm.OneClassSVM* was previously non-initialized, and had size 2. It has now size 1 with the correct value. #15099 by Nicolas Hug.
- [FIX] fixed a bug in `BaseLibSVM._sparse_fit` where n_SV=0 raised a ZeroDivisionError. #14894 by Danna Naser.
- [FIX] The liblinear solver now supports `sample_weight`. #15038 by Guillaume Lemaitre.

sklearn.tree

- [FEATURE] Adds minimal cost complexity pruning, controlled by `ccp_alpha`, to *tree.DecisionTreeClassifier*, *tree.DecisionTreeRegressor*, *tree.ExtraTreeClassifier*, *tree.ExtraTreeRegressor*, *ensemble.RandomForestClassifier*, *ensemble.RandomForestRegressor*, *ensemble.ExtraTreesClassifier*, *ensemble.ExtraTreesRegressor*, *ensemble.GradientBoostingClassifier*, and *ensemble.GradientBoostingRegressor*. #12887 by Thomas Fan.
- [API CHANGE] `presort` is now deprecated in *tree.DecisionTreeClassifier* and *tree.DecisionTreeRegressor*, and the parameter has no effect. #14907 by Adrin Jalali.
- [API CHANGE] The `classes_` and `n_classes_` attributes of *tree.DecisionTreeRegressor* are now deprecated. #15028 by Mei Guan, Nicolas Hug, and Adrin Jalali.

sklearn.utils

- [FEATURE] *check_estimator* can now generate checks by setting `generate_only=True`. Previously, running *check_estimator* will stop when the first check fails. With `generate_only=True`, all checks can run independently and report the ones that are failing. Read more in *Rolling your own estimator*. #14381 by Thomas Fan.
- [FEATURE] Added a pytest specific decorator, *parametrize_with_checks*, to parametrize estimator checks for a list of estimators. #14381 by Thomas Fan.
- [FEATURE] A new random variable, `utils.fixes.loguniform` implements a log-uniform random variable (e.g., for use in RandomizedSearchCV). For example, the outcomes `1`, `10` and `100` are all equally likely for `loguniform(1, 100)`. See #11232 by Scott Sievert and Nathaniel Saul, and `SciPy PR 10815 <https://github.com/scipy/scipy/pull/10815>`.
- [ENHANCEMENT] *utils.safe_indexing* (now deprecated) accepts an `axis` parameter to index array-like across rows and columns. The column indexing can be done on NumPy array, SciPy sparse matrix, and Pandas DataFrame. An additional refactoring was done. #14035 and #14475 by Guillaume Lemaitre.
- [ENHANCEMENT] *utils.extmath.safe_sparse_dot* works between 3D+ ndarray and sparse matrix. #14538 by Jérémie du Boisberranger.
- [FIX] *utils.check_array* is now raising an error instead of casting NaN to integer. #14872 by Roman Yurchak.
- [FIX] *utils.check_array* will now correctly detect numeric dtypes in pandas dataframes, fixing a bug where `float32` was upcast to `float64` unnecessarily. #15094 by Andreas Müller.
- [API CHANGE] The following utils have been deprecated and are now private:
  - `choose_check_classifiers_labels`
  - `enforce_estimator_tags_y`
  - `mocking.MockDataFrame`
  - `mocking.CheckingClassifier`
  - `optimize.newton_cg`
  - `random.random_choice_csc`
  - `utils.choose_check_classifiers_labels`
  - `utils.enforce_estimator_tags_y`
  - `utils.optimize.newton_cg`

  - `utils.random.random_choice_csc`
  - `utils.safe_indexing`
  - `utils.mocking`
  - `utils.fast_dict`
  - `utils.seq_dataset`
  - `utils.weight_vector`
  - `utils.fixes.parallel_helper` (removed)
  - All of `utils.testing` except for `all_estimators` which is now in `utils`.

`sklearn.isotonic`

- [Fix] Fixed a bug where *`isotonic.IsotonicRegression.fit`* raised error when `X.dtype == 'float32'` and `X.dtype != y.dtype`. #14902 by Lucas.

Miscellaneous

- [Fix] Port `lobpcg` from SciPy which implement some bug fixes but only available in 1.3+. #13609 and #14971 by Guillaume Lemaitre.
- [API Change] Scikit-learn now converts any input data structure implementing a duck array to a numpy array (using `__array__`) to ensure consistent behavior instead of relying on `__array_function__` (see NEP 18). #14702 by Andreas Müller.
- [API Change] Replace manual checks with `check_is_fitted`. Errors thrown when using a non-fitted estimators are now more uniform. #13013 by Agamemnon Krasoulis.

Changes to estimator checks

These changes mostly affect library developers.

- Estimators are now expected to raise a `NotFittedError` if `predict` or `transform` is called before `fit`; previously an `AttributeError` or `ValueError` was acceptable. #13013 by by Agamemnon Krasoulis.
- Binary only classifiers are now supported in estimator checks. Such classifiers need to have the `binary_only=True` estimator tag. #13875 by Trevor Stephens.
- Estimators are expected to convert input data (`X`, `y`, `sample_weights`) to `numpy.ndarray` and never call `__array_function__` on the original datatype that is passed (see NEP 18). #14702 by Andreas Müller.
- `requires_positive_X` estimator tag (for models that require X to be non-negative) is now used by *`utils.estimator_checks.check_estimator`* to make sure a proper error message is raised if X contains some negative entries. #14680 by Alex Gramfort.
- Added check that pairwise estimators raise error on non-square data #14336 by Gregory Dexter.
- Added two common multioutput estimator tests `check_classifier_multioutput` and `check_regressor_multioutput`. #13392 by Rok Mihevc.
- [Fix] Added `check_transformer_data_not_an_array` to checks where missing
- [Fix] The estimators tags resolution now follows the regular MRO. They used to be overridable only once. #14884 by Andreas Müller.

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.20, including:

1.7.4 Version 0.21.3

Legend for changelogs

- [MAJOR FEATURE]: something big that you couldn't do before.
- [FEATURE]: something that you couldn't do before.
- [EFFICIENCY]: an existing feature now may not require as much computation or memory.
- [ENHANCEMENT]: a miscellaneous minor improvement.

- [FIX]: something that previously didn't work as documentated – or according to reasonable expectations – should now work.
- [API CHANGE]: you will need to change your code to have the same effect in the future; or a feature will be removed in the future.

July 30, 2019

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- The v0.20.0 release notes failed to mention a backwards incompatibility in *metrics.make_scorer* when `needs_proba=True` and `y_true` is binary. Now, the scorer function is supposed to accept a 1D `y_pred` (i.e., probability of the positive class, shape `(n_samples,)`), instead of a 2D `y_pred` (i.e., shape `(n_samples, 2)`).

Changelog

sklearn.cluster

- [FIX] Fixed a bug in *cluster.KMeans* where computation with `init='random'` was single threaded for `n_jobs > 1` or `n_jobs = -1`. #12955 by Prabakaran Kumaresshan.
- [FIX] Fixed a bug in *cluster.OPTICS* where users were unable to pass float `min_samples` and `min_cluster_size`. #14496 by Fabian Klopfer and Hanmin Qin.
- [FIX] Fixed a bug in *cluster.KMeans* where KMeans++ initialisation could rarely result in an IndexError. #11756 by Joel Nothman.

sklearn.compose

- [FIX] Fixed an issue in *compose.ColumnTransformer* where using DataFrames whose column order differs between :func:`fit` and :func:`transform` could lead to silently passing incorrect columns to the `remainder` transformer. #14237 by `Andreas Schuderer <schuderer>`.

sklearn.datasets

- [FIX] *datasets.fetch_california_housing*, *datasets.fetch_covtype*, *datasets.fetch_kddcup99*, *datasets.fetch_olivetti_faces*, *datasets.fetch_rcv1*, and *datasets.fetch_species_distributions* try to persist the previously cache using the new `joblib` if the cached data was persisted using the deprecated `sklearn.externals.joblib`. This behavior is set to be deprecated and removed in v0.23. #14197 by Adrin Jalali.

sklearn.ensemble

- [FIX] Fix zero division error in `HistGradientBoostingClassifier` and `HistGradientBoostingRegressor`. #14024 by `Nicolas Hug <NicolasHug>`.

sklearn.impute

- [Fix] Fixed a bug in *impute.SimpleImputer* and *impute.IterativeImputer* so that no errors are thrown when there are missing values in training data. #13974 by Frank Hoang <fhoang7>.

sklearn.inspection

- [Fix] Fixed a bug in *inspection.plot_partial_dependence* where target parameter was not being taken into account for multiclass problems. #14393 by Guillem G. Subies.

sklearn.linear_model

- [Fix] Fixed a bug in *linear_model.LogisticRegressionCV* where refit=False would fail depending on the 'multiclass' and 'penalty' parameters (regression introduced in 0.21). #14087 by Nicolas Hug.
- [Fix] Compatibility fix for *linear_model.ARDRegression* and Scipy>=1.3.0. Adapts to upstream changes to the default pinvh cutoff threshold which otherwise results in poor accuracy in some cases. #14067 by Tim Staley.

sklearn.neighbors

- [Fix] Fixed a bug in *neighbors.NeighborhoodComponentsAnalysis* where the validation of initial parameters n_components, max_iter and tol required too strict types. #14092 by Jérémie du Boisberranger.

sklearn.tree

- [Fix] Fixed bug in *tree.export_text* when the tree has one feature and a single feature name is passed in. #14053 by Thomas Fan.
- [Fix] Fixed an issue with plot_tree where it displayed entropy calculations even for gini criterion in DecisionTreeClassifiers. #13947 by Frank Hoang.

1.7.5 Version 0.21.2

24 May 2019

Changelog

sklearn.decomposition

- [Fix] Fixed a bug in *cross_decomposition.CCA* improving numerical stability when Y is close to zero. #13903 by Thomas Fan.

sklearn.metrics

- [Fix] Fixed a bug in *metrics.pairwise.euclidean_distances* where a part of the distance matrix was left un-instanciated for suffiently large float32 datasets (regression introduced in 0.21). #13910 by Jérémie du Boisberranger.

sklearn.preprocessing

- [Fix] Fixed a bug in *preprocessing.OneHotEncoder* where the new `drop` parameter was not reflected in `get_feature_names`. #13894 by James Myatt.

sklearn.utils.sparsefuncs

- [Fix] Fixed a bug where `min_max_axis` would fail on 32-bit systems for certain large inputs. This affects *preprocessing.MaxAbsScaler*, *preprocessing.normalize* and *preprocessing.LabelBinarizer*. #13741 by Roddy MacSween.

1.7.6 Version 0.21.1

17 May 2019

This is a bug-fix release to primarily resolve some packaging issues in version 0.21.0. It also includes minor documentation improvements and some bug fixes.

Changelog

sklearn.inspection

- [Fix] Fixed a bug in *inspection.partial_dependence* to only check classifier and not regressor for the multiclass-multioutput case. #14309 by Guillaume Lemaitre.

sklearn.metrics

- [Fix] Fixed a bug in *metrics.pairwise_distances* where it would raise `AttributeError` for boolean metrics when `X` had a boolean dtype and `Y == None`. #13864 by Paresh Mathur.
- [Fix] Fixed two bugs in *metrics.pairwise_distances* when `n_jobs > 1`. First it used to return a distance matrix with same dtype as input, even for integer dtype. Then the diagonal was not zeros for euclidean metric when `Y` is `X`. #13877 by Jérémie du Boisberranger.

sklearn.neighbors

- [Fix] Fixed a bug in *neighbors.KernelDensity* which could not be restored from a pickle if `sample_weight` had been used. #13772 by Aditya Vyas.

1.7.7 Version 0.21.0

May 2019

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- *discriminant_analysis.LinearDiscriminantAnalysis* for multiclass classification. [FIX]
- *discriminant_analysis.LinearDiscriminantAnalysis* with 'eigen' solver. [FIX]
- *linear_model.BayesianRidge* [FIX]
- Decision trees and derived ensembles when both `max_depth` and `max_leaf_nodes` are set. [FIX]
- *linear_model.LogisticRegression* and *linear_model.LogisticRegressionCV* with 'saga' solver. [FIX]
- *ensemble.GradientBoostingClassifier* [FIX]
- *sklearn.feature_extraction.text.HashingVectorizer*, *sklearn.feature_extraction.text.TfidfVectorizer*, and *sklearn.feature_extraction.text.CountVectorizer* [FIX]
- *neural_network.MLPClassifier* [FIX]
- *svm.SVC.decision_function* and *multiclass.OneVsOneClassifier.decision_function*. [FIX]
- *linear_model.SGDClassifier* and any derived classifiers. [FIX]
- Any model using the `linear_model._sag.sag_solver` function with a `0` seed, including *linear_model.LogisticRegression*, *linear_model.LogisticRegressionCV*, *linear_model.Ridge*, and *linear_model.RidgeCV* with 'sag' solver. [FIX]
- *linear_model.RidgeCV* when using generalized cross-validation with sparse inputs. [FIX]

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

Known Major Bugs

- The default `max_iter` for *linear_model.LogisticRegression* is too small for many solvers given the default `tol`. In particular, we accidentally changed the default `max_iter` for the liblinear solver from 1000 to 100 iterations in #3591 released in version 0.16. In a future release we hope to choose better default `max_iter` and `tol` heuristically depending on the solver (see #13317).

Changelog

Support for Python 3.4 and below has been officially dropped.

sklearn.base

- [API CHANGE] The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *metrics.r2_score*. This will influence the `score` method of all the multioutput regressors (except for *multioutput.MultiOutputRegressor*). #13157 by Hanmin Qin.

sklearn.calibration

- [Enhancement] Added support to bin the data passed into *calibration.calibration_curve* by quantiles instead of uniformly between 0 and 1. #13086 by Scott Cole.
- [Enhancement] Allow n-dimensional arrays as input for `calibration.CalibratedClassifierCV`. #13485 by William de Vazelhes.

sklearn.cluster

- [Major Feature] A new clustering algorithm: *cluster.OPTICS*: an algorithm related to *cluster.DBSCAN*, that has hyperparameters easier to set and that scales better, by Shane, Adrin Jalali, Erich Schubert, Hanmin Qin, and Assia Benbihi.
- [Fix] Fixed a bug where *cluster.Birch* could occasionally raise an AttributeError. #13651 by Joel Nothman.
- [Fix] Fixed a bug in *cluster.KMeans* where empty clusters weren't correctly relocated when using sample weights. #13486 by Jérémie du Boisberranger.
- [API Change] The `n_components_` attribute in *cluster.AgglomerativeClustering* and *cluster.FeatureAgglomeration* has been renamed to `n_connected_components_`. #13427 by Stephane Couvreur.
- [Enhancement] *cluster.AgglomerativeClustering* and *cluster.FeatureAgglomeration* now accept a `distance_threshold` parameter which can be used to find the clusters instead of `n_clusters`. #9069 by Vathsala Achar and Adrin Jalali.

sklearn.compose

- [API Change] *compose.ColumnTransformer* is no longer an experimental feature. #13835 by Hanmin Qin.

sklearn.datasets

- [Fix] Added support for 64-bit group IDs and pointers in SVMLight files. #10727 by Bryan K Woods.
- [Fix] *datasets.load_sample_images* returns images with a deterministic order. #13250 by Thomas Fan.

sklearn.decomposition

- [Enhancement] *decomposition.KernelPCA* now has deterministic output (resolved sign ambiguity in eigenvalue decomposition of the kernel matrix). #13241 by Aurélien Bellet.
- [Fix] Fixed a bug in *decomposition.KernelPCA*, `fit().transform()` now produces the correct output (the same as `fit_transform()`) in case of non-removed zero eigenvalues (`remove_zero_eig=False`). `fit_inverse_transform` was also accelerated by using the same trick as `fit_transform` to compute the transform of `X`. #12143 by Sylvain Marié
- [Fix] Fixed a bug in *decomposition.NMF* where `init = 'nndsvd'`, `init = 'nndsvda'`, and `init = 'nndsvdar'` are allowed when `n_components < n_features` instead of `n_components <= min(n_samples, n_features)`. #11650 by Hossein Pourbozorg and Zijie (ZJ) Poh.

- [API CHANGE] The default value of the `init` argument in *decomposition.non_negative_factorization* will change from `random` to `None` in version 0.23 to make it consistent with *decomposition.NMF*. A FutureWarning is raised when the default value is used. #12988 by Zijie (ZJ) Poh.

sklearn.discriminant_analysis

- [ENHANCEMENT] *discriminant_analysis.LinearDiscriminantAnalysis* now preserves `float32` and `float64` dtypes. #8769 and #11000 by Thibault Sejourne
- [FIX] A `ChangedBehaviourWarning` is now raised when *discriminant_analysis.LinearDiscriminantAnalysis* is given as parameter `n_components > min(n_features, n_classes - 1)`, and `n_components` is changed to `min(n_features, n_classes - 1)` if so. Previously the change was made, but silently. #11526 by William de Vazelhes.
- [FIX] Fixed a bug in *discriminant_analysis.LinearDiscriminantAnalysis* where the predicted probabilities would be incorrectly computed in the multiclass case. #6848, by Agamemnon Krasoulis and `Guillaume Lemaitre <glemaitre>`.
- [FIX] Fixed a bug in *discriminant_analysis.LinearDiscriminantAnalysis* where the predicted probabilities would be incorrectly computed with `eigen` solver. #11727, by Agamemnon Krasoulis.

sklearn.dummy

- [FIX] Fixed a bug in *dummy.DummyClassifier* where the `predict_proba` method was returning int32 array instead of float64 for the `stratified` strategy. #13266 by Christos Aridas.
- [FIX] Fixed a bug in *dummy.DummyClassifier* where it was throwing a dimension mismatch error in prediction time if a column vector `y` with `shape=(n, 1)` was given at `fit` time. #13545 by Nick Sorros and Adrin Jalali.

sklearn.ensemble

- [MAJOR FEATURE] Add two new implementations of gradient boosting trees: *ensemble.HistGradientBoostingClassifier* and *ensemble.HistGradientBoostingRegressor*. The implementation of these estimators is inspired by LightGBM and can be orders of magnitude faster than *ensemble.GradientBoostingRegressor* and *ensemble.GradientBoostingClassifier* when the number of samples is larger than tens of thousands of samples. The API of these new estimators is slightly different, and some of the features from *ensemble.GradientBoostingClassifier* and *ensemble.GradientBoostingRegressor* are not yet supported.

  These new estimators are experimental, which means that their results or their API might change without any deprecation cycle. To use them, you need to explicitly import `enable_hist_gradient_boosting`:

```
>>> # explicitly require this experimental feature
>>> from sklearn.experimental import enable_hist_gradient_boosting  # noqa
>>> # now you can import normally from sklearn.ensemble
>>> from sklearn.ensemble import HistGradientBoostingClassifier
```

  #12807 by Nicolas Hug.

- [FEATURE] Add *ensemble.VotingRegressor* which provides an equivalent of *ensemble.VotingClassifier* for regression problems. #12513 by Ramil Nugmanov and Mohamed Ali Jamaoui.

- [Efficiency] Make *ensemble.IsolationForest* prefer threads over processes when running with `n_jobs > 1` as the underlying decision tree fit calls do release the GIL. This changes reduces memory usage and communication overhead. #12543 by Isaac Storch and Olivier Grisel.
- [Efficiency] Make *ensemble.IsolationForest* more memory efficient by avoiding keeping in memory each tree prediction. #13260 by Nicolas Goix.
- [Efficiency] *ensemble.IsolationForest* now uses chunks of data at prediction step, thus capping the memory usage. #13283 by Nicolas Goix.
- [Efficiency] *sklearn.ensemble.GradientBoostingClassifier* and *sklearn.ensemble.GradientBoostingRegressor* now keep the input `y` as `float64` to avoid it being copied internally by trees. #13524 by Adrin Jalali.
- [Enhancement] Minimized the validation of X in *ensemble.AdaBoostClassifier* and *ensemble.AdaBoostRegressor* #13174 by Christos Aridas.
- [Enhancement] *ensemble.IsolationForest* now exposes `warm_start` parameter, allowing iterative addition of trees to an isolation forest. #13496 by Peter Marko.
- [Fix] The values of `feature_importances_` in all random forest based models (i.e. *ensemble.RandomForestClassifier*, *ensemble.RandomForestRegressor*, *ensemble.ExtraTreesClassifier*, *ensemble.ExtraTreesRegressor*, *ensemble.RandomTreesEmbedding*, *ensemble.GradientBoostingClassifier*, and *ensemble.GradientBoostingRegressor*) now:
  - sum up to `1`
  - all the single node trees in feature importance calculation are ignored
  - in case all trees have only one single node (i.e. a root node), feature importances will be an array of all zeros.

  #13636 and #13620 by Adrin Jalali.
- [Fix] Fixed a bug in *ensemble.GradientBoostingClassifier* and *ensemble.GradientBoostingRegressor*, which didn't support scikit-learn estimators as the initial estimator. Also added support of initial estimator which does not support sample weights. #12436 by Jérémie du Boisberranger and #12983 by Nicolas Hug.
- [Fix] Fixed the output of the average path length computed in *ensemble.IsolationForest* when the input is either 0, 1 or 2. #13251 by Albert Thomas and joshuakennethjones.
- [Fix] Fixed a bug in *ensemble.GradientBoostingClassifier* where the gradients would be incorrectly computed in multiclass classification problems. #12715 by Nicolas Hug.
- [Fix] Fixed a bug in *ensemble.GradientBoostingClassifier* where validation sets for early stopping were not sampled with stratification. #13164 by Nicolas Hug.
- [Fix] Fixed a bug in *ensemble.GradientBoostingClassifier* where the default initial prediction of a multiclass classifier would predict the classes priors instead of the log of the priors. #12983 by Nicolas Hug.
- [Fix] Fixed a bug in *ensemble.RandomForestClassifier* where the `predict` method would error for multiclass multioutput forests models if any targets were strings. #12834 by Elizabeth Sander.
- [Fix] Fixed a bug in `ensemble.gradient_boosting.LossFunction` and `ensemble.gradient_boosting.LeastSquaresError` where the default value of `learning_rate` in `update_terminal_regions` is not consistent with the document and the caller functions. Note however that directly using these loss functions is deprecated. #6463 by movelikeriver.
- [Fix] `ensemble.partial_dependence` (and consequently the new version *sklearn.inspection.partial_dependence*) now takes sample weights into account for the partial dependence computation when the gradient boosting model has been trained with sample weights. #13193 by Samuel O. Ronsin.

- [API CHANGE] `ensemble.partial_dependence` and `ensemble.plot_partial_dependence` are now deprecated in favor of *inspection.partial_dependence* and *inspection.plot_partial_dependence*. #12599 by Trevor Stephens and Nicolas Hug.
- [FIX] *ensemble.VotingClassifier* and *ensemble.VotingRegressor* were failing during `fit` in one of the estimators was set to `None` and `sample_weight` was not `None`. #13779 by Guillaume Lemaitre.
- [API CHANGE] *ensemble.VotingClassifier* and *ensemble.VotingRegressor* accept `'drop'` to disable an estimator in addition to `None` to be consistent with other estimators (i.e., *pipeline.FeatureUnion* and *compose.ColumnTransformer*). #13780 by Guillaume Lemaitre.

sklearn.externals

- [API CHANGE] Deprecated `externals.six` since we have dropped support for Python 2.7. #12916 by Hanmin Qin.

sklearn.feature_extraction

- [FIX] If `input='file'` or `input='filename'`, and a callable is given as the `analyzer`, *sklearn.feature_extraction.text.HashingVectorizer*, *sklearn.feature_extraction.text.TfidfVectorizer*, and *sklearn.feature_extraction.text.CountVectorizer* now read the data from the file(s) and then pass it to the given `analyzer`, instead of passing the file name(s) or the file object(s) to the analyzer. #13641 by Adrin Jalali.

sklearn.impute

- [MAJOR FEATURE] Added *impute.IterativeImputer*, which is a strategy for imputing missing values by modeling each feature with missing values as a function of other features in a round-robin fashion. #8478 and #12177 by Sergey Feldman and Ben Lawson.

  The API of IterativeImputer is experimental and subject to change without any deprecation cycle. To use them, you need to explicitly import `enable_iterative_imputer`:

```
>>> from sklearn.experimental import enable_iterative_imputer  # noqa
>>> # now you can import normally from sklearn.impute
>>> from sklearn.impute import IterativeImputer
```

- [FEATURE] The *impute.SimpleImputer* and *impute.IterativeImputer* have a new parameter `'add_indicator'`, which simply stacks a *impute.MissingIndicator* transform into the output of the imputer's transform. That allows a predictive estimator to account for missingness. #12583, #13601 by Danylo Baibak.
- [FIX] In *impute.MissingIndicator* avoid implicit densification by raising an exception if input is sparse add `missing_values` property is set to 0. #13240 by Bartosz Telenczuk.
- [FIX] Fixed two bugs in *impute.MissingIndicator*. First, when `X` is sparse, all the non-zero non missing values used to become explicit False in the transformed data. Then, when `features='missing-only'`, all features used to be kept if there were no missing values at all. #13562 by Jérémie du Boisberranger.

sklearn.inspection

(new subpackage)

- [FEATURE] Partial dependence plots (*inspection.plot_partial_dependence*) are now supported for any regressor or classifier (provided that they have a `predict_proba` method). #12599 by Trevor Stephens and Nicolas Hug.

sklearn.isotonic

- [FEATURE] Allow different dtypes (such as float32) in *isotonic.IsotonicRegression*. #8769 by Vlad Niculae

sklearn.linear_model

- [ENHANCEMENT] *linear_model.Ridge* now preserves `float32` and `float64` dtypes. #8769 and #11000 by Guillaume Lemaitre, and Joan Massich
- [FEATURE] *linear_model.LogisticRegression* and *linear_model.LogisticRegressionCV* now support Elastic-Net penalty, with the 'saga' solver. #11646 by Nicolas Hug.
- [FEATURE] Added *linear_model.lars_path_gram*, which is *linear_model.lars_path* in the sufficient stats mode, allowing users to compute *linear_model.lars_path* without providing `X` and `y`. #11699 by Kuai Yu.
- [EFFICIENCY] `linear_model.make_dataset` now preserves `float32` and `float64` dtypes, reducing memory consumption in stochastic gradient, SAG and SAGA solvers. #8769 and #11000 by Nelle Varoquaux, Arthur Imbert, Guillaume Lemaitre, and Joan Massich
- [ENHANCEMENT] *linear_model.LogisticRegression* now supports an unregularized objective when `penalty='none'` is passed. This is equivalent to setting `C=np.inf` with l2 regularization. Not supported by the liblinear solver. #12860 by Nicolas Hug.
- [ENHANCEMENT] `sparse_cg` solver in *linear_model.Ridge* now supports fitting the intercept (i.e. `fit_intercept=True`) when inputs are sparse. #13336 by Bartosz Telenczuk.
- [ENHANCEMENT] The coordinate descent solver used in `Lasso`, `ElasticNet`, etc. now issues a `ConvergenceWarning` when it completes without meeting the desired toleranbce. #11754 and #13397 by Brent Fagan and Adrin Jalali.
- [FIX] Fixed a bug in *linear_model.LogisticRegression* and *linear_model.LogisticRegressionCV* with 'saga' solver, where the weights would not be correctly updated in some cases. #11646 by Tom Dupre la Tour.
- [FIX] Fixed the posterior mean, posterior covariance and returned regularization parameters in *linear_model.BayesianRidge*. The posterior mean and the posterior covariance were not the ones computed with the last update of the regularization parameters and the returned regularization parameters were not the final ones. Also fixed the formula of the log marginal likelihood used to compute the score when `compute_score=True`. #12174 by Albert Thomas.
- [FIX] Fixed a bug in *linear_model.LassoLarsIC*, where user input `copy_X=False` at instance creation would be overridden by default parameter value `copy_X=True` in `fit`. #12972 by Lucio Fernandez-Arjona
- [FIX] Fixed a bug in *linear_model.LinearRegression* that was not returning the same coeffecients and intercepts with `fit_intercept=True` in sparse and dense case. #13279 by Alexandre Gramfort
- [FIX] Fixed a bug in *linear_model.HuberRegressor* that was broken when `X` was of dtype bool. #13328 by Alexandre Gramfort.

- [FIX] Fixed a performance issue of `saga` and `sag` solvers when called in a `joblib.Parallel` setting with `n_jobs > 1` and `backend="threading"`, causing them to perform worse than in the sequential case. #13389 by Pierre Glaser.
- [FIX] Fixed a bug in `linear_model.stochastic_gradient.BaseSGDClassifier` that was not deterministic when trained in a multi-class setting on several threads. #13422 by Clément Doumouro.
- [FIX] Fixed bug in *linear_model.ridge_regression*, *linear_model.Ridge* and *linear_model.RidgeClassifier* that caused unhandled exception for arguments `return_intercept=True` and `solver=auto` (default) or any other solver different from `sag`. #13363 by Bartosz Telenczuk
- [FIX] *linear_model.ridge_regression* will now raise an exception if `return_intercept=True` and solver is different from `sag`. Previously, only warning was issued. #13363 by Bartosz Telenczuk
- [FIX] *linear_model.ridge_regression* will choose `sparse_cg` solver for sparse inputs when `solver=auto` and `sample_weight` is provided (previously `cholesky` solver was selected). #13363 by Bartosz Telenczuk
- [API CHANGE] The use of *linear_model.lars_path* with `X=None` while passing `Gram` is deprecated in version 0.21 and will be removed in version 0.23. Use *linear_model.lars_path_gram* instead. #11699 by Kuai Yu.
- [API CHANGE] *linear_model.logistic_regression_path* is deprecated in version 0.21 and will be removed in version 0.23. #12821 by Nicolas Hug.
- [FIX] *linear_model.RidgeCV* with generalized cross-validation now correctly fits an intercept when `fit_intercept=True` and the design matrix is sparse. #13350 by Jérôme Dockès

sklearn.manifold

- [EFFICIENCY] Make `manifold.tsne.trustworthiness` use an inverted index instead of an `np.where` lookup to find the rank of neighbors in the input space. This improves efficiency in particular when computed with lots of neighbors and/or small datasets. #9907 by William de Vazelhes.

sklearn.metrics

- [FEATURE] Added the *metrics.max_error* metric and a corresponding `'max_error'` scorer for single output regression. #12232 by Krishna Sangeeth.
- [FEATURE] Add *metrics.multilabel_confusion_matrix*, which calculates a confusion matrix with true positive, false positive, false negative and true negative counts for each class. This facilitates the calculation of set-wise metrics such as recall, specificity, fall out and miss rate. #11179 by Shangwu Yao and Joel Nothman.
- [FEATURE] *metrics.jaccard_score* has been added to calculate the Jaccard coefficient as an evaluation metric for binary, multilabel and multiclass tasks, with an interface analogous to *metrics.f1_score*. #13151 by Gaurav Dhingra and Joel Nothman.
- [FEATURE] Added *metrics.pairwise.haversine_distances* which can be accessed with `metric='pairwise'` through *metrics.pairwise_distances* and estimators. (Haversine distance was previously available for nearest neighbors calculation.) #12568 by Wei Xue, Emmanuel Arias and Joel Nothman.
- [EFFICIENCY] Faster *metrics.pairwise_distances* with `n_jobs` > 1 by using a thread-based backend, instead of process-based backends. #8216 by Pierre Glaser and Romuald Menuet
- [EFFICIENCY] The pairwise manhattan distances with sparse input now uses the BLAS shipped with scipy instead of the bundled BLAS. #12732 by Jérémie du Boisberranger

- [ENHANCEMENT] Use label `accuracy` instead of `micro-average` on *metrics.classification_report* to avoid confusion. `micro-average` is only shown for multi-label or multi-class with a subset of classes because it is otherwise identical to accuracy. #12334 by Emmanuel Arias, Joel Nothman and Andreas Müller
- [ENHANCEMENT] Added `beta` parameter to *metrics.homogeneity_completeness_v_measure* and *metrics.v_measure_score* to configure the tradeoff between homogeneity and completeness. #13607 by Stephane Couvreur and and Ivan Sanchez.
- [FIX] The metric *metrics.r2_score* is degenerate with a single sample and now it returns NaN and raises *exceptions.UndefinedMetricWarning*. #12855 by Pawel Sendyk.
- [FIX] Fixed a bug where *metrics.brier_score_loss* will sometimes return incorrect result when there's only one class in `y_true`. #13628 by Hanmin Qin.
- [FIX] Fixed a bug in *metrics.label_ranking_average_precision_score* where sample_weight wasn't taken into account for samples with degenerate labels. #13447 by Dan Ellis.
- [API CHANGE] The parameter `labels` in *metrics.hamming_loss* is deprecated in version 0.21 and will be removed in version 0.23. #10580 by Reshama Shaikh and Sandra Mitrovic.
- [FIX] The function *metrics.pairwise.euclidean_distances*, and therefore several estimators with `metric='euclidean'`, suffered from numerical precision issues with `float32` features. Precision has been increased at the cost of a small drop of performance. #13554 by @Celelibi and Jérémie du Boisberranger.
- [API CHANGE] *metrics.jaccard_similarity_score* is deprecated in favour of the more consistent *metrics.jaccard_score*. The former behavior for binary and multiclass targets is broken. #13151 by Joel Nothman.

sklearn.mixture

- [FIX] Fixed a bug in `mixture.BaseMixture` and therefore on estimators based on it, i.e. *mixture.GaussianMixture* and *mixture.BayesianGaussianMixture*, where `fit_predict` and `fit.predict` were not equivalent. #13142 by Jérémie du Boisberranger.

sklearn.model_selection

- [FEATURE] Classes *GridSearchCV* and *RandomizedSearchCV* now allow for refit=callable to add flexibility in identifying the best estimator. See *Balance model complexity and cross-validated score*. #11354 by Wenhao Zhang, Joel Nothman and Adrin Jalali.
- [ENHANCEMENT] Classes *GridSearchCV*, *RandomizedSearchCV*, and methods *cross_val_score*, *cross_val_predict*, *cross_validate*, now print train scores when `return_train_scores` is True and `verbose` > 2. For *learning_curve*, and *validation_curve* only the latter is required. #12613 and #12669 by Marc Torrellas.
- [ENHANCEMENT] Some *CV splitter* classes and `model_selection.train_test_split` now raise `ValueError` when the resulting training set is empty. #12861 by Nicolas Hug.
- [FIX] Fixed a bug where *model_selection.StratifiedKFold* shuffles each class's samples with the same `random_state`, making `shuffle=True` ineffective. #13124 by Hanmin Qin.
- [FIX] Added ability for *model_selection.cross_val_predict* to handle multi-label (and multioutput-multiclass) targets with `predict_proba`-type methods. #8773 by Stephen Hoover.
- [FIX] Fixed an issue in *cross_val_predict* where `method="predict_proba"` returned always `0.0` when one of the classes was excluded in a cross-validation fold. #13366 by Guillaume Fournier

sklearn.multiclass

- [Fix] Fixed an issue in *multiclass.OneVsOneClassifier.decision_function* where the decision_function value of a given sample was different depending on whether the decision_function was evaluated on the sample alone or on a batch containing this same sample due to the scaling used in decision_function. #10440 by Jonathan Ohayon.

sklearn.multioutput

- [Fix] Fixed a bug in *multioutput.MultiOutputClassifier* where the `predict_proba` method incorrectly checked for `predict_proba` attribute in the estimator object. #12222 by Rebekah Kim

sklearn.neighbors

- [Major Feature] Added *neighbors.NeighborhoodComponentsAnalysis* for metric learning, which implements the Neighborhood Components Analysis algorithm. #10058 by William de Vazelhes and John Chiotellis.
- [API Change] Methods in *neighbors.NearestNeighbors* : *kneighbors*, *radius_neighbors*, *kneighbors_graph*, *radius_neighbors_graph* now raise `NotFittedError`, rather than `AttributeError`, when called before `fit` #12279 by Krishna Sangeeth.

sklearn.neural_network

- [Fix] Fixed a bug in *neural_network.MLPClassifier* and *neural_network.MLPRegressor* where the option `shuffle=False` was being ignored. #12582 by Sam Waterbury.
- [Fix] Fixed a bug in *neural_network.MLPClassifier* where validation sets for early stopping were not sampled with stratification. In the multilabel case however, splits are still not stratified. #13164 by Nicolas Hug.

sklearn.pipeline

- [Feature] *pipeline.Pipeline* can now use indexing notation (e.g. `my_pipeline[0:-1]`) to extract a subsequence of steps as another Pipeline instance. A Pipeline can also be indexed directly to extract a particular step (e.g. `my_pipeline['svc']`), rather than accessing `named_steps`. #2568 by Joel Nothman.
- [Feature] Added optional parameter `verbose` in *pipeline.Pipeline*, *compose.ColumnTransformer* and *pipeline.FeatureUnion* and corresponding `make_` helpers for showing progress and timing of each step. #11364 by Baze Petrushev, Karan Desai, Joel Nothman, and Thomas Fan.
- [Enhancement] *pipeline.Pipeline* now supports using `'passthrough'` as a transformer, with the same effect as `None`. #11144 by Thomas Fan.
- [Enhancement] *pipeline.Pipeline* implements `__len__` and therefore `len(pipeline)` returns the number of steps in the pipeline. #13439 by Lakshya KD.

sklearn.preprocessing

- [Feature] *preprocessing.OneHotEncoder* now supports dropping one feature per category with a new drop parameter. #12908 by Drew Johnston.

- [EFFICIENCY] *preprocessing.OneHotEncoder* and *preprocessing.OrdinalEncoder* now handle pandas DataFrames more efficiently. #13253 by @maikia.
- [EFFICIENCY] Make *preprocessing.MultiLabelBinarizer* cache class mappings instead of calculating it every time on the fly. #12116 by Ekaterina Krivich and Joel Nothman.
- [EFFICIENCY] *preprocessing.PolynomialFeatures* now supports compressed sparse row (CSR) matrices as input for degrees 2 and 3. This is typically much faster than the dense case as it scales with matrix density and expansion degree (on the order of density^degree), and is much, much faster than the compressed sparse column (CSC) case. #12197 by Andrew Nystrom.
- [EFFICIENCY] Speed improvement in *preprocessing.PolynomialFeatures*, in the dense case. Also added a new parameter `order` which controls output order for further speed performances. #12251 by Tom Dupre la Tour.
- [FIX] Fixed the calculation overflow when using a float16 dtype with *preprocessing.StandardScaler*. #13007 by Raffaello Baluyot
- [FIX] Fixed a bug in *preprocessing.QuantileTransformer* and *preprocessing.quantile_transform* to force n_quantiles to be at most equal to n_samples. Values of n_quantiles larger than n_samples were either useless or resulting in a wrong approximation of the cumulative distribution function estimator. #13333 by Albert Thomas.
- [API CHANGE] The default value of `copy` in *preprocessing.quantile_transform* will change from False to True in 0.23 in order to make it more consistent with the default `copy` values of other functions in `preprocessing` and prevent unexpected side effects by modifying the value of `X` inplace. #13459 by Hunter McGushion.

sklearn.svm

- [FIX] Fixed an issue in *svm.SVC.decision_function* when `decision_function_shape='ovr'`. The decision_function value of a given sample was different depending on whether the decision_function was evaluated on the sample alone or on a batch containing this same sample due to the scaling used in decision_function. #10440 by Jonathan Ohayon.

sklearn.tree

- [FEATURE] Decision Trees can now be plotted with matplotlib using *tree.plot_tree* without relying on the `dot` library, removing a hard-to-install dependency. #8508 by Andreas Müller.
- [FEATURE] Decision Trees can now be exported in a human readable textual format using *tree.export_text*. #6261 by `Giuseppe Vettigli <JustGlowing>`.
- [FEATURE] `get_n_leaves()` and `get_depth()` have been added to `tree.BaseDecisionTree` and consequently all estimators based on it, including *tree.DecisionTreeClassifier*, *tree.DecisionTreeRegressor*, *tree.ExtraTreeClassifier*, and *tree.ExtraTreeRegressor*. #12300 by Adrin Jalali.
- [FIX] Trees and forests did not previously `predict` multi-output classification targets with string labels, despite accepting them in `fit`. #11458 by Mitar Milutinovic.
- [FIX] Fixed an issue with `tree.BaseDecisionTree` and consequently all estimators based on it, including *tree.DecisionTreeClassifier*, *tree.DecisionTreeRegressor*, *tree.ExtraTreeClassifier*, and *tree.ExtraTreeRegressor*, where they used to exceed the given `max_depth` by 1 while expanding the tree if `max_leaf_nodes` and `max_depth` were both specified by the user. Please note that this also affects all ensemble methods using decision trees. #12344 by Adrin Jalali.

sklearn.utils

- [FEATURE] *utils.resample* now accepts a `stratify` parameter for sampling according to class distributions. #13549 by Nicolas Hug.
- [API CHANGE] Deprecated `warn_on_dtype` parameter from *utils.check_array* and *utils.check_X_y*. Added explicit warning for dtype conversion in `check_pairwise_arrays` if the `metric` being passed is a pairwise boolean metric. #13382 by Prathmesh Savale.

Multiple modules

- [MAJOR FEATURE] The `__repr__()` method of all estimators (used when calling `print(estimator)`) has been entirely re-written, building on Python's pretty printing standard library. All parameters are printed by default, but this can be altered with the `print_changed_only` option in *sklearn.set_config*. #11705 by Nicolas Hug.
- [MAJOR FEATURE] Add estimators tags: these are annotations of estimators that allow programmatic inspection of their capabilities, such as sparse matrix support, supported output types and supported methods. Estimator tags also determine the tests that are run on an estimator when `check_estimator` is called. Read more in the *User Guide*. #8022 by Andreas Müller.
- [EFFICIENCY] Memory copies are avoided when casting arrays to a different dtype in multiple estimators. #11973 by Roman Yurchak.
- [FIX] Fixed a bug in the implementation of the `our_rand_r` helper function that was not behaving consistently across platforms. #13422 by Madhura Parikh and Clément Doumouro.

Miscellaneous

- [ENHANCEMENT] Joblib is no longer vendored in scikit-learn, and becomes a dependency. Minimal supported version is joblib 0.11, however using version >= 0.13 is strongly recommended. #13531 by Roman Yurchak.

Changes to estimator checks

These changes mostly affect library developers.

- Add `check_fit_idempotent` to *check_estimator*, which checks that when `fit` is called twice with the same data, the ouput of `predict`, `predict_proba`, `transform`, and `decision_function` does not change. #12328 by Nicolas Hug
- Many checks can now be disabled or configured with *Estimator Tags*. #8022 by Andreas Müller.

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.20, including:

1.7.8 Version 0.20.4

July 30, 2019

This is a bug-fix release with some bug fixes applied to version 0.20.3.

Changelog

The bundled version of joblib was upgraded from 0.13.0 to 0.13.2.

sklearn.cluster

- [Fix] Fixed a bug in *cluster.KMeans* where KMeans++ initialisation could rarely result in an IndexError. #11756 by Joel Nothman.

sklearn.compose

- [Fix] Fixed an issue in *compose.ColumnTransformer* where using DataFrames whose column order differs between :func:`fit` and :func:`transform` could lead to silently passing incorrect columns to the `remainder` transformer. #14237 by `Andreas Schuderer <schuderer>`.

sklearn.decomposition

- [Fix] Fixed a bug in *cross_decomposition.CCA* improving numerical stability when `Y` is close to zero. #13903 by Thomas Fan.

sklearn.model_selection

- [Fix] Fixed a bug where *model_selection.StratifiedKFold* shuffles each class's samples with the same `random_state`, making `shuffle=True` ineffective. #13124 by Hanmin Qin.

sklearn.neighbors

- [Fix] Fixed a bug in *neighbors.KernelDensity* which could not be restored from a pickle if `sample_weight` had been used. #13772 by Aditya Vyas.

1.7.9 Version 0.20.3

March 1, 2019

This is a bug-fix release with some minor documentation improvements and enhancements to features released in 0.20.0.

Changelog

sklearn.cluster

- [Fix] Fixed a bug in *cluster.KMeans* where computation was single threaded when `n_jobs > 1` or `n_jobs = -1`. #12949 by Prabakaran Kumaresshan.

sklearn.compose

- [Fix] Fixed a bug in *compose.ColumnTransformer* to handle negative indexes in the columns list of the transformers. #12946 by Pierre Tallotte.

sklearn.covariance

- [Fix] Fixed a regression in *covariance.graphical_lasso* so that the case `n_features=2` is handled correctly. #13276 by Aurélien Bellet.

sklearn.decomposition

- [Fix] Fixed a bug in *decomposition.sparse_encode* where computation was single threaded when `n_jobs > 1` or `n_jobs = -1`. #13005 by Prabakaran Kumaresshan.

sklearn.datasets

- [Efficiency] *sklearn.datasets.fetch_openml* now loads data by streaming, avoiding high memory usage. #13312 by Joris Van den Bossche.

sklearn.feature_extraction

- [Fix] Fixed a bug in *feature_extraction.text.CountVectorizer* which would result in the sparse feature matrix having conflicting `indptr` and `indices` precisions under very large vocabularies. #11295 by Gabriel Vacaliuc.

sklearn.impute

- [Fix] add support for non-numeric data in *sklearn.impute.MissingIndicator* which was not supported while *sklearn.impute.SimpleImputer* was supporting this for some imputation strategies. #13046 by Guillaume Lemaitre.

sklearn.linear_model

- [Fix] Fixed a bug in *linear_model.MultiTaskElasticNet* and *linear_model.MultiTaskLasso* which were breaking when `warm_start = True`. #12360 by Aakanksha Joshi.

sklearn.preprocessing

- [Fix] Fixed a bug in *preprocessing.KBinsDiscretizer* where `strategy='kmeans'` fails with an error during transformation due to unsorted bin edges. #13134 by Sandro Casagrande.
- [Fix] Fixed a bug in *preprocessing.OneHotEncoder* where the deprecation of `categorical_features` was handled incorrectly in combination with `handle_unknown='ignore'`. #12881 by Joris Van den Bossche.
- [Fix] Bins whose width are too small (i.e., <= 1e-8) are removed with a warning in *preprocessing.KBinsDiscretizer*. #13165 by Hanmin Qin.

sklearn.svm

- [Fix] Fixed a bug in *svm.SVC*, *svm.NuSVC*, *svm.SVR*, *svm.NuSVR* and *svm.OneClassSVM* where the `scale` option of parameter `gamma` is erroneously defined as `1 / (n_features * X.std())`. It's now defined as `1 / (n_features * X.var())`. #13221 by Hanmin Qin.

Code and Documentation Contributors

1.7.10 Version 0.20.2

December 20, 2018

This is a bug-fix release with some minor documentation improvements and enhancements to features released in 0.20.0.

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- *sklearn.neighbors* when `metric=='jaccard'` (bug fix)
- use of `'seuclidean'` or `'mahalanobis'` metrics in some cases (bug fix)

Changelog

sklearn.compose

- [Fix] Fixed an issue in *compose.make_column_transformer* which raises unexpected error when columns is pandas Index or pandas Series. #12704 by Hanmin Qin.

sklearn.metrics

- [Fix] Fixed a bug in *metrics.pairwise_distances* and *metrics.pairwise_distances_chunked* where parameters `V` of `"seuclidean"` and `VI` of `"mahalanobis"` metrics were computed after the data was split into chunks instead of being pre-computed on whole data. #12701 by Jeremie du Boisberranger.

sklearn.neighbors

- [Fix] Fixed *sklearn.neighbors.DistanceMetric* jaccard distance function to return 0 when two all-zero vectors are compared. #12685 by Thomas Fan.

sklearn.utils

- [Fix] Calling *utils.check_array* on `pandas.Series` with categorical data, which raised an error in 0.20.0, now returns the expected output again. #12699 by Joris Van den Bossche.

Code and Documentation Contributors

With thanks to:

adanhawth, Adrin Jalali, Albert Thomas, Andreas Mueller, Dan Stine, Feda Curic, Hanmin Qin, Jan S, jeremiedbb, Joel Nothman, Joris Van den Bossche, josephsalmon, Katrin Leinweber, Loic Esteve, Muhammad Hassaan Rafique, Nicolas Hug, Olivier Grisel, Paul Paczuski, Reshama Shaikh, Sam Waterbury, Shivam Kotwalia, Thomas Fan

1.7.11 Version 0.20.1

November 21, 2018

This is a bug-fix release with some minor documentation improvements and enhancements to features released in 0.20.0. Note that we also include some API changes in this release, so you might get some extra warnings after updating from 0.20.0 to 0.20.1.

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- *decomposition.IncrementalPCA* (bug fix)

Changelog

sklearn.cluster

- [Efficiency] make *cluster.MeanShift* no longer try to do nested parallelism as the overhead would hurt performance significantly when `n_jobs > 1`. #12159 by Olivier Grisel.
- [Fix] Fixed a bug in *cluster.DBSCAN* with precomputed sparse neighbors graph, which would add explicitly zeros on the diagonal even when already present. #12105 by Tom Dupre la Tour.

sklearn.compose

- [Fix] Fixed an issue in *compose.ColumnTransformer* when stacking columns with types not convertible to a numeric. #11912 by Adrin Jalali.
- [API Change] *compose.ColumnTransformer* now applies the `sparse_threshold` even if all transformation results are sparse. #12304 by Andreas Müller.
- [API Change] *compose.make_column_transformer* now expects `(transformer, columns)` instead of `(columns, transformer)` to keep consistent with *compose.ColumnTransformer*. #12339 by Adrin Jalali.

sklearn.datasets

- [Fix] *datasets.fetch_openml* to correctly use the local cache. #12246 by Jan N. van Rijn.
- [Fix] *datasets.fetch_openml* to correctly handle ignore attributes and row id attributes. #12330 by Jan N. van Rijn.
- [Fix] Fixed integer overflow in *datasets.make_classification* for values of `n_informative` parameter larger than 64. #10811 by Roman Feldbauer.
- [Fix] Fixed olivetti faces dataset `DESCR` attribute to point to the right location in *datasets.fetch_olivetti_faces*. #12441 by Jérémie du Boisberranger
- [Fix] *datasets.fetch_openml* to retry downloading when reading from local cache fails. #12517 by Thomas Fan.

sklearn.decomposition

- [FIX] Fixed a regression in *decomposition.IncrementalPCA* where 0.20.0 raised an error if the number of samples in the final batch for fitting IncrementalPCA was smaller than n_components. #12234 by Ming Li.

sklearn.ensemble

- [FIX] Fixed a bug mostly affecting *ensemble.RandomForestClassifier* where `class_weight='balanced_subsample'` failed with more than 32 classes. #12165 by Joel Nothman.
- [FIX] Fixed a bug affecting *ensemble.BaggingClassifier*, *ensemble.BaggingRegressor* and *ensemble.IsolationForest*, where `max_features` was sometimes rounded down to zero. #12388 by Connor Tann.

sklearn.feature_extraction

- [FIX] Fixed a regression in v0.20.0 where *feature_extraction.text.CountVectorizer* and other text vectorizers could error during stop words validation with custom preprocessors or tokenizers. #12393 by Roman Yurchak.

sklearn.linear_model

- [FIX] *linear_model.SGDClassifier* and variants with `early_stopping=True` would not use a consistent validation split in the multiclass case and this would cause a crash when using those estimators as part of parallel parameter search or cross-validation. #12122 by Olivier Grisel.
- [FIX] Fixed a bug affecting `SGDClassifier` in the multiclass case. Each one-versus-all step is run in a `joblib.Parallel` call and mutating a common parameter, causing a segmentation fault if called within a backend using processes and not threads. We now use `require=sharedmem` at the `joblib.Parallel` instance creation. #12518 by Pierre Glaser and Olivier Grisel.

sklearn.metrics

- [FIX] Fixed a bug in `metrics.pairwise.pairwise_distances_argmin_min` which returned the square root of the distance when the metric parameter was set to "euclidean". #12481 by Jérémie du Boisberranger.
- [FIX] Fixed a bug in `metrics.pairwise.pairwise_distances_chunked` which didn't ensure the diagonal is zero for euclidean distances. #12612 by Andreas Müller.
- [API CHANGE] The *metrics.calinski_harabaz_score* has been renamed to *metrics.calinski_harabasz_score* and will be removed in version 0.23. #12211 by Lisa Thomas, Mark Hannel and Melissa Ferrari.

sklearn.mixture

- [FIX] Ensure that the `fit_predict` method of *mixture.GaussianMixture* and *mixture.BayesianGaussianMixture* always yield assignments consistent with `fit` followed by `predict` even if the convergence criterion is too loose or not met. #12451 by Olivier Grisel.

sklearn.neighbors

- [FIX] force the parallelism backend to `threading` for *neighbors.KDTree* and *neighbors.BallTree* in Python 2.7 to avoid pickling errors caused by the serialization of their methods. #12171 by Thomas Moreau.

sklearn.preprocessing

- [FIX] Fixed bug in *preprocessing.OrdinalEncoder* when passing manually specified categories. #12365 by Joris Van den Bossche.
- [FIX] Fixed bug in *preprocessing.KBinsDiscretizer* where the `transform` method mutates the `_encoder` attribute. The `transform` method is now thread safe. #12514 by Hanmin Qin.
- [FIX] Fixed a bug in *preprocessing.PowerTransformer* where the Yeo-Johnson transform was incorrect for lambda parameters outside of `[0, 2]` #12522 by Nicolas Hug.
- [FIX] Fixed a bug in *preprocessing.OneHotEncoder* where transform failed when set to ignore unknown numpy strings of different lengths #12471 by Gabriel Marzinotto.
- [API CHANGE] The default value of the `method` argument in *preprocessing.power_transform* will be changed from `box-cox` to `yeo-johnson` to match *preprocessing.PowerTransformer* in version 0.23. A FutureWarning is raised when the default value is used. #12317 by Eric Chang.

sklearn.utils

- [FIX] Use float64 for mean accumulator to avoid floating point precision issues in *preprocessing.StandardScaler* and *decomposition.IncrementalPCA* when using float32 datasets. #12338 by bauks.
- [FIX] Calling *utils.check_array* on `pandas.Series`, which raised an error in 0.20.0, now returns the expected output again. #12625 by Andreas Müller

Miscellaneous

- [FIX] When using site joblib by setting the environment variable `SKLEARN_SITE_JOBLIB`, added compatibility with joblib 0.11 in addition to 0.12+. #12350 by Joel Nothman and Roman Yurchak.
- [FIX] Make sure to avoid raising `FutureWarning` when calling `np.vstack` with numpy 1.16 and later (use list comprehensions instead of generator expressions in many locations of the scikit-learn code base). #12467 by Olivier Grisel.
- [API CHANGE] Removed all mentions of `sklearn.externals.joblib`, and deprecated joblib methods exposed in `sklearn.utils`, except for *utils.parallel_backend* and *utils.register_parallel_backend*, which allow users to configure parallel computation in scikit-learn. Other functionalities are part of joblib. package and should be used directly, by installing it. The goal of this change is to prepare for unvendoring joblib in future version of scikit-learn. #12345 by Thomas Moreau

1.7.12 Version 0.20.0

September 25, 2018

This release packs in a mountain of bug fixes, features and enhancements for the Scikit-learn library, and improvements to the documentation and examples. Thanks to our contributors!

This release is dedicated to the memory of Raghav Rajagopalan.

Warning: Version 0.20 is the last version of scikit-learn to support Python 2.7 and Python 3.4. Scikit-learn 0.21 will require Python 3.5 or higher.

Highlights

We have tried to improve our support for common data-science use-cases including missing values, categorical variables, heterogeneous data, and features/targets with unusual distributions. Missing values in features, represented by NaNs, are now accepted in column-wise preprocessing such as scalers. Each feature is fitted disregarding NaNs, and data containing NaNs can be transformed. The new `impute` module provides estimators for learning despite missing data.

`ColumnTransformer` handles the case where different features or columns of a pandas.DataFrame need different preprocessing. String or pandas Categorical columns can now be encoded with *`OneHotEncoder`* or *`OrdinalEncoder`*.

`TransformedTargetRegressor` helps when the regression target needs to be transformed to be modeled. *`PowerTransformer`* and *`KBinsDiscretizer`* join *`QuantileTransformer`* as non-linear transformations.

Beyond this, we have added *sample_weight* support to several estimators (including *`KMeans`*, *`BayesianRidge`* and *`KernelDensity`*) and improved stopping criteria in others (including *`MLPRegressor`*, *`GradientBoostingRegressor`* and *`SGDRegressor`*).

This release is also the first to be accompanied by a *Glossary of Common Terms and API Elements* developed by Joel Nothman. The glossary is a reference resource to help users and contributors become familiar with the terminology and conventions used in Scikit-learn.

Sorry if your contribution didn't make it into the highlights. There's a lot here...

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- *`cluster.MeanShift`* (bug fix)
- *`decomposition.IncrementalPCA`* in Python 2 (bug fix)

- *decomposition.SparsePCA* (bug fix)
- *ensemble.GradientBoostingClassifier* (bug fix affecting feature importances)
- *isotonic.IsotonicRegression* (bug fix)
- *linear_model.ARDRegression* (bug fix)
- *linear_model.LogisticRegressionCV* (bug fix)
- *linear_model.OrthogonalMatchingPursuit* (bug fix)
- *linear_model.PassiveAggressiveClassifier* (bug fix)
- *linear_model.PassiveAggressiveRegressor* (bug fix)
- *linear_model.Perceptron* (bug fix)
- *linear_model.SGDClassifier* (bug fix)
- *linear_model.SGDRegressor* (bug fix)
- *metrics.roc_auc_score* (bug fix)
- *metrics.roc_curve* (bug fix)
- neural_network.BaseMultilayerPerceptron (bug fix)
- *neural_network.MLPClassifier* (bug fix)
- *neural_network.MLPRegressor* (bug fix)
- The v0.19.0 release notes failed to mention a backwards incompatibility with *model_selection.StratifiedKFold* when `shuffle=True` due to #7823.

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

Known Major Bugs

- #11924: *linear_model.LogisticRegressionCV* with `solver='lbfgs'` and `multi_class='multinomial'` may be non-deterministic or otherwise broken on macOS. This appears to be the case on Travis CI servers, but has not been confirmed on personal MacBooks! This issue has been present in previous releases.
- #9354: *metrics.pairwise.euclidean_distances* (which is used several times throughout the library) gives results with poor precision, which particularly affects its use with 32-bit float inputs. This became more problematic in versions 0.18 and 0.19 when some algorithms were changed to avoid casting 32-bit data into 64-bit.

Changelog

Support for Python 3.3 has been officially dropped.

sklearn.cluster

- [Major Feature] *cluster.AgglomerativeClustering* now supports Single Linkage clustering via `linkage='single'`. #9372 by Leland McInnes and Steve Astels.
- [Feature] *cluster.KMeans* and *cluster.MiniBatchKMeans* now support sample weights via new parameter `sample_weight` in `fit` function. #10933 by Johannes Hansen.

- [EFFICIENCY] *cluster.KMeans*, *cluster.MiniBatchKMeans* and *cluster.k_means* passed with `algorithm='full'` now enforces row-major ordering, improving runtime. #10471 by Gaurav Dhingra.
- [EFFICIENCY] *cluster.DBSCAN* now is parallelized according to `n_jobs` regardless of `algorithm`. #8003 by Joël Billaud.
- [ENHANCEMENT] *cluster.KMeans* now gives a warning if the number of distinct clusters found is smaller than `n_clusters`. This may occur when the number of distinct points in the data set is actually smaller than the number of cluster one is looking for. #10059 by Christian Braune.
- [FIX] Fixed a bug where the `fit` method of *cluster.AffinityPropagation* stored cluster centers as 3d array instead of 2d array in case of non-convergence. For the same class, fixed undefined and arbitrary behavior in case of training data where all samples had equal similarity. #9612. By Jonatan Samoocha.
- [FIX] Fixed a bug in *cluster.spectral_clustering* where the normalization of the spectrum was using a division instead of a multiplication. #8129 by Jan Margeta, Guillaume Lemaitre, and Devansh D..
- [FIX] Fixed a bug in `cluster.k_means_elkan` where the returned `iteration` was 1 less than the correct value. Also added the missing `n_iter_` attribute in the docstring of *cluster.KMeans*. #11353 by Jeremie du Boisberranger.
- [FIX] Fixed a bug in *cluster.mean_shift* where the assigned labels were not deterministic if there were multiple clusters with the same intensities. #11901 by Adrin Jalali.
- [API CHANGE] Deprecate `pooling_func` unused parameter in *cluster.AgglomerativeClustering*. #9875 by Kumar Ashutosh.

sklearn.compose

- New module.
- [MAJOR FEATURE] Added *compose.ColumnTransformer*, which allows to apply different transformers to different columns of arrays or pandas DataFrames. #9012 by Andreas Müller and Joris Van den Bossche, and #11315 by Thomas Fan.
- [MAJOR FEATURE] Added the *compose.TransformedTargetRegressor* which transforms the target y before fitting a regression model. The predictions are mapped back to the original space via an inverse transform. #9041 by Andreas Müller and Guillaume Lemaitre.

sklearn.covariance

- [EFFICIENCY] Runtime improvements to *covariance.GraphicalLasso*. #9858 by Steven Brown.
- [API CHANGE] The `covariance.graph_lasso`, `covariance.GraphLasso` and `covariance.GraphLassoCV` have been renamed to *covariance.graphical_lasso*, *covariance.GraphicalLasso* and *covariance.GraphicalLassoCV* respectively and will be removed in version 0.22. #9993 by Artiem Krinitsyn

sklearn.datasets

- [MAJOR FEATURE] Added *datasets.fetch_openml* to fetch datasets from OpenML. OpenML is a free, open data sharing platform and will be used instead of mldata as it provides better service availability. #9908 by Andreas Müller and Jan N. van Rijn.
- [FEATURE] In *datasets.make_blobs*, one can now pass a list to the `n_samples` parameter to indicate the number of samples to generate per cluster. #8617 by Maskani Filali Mohamed and Konstantinos Katrioplas.

- [FEATURE] Add `filename` attribute to `datasets` that have a CSV file. #9101 by alex-33 and Maskani Filali Mohamed.
- [FEATURE] `return_X_y` parameter has been added to several dataset loaders. #10774 by Chris Catalfo.
- [FIX] Fixed a bug in *`datasets.load_boston`* which had a wrong data point. #10795 by Takeshi Yoshizawa.
- [FIX] Fixed a bug in *`datasets.load_iris`* which had two wrong data points. #11082 by Sadhana Srinivasan and Hanmin Qin.
- [FIX] Fixed a bug in *`datasets.fetch_kddcup99`*, where data were not properly shuffled. #9731 by Nicolas Goix.
- [FIX] Fixed a bug in *`datasets.make_circles`*, where no odd number of data points could be generated. #10045 by Christian Braune.
- [API CHANGE] Deprecated `sklearn.datasets.fetch_mldata` to be removed in version 0.22. mldata.org is no longer operational. Until removal it will remain possible to load cached datasets. #11466 by Joel Nothman.

sklearn.decomposition

- [FEATURE] *`decomposition.dict_learning`* functions and models now support positivity constraints. This applies to the dictionary and sparse code. #6374 by John Kirkham.
- [FEATURE] [FIX] *`decomposition.SparsePCA`* now exposes `normalize_components`. When set to True, the train and test data are centered with the train mean respectively during the fit phase and the transform phase. This fixes the behavior of SparsePCA. When set to False, which is the default, the previous abnormal behaviour still holds. The False value is for backward compatibility and should not be used. #11585 by Ivan Panico.
- [EFFICIENCY] Efficiency improvements in *`decomposition.dict_learning`*. #11420 and others by John Kirkham.
- [FIX] Fix for uninformative error in *`decomposition.IncrementalPCA`*: now an error is raised if the number of components is larger than the chosen batch size. The `n_components=None` case was adapted accordingly. #6452. By Wally Gauze.
- [FIX] Fixed a bug where the `partial_fit` method of *`decomposition.IncrementalPCA`* used integer division instead of float division on Python 2. #9492 by James Bourbeau.
- [FIX] In *`decomposition.PCA`* selecting a n_components parameter greater than the number of samples now raises an error. Similarly, the `n_components=None` case now selects the minimum of `n_samples` and `n_features`. #8484 by Wally Gauze.
- [FIX] Fixed a bug in *`decomposition.PCA`* where users will get unexpected error with large datasets when `n_components='mle'` on Python 3 versions. #9886 by Hanmin Qin.
- [FIX] Fixed an underflow in calculating KL-divergence for *`decomposition.NMF`* #10142 by Tom Dupre la Tour.
- [FIX] Fixed a bug in *`decomposition.SparseCoder`* when running OMP sparse coding in parallel using read-only memory mapped datastructures. #5956 by Vighnesh Birodkar and Olivier Grisel.

sklearn.discriminant_analysis

- [EFFICIENCY] Memory usage improvement for `_class_means` and `_class_cov` in `discriminant_analysis`. #10898 by Nanxin Chen.

sklearn.dummy

- [FEATURE] *dummy.DummyRegressor* now has a `return_std` option in its `predict` method. The returned standard deviations will be zeros.
- [FEATURE] *dummy.DummyClassifier* and *dummy.DummyRegressor* now only require X to be an object with finite length or shape. #9832 by Vrishank Bhardwaj.
- [FEATURE] *dummy.DummyClassifier* and *dummy.DummyRegressor* can now be scored without supplying test samples. #11951 by Rüdiger Busche.

sklearn.ensemble

- [FEATURE] *ensemble.BaggingRegressor* and *ensemble.BaggingClassifier* can now be fit with missing/non-finite values in X and/or multi-output Y to support wrapping pipelines that perform their own imputation. #9707 by Jimmy Wan.
- [FEATURE] *ensemble.GradientBoostingClassifier* and *ensemble.GradientBoostingRegressor* now support early stopping via `n_iter_no_change`, `validation_fraction` and `tol`. #7071 by Raghav RV
- [FEATURE] Added `named_estimators_` parameter in *ensemble.VotingClassifier* to access fitted estimators. #9157 by Herilalaina Rakotoarison.
- [FIX] Fixed a bug when fitting *ensemble.GradientBoostingClassifier* or *ensemble.GradientBoostingRegressor* with `warm_start=True` which previously raised a segmentation fault due to a non-conversion of CSC matrix into CSR format expected by `decision_function`. Similarly, Fortran-ordered arrays are converted to C-ordered arrays in the dense case. #9991 by Guillaume Lemaitre.
- [FIX] Fixed a bug in *ensemble.GradientBoostingRegressor* and *ensemble.GradientBoostingClassifier* to have feature importances summed and then normalized, rather than normalizing on a per-tree basis. The previous behavior over-weighted the Gini importance of features that appear in later stages. This issue only affected feature importances. #11176 by Gil Forsyth.
- [API CHANGE] The default value of the `n_estimators` parameter of *ensemble.RandomForestClassifier*, *ensemble.RandomForestRegressor*, *ensemble.ExtraTreesClassifier*, *ensemble.ExtraTreesRegressor*, and *ensemble.RandomTreesEmbedding* will change from 10 in version 0.20 to 100 in 0.22. A FutureWarning is raised when the default value is used. #11542 by Anna Ayzenshtat.
- [API CHANGE] Classes derived from `ensemble.BaseBagging`. The attribute `estimators_samples_` will return a list of arrays containing the indices selected for each bootstrap instead of a list of arrays containing the mask of the samples selected for each bootstrap. Indices allows to repeat samples while mask does not allow this functionality. #9524 by Guillaume Lemaitre.
- [FIX] `ensemble.BaseBagging` where one could not deterministically reproduce `fit` result using the object attributes when `random_state` is set. #9723 by Guillaume Lemaitre.

sklearn.feature_extraction

- [FEATURE] Enable the call to *get_feature_names* in unfitted *feature_extraction.text.CountVectorizer* initialized with a vocabulary. #10908 by Mohamed Maskani.
- [ENHANCEMENT] `idf_` can now be set on a *feature_extraction.text.TfidfTransformer*. #10899 by Sergey Melderis.

- [Fix] Fixed a bug in *feature_extraction.image.extract_patches_2d* which would throw an exception if `max_patches` was greater than or equal to the number of all possible patches rather than simply returning the number of possible patches. #10101 by Varun Agrawal
- [Fix] Fixed a bug in *feature_extraction.text.CountVectorizer*, *feature_extraction.text.TfidfVectorizer*, *feature_extraction.text.HashingVectorizer* to support 64 bit sparse array indexing necessary to process large datasets with more than $2 \cdot 10^9$ tokens (words or n-grams). #9147 by Claes-Fredrik Mannby and Roman Yurchak.
- [Fix] Fixed bug in *feature_extraction.text.TfidfVectorizer* which was ignoring the parameter `dtype`. In addition, *feature_extraction.text.TfidfTransformer* will preserve `dtype` for floating and raise a warning if `dtype` requested is integer. #10441 by Mayur Kulkarni and Guillaume Lemaitre.

sklearn.feature_selection

- [Feature] Added select K best features functionality to *feature_selection.SelectFromModel*. #6689 by Nihar Sheth and Quazi Rahman.
- [Feature] Added `min_features_to_select` parameter to *feature_selection.RFECV* to bound evaluated features counts. #11293 by Brent Yi.
- [Feature] *feature_selection.RFECV*'s fit method now supports *groups*. #9656 by Adam Greenhall.
- [Fix] Fixed computation of `n_features_to_compute` for edge case with tied CV scores in *feature_selection.RFECV*. #9222 by Nick Hoh.

sklearn.gaussian_process

- [Efficiency] In *gaussian_process.GaussianProcessRegressor*, method `predict` is faster when using `return_std=True` in particular more when called several times in a row. #9234 by andrewww and Minghui Liu.

sklearn.impute

- New module, adopting `preprocessing.Imputer` as *impute.SimpleImputer* with minor changes (see under preprocessing below).
- [Major Feature] Added *impute.MissingIndicator* which generates a binary indicator for missing values. #8075 by Maniteja Nandana and Guillaume Lemaitre.
- [Feature] The *impute.SimpleImputer* has a new strategy, `'constant'`, to complete missing values with a fixed one, given by the `fill_value` parameter. This strategy supports numeric and non-numeric data, and so does the `'most_frequent'` strategy now. #11211 by Jeremie du Boisberranger.

sklearn.isotonic

- [Fix] Fixed a bug in *isotonic.IsotonicRegression* which incorrectly combined weights when fitting a model to data involving points with identical X values. #9484 by Dallas Card

sklearn.linear_model

- [FEATURE] *linear_model.SGDClassifier*, *linear_model.SGDRegressor*, *linear_model.PassiveAggressiveClassifier*, *linear_model.PassiveAggressiveRegressor* and *linear_model.Perceptron* now expose `early_stopping`, `validation_fraction` and `n_iter_no_change` parameters, to stop optimization monitoring the score on a validation set. A new learning rate `"adaptive"` strategy divides the learning rate by 5 each time `n_iter_no_change` consecutive epochs fail to improve the model. #9043 by Tom Dupre la Tour.
- [FEATURE] Add `sample_weight` parameter to the fit method of *linear_model.BayesianRidge* for weighted linear regression. #10112 by Peter St. John.
- [FIX] Fixed a bug in `logistic.logistic_regression_path` to ensure that the returned coefficients are correct when `multiclass='multinomial'`. Previously, some of the coefficients would override each other, leading to incorrect results in *linear_model.LogisticRegressionCV*. #11724 by Nicolas Hug.
- [FIX] Fixed a bug in *linear_model.LogisticRegression* where when using the parameter `multi_class='multinomial'`, the `predict_proba` method was returning incorrect probabilities in the case of binary outcomes. #9939 by Roger Westover.
- [FIX] Fixed a bug in *linear_model.LogisticRegressionCV* where the `score` method always computes accuracy, not the metric given by the `scoring` parameter. #10998 by Thomas Fan.
- [FIX] Fixed a bug in *linear_model.LogisticRegressionCV* where the 'ovr' strategy was always used to compute cross-validation scores in the multiclass setting, even if `'multinomial'` was set. #8720 by William de Vazelhes.
- [FIX] Fixed a bug in *linear_model.OrthogonalMatchingPursuit* that was broken when setting `normalize=False`. #10071 by Alexandre Gramfort.
- [FIX] Fixed a bug in *linear_model.ARDRegression* which caused incorrectly updated estimates for the standard deviation and the coefficients. #10153 by Jörg Döpfert.
- [FIX] Fixed a bug in *linear_model.ARDRegression* and *linear_model.BayesianRidge* which caused NaN predictions when fitted with a constant target. #10095 by Jörg Döpfert.
- [FIX] Fixed a bug in *linear_model.RidgeClassifierCV* where the parameter `store_cv_values` was not implemented though it was documented in `cv_values` as a way to set up the storage of cross-validation values for different alphas. #10297 by Mabel Villalba-Jiménez.
- [FIX] Fixed a bug in *linear_model.ElasticNet* which caused the input to be overridden when using parameter `copy_X=True` and `check_input=False`. #10581 by Yacine Mazari.
- [FIX] Fixed a bug in *sklearn.linear_model.Lasso* where the coefficient had wrong shape when `fit_intercept=False`. #10687 by Martin Hahn.
- [FIX] Fixed a bug in *sklearn.linear_model.LogisticRegression* where the `multi_class='multinomial'` with binary output `with warm_start=True` #10836 by Aishwarya Srinivasan.
- [FIX] Fixed a bug in *linear_model.RidgeCV* where using integer `alphas` raised an error. #10397 by Mabel Villalba-Jiménez.
- [FIX] Fixed condition triggering gap computation in *linear_model.Lasso* and *linear_model.ElasticNet* when working with sparse matrices. #10992 by Alexandre Gramfort.
- [FIX] Fixed a bug in *linear_model.SGDClassifier*, *linear_model.SGDRegressor*, *linear_model.PassiveAggressiveClassifier*, *linear_model.PassiveAggressiveRegressor* and *linear_model.Perceptron*, where the stopping criterion was stopping the algorithm before convergence. A parameter `n_iter_no_change` was added and set by default to 5. Previous behavior is equivalent to setting the parameter to 1. #9043 by Tom Dupre la Tour.

- [FIX] Fixed a bug where liblinear and libsvm-based estimators would segfault if passed a scipy.sparse matrix with 64-bit indices. They now raise a ValueError. #11327 by Karan Dhingra and Joel Nothman.
- [API CHANGE] The default values of the `solver` and `multi_class` parameters of *`linear_model.LogisticRegression`* will change respectively from `'liblinear'` and `'ovr'` in version 0.20 to `'lbfgs'` and `'auto'` in version 0.22. A FutureWarning is raised when the default values are used. #11905 by Tom Dupre la Tour and Joel Nothman.
- [API CHANGE] Deprecate `positive=True` option in *`linear_model.Lars`* as the underlying implementation is broken. Use *`linear_model.Lasso`* instead. #9837 by Alexandre Gramfort.
- [API CHANGE] `n_iter_` may vary from previous releases in *`linear_model.LogisticRegression`* with `solver='lbfgs'` and *`linear_model.HuberRegressor`*. For Scipy <= 1.0.0, the optimizer could perform more than the requested maximum number of iterations. Now both estimators will report at most `max_iter` iterations even if more were performed. #10723 by Joel Nothman.

sklearn.manifold

- [EFFICIENCY] Speed improvements for both 'exact' and 'barnes_hut' methods in *`manifold.TSNE`*. #10593 and #10610 by Tom Dupre la Tour.
- [FEATURE] Support sparse input in *`manifold.Isomap.fit`*. #8554 by Leland McInnes.
- [FEATURE] `manifold.t_sne.trustworthiness` accepts metrics other than Euclidean. #9775 by William de Vazelhes.
- [FIX] Fixed a bug in *`manifold.spectral_embedding`* where the normalization of the spectrum was using a division instead of a multiplication. #8129 by Jan Margeta, Guillaume Lemaitre, and Devansh D..
- [API CHANGE] [FEATURE] Deprecate `precomputed` parameter in function `manifold.t_sne.trustworthiness`. Instead, the new parameter `metric` should be used with any compatible metric including 'precomputed', in which case the input matrix `X` should be a matrix of pairwise distances or squared distances. #9775 by William de Vazelhes.
- [API CHANGE] Deprecate `precomputed` parameter in function `manifold.t_sne.trustworthiness`. Instead, the new parameter `metric` should be used with any compatible metric including 'precomputed', in which case the input matrix `X` should be a matrix of pairwise distances or squared distances. #9775 by William de Vazelhes.

sklearn.metrics

- [MAJOR FEATURE] Added the *`metrics.davies_bouldin_score`* metric for evaluation of clustering models without a ground truth. #10827 by Luis Osa.
- [MAJOR FEATURE] Added the *`metrics.balanced_accuracy_score`* metric and a corresponding `'balanced_accuracy'` scorer for binary and multiclass classification. #8066 by @xyguo and Aman Dalmia, and #10587 by Joel Nothman.
- [FEATURE] Partial AUC is available via `max_fpr` parameter in *`metrics.roc_auc_score`*. #3840 by Alexander Niederbühl.
- [FEATURE] A scorer based on *`metrics.brier_score_loss`* is also available. #9521 by Hanmin Qin.
- [FEATURE] Added control over the normalization in *`metrics.normalized_mutual_info_score`* and *`metrics.adjusted_mutual_info_score`* via the `average_method` parameter. In version 0.22, the default normalizer for each will become the *arithmetic* mean of the entropies of each clustering. #11124 by Arya McCarthy.

- [FEATURE] Added `output_dict` parameter in *metrics.classification_report* to return classification statistics as dictionary. #11160 by Dan Barkhorn.
- [FEATURE] *metrics.classification_report* now reports all applicable averages on the given data, including micro, macro and weighted average as well as samples average for multilabel data. #11679 by Alexander Pacha.
- [FEATURE] *metrics.average_precision_score* now supports binary `y_true` other than `{0, 1}` or `{-1, 1}` through `pos_label` parameter. #9980 by Hanmin Qin.
- [FEATURE] *metrics.label_ranking_average_precision_score* now supports `sample_weight`. #10845 by Jose Perez-Parras Toledano.
- [FEATURE] Add `dense_output` parameter to *metrics.pairwise.linear_kernel*. When False and both inputs are sparse, will return a sparse matrix. #10999 by Taylor G Smith.
- [EFFICIENCY] *metrics.silhouette_score* and *metrics.silhouette_samples* are more memory efficient and run faster. This avoids some reported freezes and MemoryErrors. #11135 by Joel Nothman.
- [FIX] Fixed a bug in *metrics.precision_recall_fscore_support* when truncated `range(n_labels)` is passed as value for `labels`. #10377 by Gaurav Dhingra.
- [FIX] Fixed a bug due to floating point error in *metrics.roc_auc_score* with non-integer sample weights. #9786 by Hanmin Qin.
- [FIX] Fixed a bug where *metrics.roc_curve* sometimes starts on y-axis instead of (0, 0), which is inconsistent with the document and other implementations. Note that this will not influence the result from *metrics.roc_auc_score* #10093 by alexryndin and Hanmin Qin.
- [FIX] Fixed a bug to avoid integer overflow. Casted product to 64 bits integer in *metrics.mutual_info_score*. #9772 by Kumar Ashutosh.
- [FIX] Fixed a bug where *metrics.average_precision_score* will sometimes return `nan` when `sample_weight` contains 0. #9980 by Hanmin Qin.
- [FIX] Fixed a bug in *metrics.fowlkes_mallows_score* to avoid integer overflow. Casted return value of `contingency_matrix` to `int64` and computed product of square roots rather than square root of product. #9515 by Alan Liddell and Manh Dao.
- [API CHANGE] Deprecate `reorder` parameter in *metrics.auc* as it's no longer required for *metrics.roc_auc_score*. Moreover using `reorder=True` can hide bugs due to floating point error in the input. #9851 by Hanmin Qin.
- [API CHANGE] In *metrics.normalized_mutual_info_score* and *metrics.adjusted_mutual_info_score*, warn that `average_method` will have a new default value. In version 0.22, the default normalizer for each will become the *arithmetic* mean of the entropies of each clustering. Currently, *metrics.normalized_mutual_info_score* uses the default of `average_method='geometric'`, and *metrics.adjusted_mutual_info_score* uses the default of `average_method='max'` to match their behaviors in version 0.19. #11124 by Arya McCarthy.
- [API CHANGE] The `batch_size` parameter to *metrics.pairwise_distances_argmin_min* and *metrics.pairwise_distances_argmin* is deprecated to be removed in v0.22. It no longer has any effect, as batch size is determined by global `working_memory` config. See *Limiting Working Memory*. #10280 by Joel Nothman and Aman Dalmia.

sklearn.mixture

- [FEATURE] Added function *fit_predict* to *mixture.GaussianMixture* and *mixture.GaussianMixture*, which is essentially equivalent to calling *fit* and *predict*. #10336 by Shu Haoran and Andrew Peng.

- [Fix] Fixed a bug in `mixture.BaseMixture` where the reported `n_iter_` was missing an iteration. It affected *mixture.GaussianMixture* and *mixture.BayesianGaussianMixture*. #10740 by Erich Schubert and Guillaume Lemaitre.
- [Fix] Fixed a bug in `mixture.BaseMixture` and its subclasses *mixture.GaussianMixture* and *mixture.BayesianGaussianMixture* where the `lower_bound_` was not the max lower bound across all initializations (when `n_init > 1`), but just the lower bound of the last initialization. #10869 by Aurélien Géron.

sklearn.model_selection

- [Feature] Add `return_estimator` parameter in *model_selection.cross_validate* to return estimators fitted on each split. #9686 by Aurélien Bellet.
- [Feature] New `refit_time_` attribute will be stored in *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV* if `refit` is set to `True`. This will allow measuring the complete time it takes to perform hyperparameter optimization and refitting the best model on the whole dataset. #11310 by Matthias Feurer.
- [Feature] Expose `error_score` parameter in *model_selection.cross_validate*, *model_selection.cross_val_score*, *model_selection.learning_curve* and *model_selection.validation_curve* to control the behavior triggered when an error occurs in `model_selection._fit_and_score`. #11576 by Samuel O. Ronsin.
- [Feature] `BaseSearchCV` now has an experimental, private interface to support customized parameter search strategies, through its `_run_search` method. See the implementations in *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV* and please provide feedback if you use this. Note that we do not assure the stability of this API beyond version 0.20. #9599 by Joel Nothman
- [Enhancement] Add improved error message in *model_selection.cross_val_score* when multiple metrics are passed in `scoring` keyword. #11006 by Ming Li.
- [API Change] The default number of cross-validation folds `cv` and the default number of splits `n_splits` in the *model_selection.KFold*-like splitters will change from 3 to 5 in 0.22 as 3-fold has a lot of variance. #11557 by Alexandre Boucaud.
- [API Change] The default of `iid` parameter of *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV* will change from `True` to `False` in version 0.22 to correspond to the standard definition of cross-validation, and the parameter will be removed in version 0.24 altogether. This parameter is of greatest practical significance where the sizes of different test sets in cross-validation were very unequal, i.e. in group-based CV strategies. #9085 by Laurent Direr and Andreas Müller.
- [API Change] The default value of the `error_score` parameter in *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV* will change to `np.NaN` in version 0.22. #10677 by Kirill Zhdanovich.
- [API Change] Changed ValueError exception raised in *model_selection.ParameterSampler* to a UserWarning for case where the class is instantiated with a greater value of `n_iter` than the total space of parameters in the parameter grid. `n_iter` now acts as an upper bound on iterations. #10982 by Juliet Lawton
- [API Change] Invalid input for *model_selection.ParameterGrid* now raises TypeError. #10928 by Solutus Immensus

sklearn.multioutput

- [Major Feature] Added *multioutput.RegressorChain* for multi-target regression. #9257 by Kumar

Ashutosh.

sklearn.naive_bayes

- [Major Feature] Added *naive_bayes.ComplementNB*, which implements the Complement Naive Bayes classifier described in Rennie et al. (2003). #8190 by Michael A. Alcorn.
- [Feature] Add `var_smoothing` parameter in *naive_bayes.GaussianNB* to give a precise control over variances calculation. #9681 by Dmitry Mottl.
- [Fix] Fixed a bug in *naive_bayes.GaussianNB* which incorrectly raised error for prior list which summed to 1. #10005 by Gaurav Dhingra.
- [Fix] Fixed a bug in *naive_bayes.MultinomialNB* which did not accept vector valued pseudocounts (alpha). #10346 by Tobias Madsen

sklearn.neighbors

- [Efficiency] *neighbors.RadiusNeighborsRegressor* and *neighbors.RadiusNeighborsClassifier* are now parallelized according to `n_jobs` regardless of `algorithm`. #10887 by Joël Billaud.
- [Efficiency] `Nearest neighbors` query methods are now more memory efficient when `algorithm='brute'`. #11136 by Joel Nothman and Aman Dalmia.
- [Feature] Add `sample_weight` parameter to the fit method of *neighbors.KernelDensity* to enable weighting in kernel density estimation. #4394 by Samuel O. Ronsin.
- [Feature] Novelty detection with *neighbors.LocalOutlierFactor*: Add a `novelty` parameter to *neighbors.LocalOutlierFactor*. When `novelty` is set to True, *neighbors.LocalOutlierFactor* can then be used for novelty detection, i.e. predict on new unseen data. Available prediction methods are `predict`, `decision_function` and `score_samples`. By default, `novelty` is set to `False`, and only the `fit_predict` method is avaiable. By Albert Thomas.
- [Fix] Fixed a bug in *neighbors.NearestNeighbors* where fitting a NearestNeighbors model fails when a) the distance metric used is a callable and b) the input to the NearestNeighbors model is sparse. #9579 by Thomas Kober.
- [Fix] Fixed a bug so `predict` in *neighbors.RadiusNeighborsRegressor* can handle empty neighbor set when using non uniform weights. Also raises a new warning when no neighbors are found for samples. #9655 by Andreas Bjerre-Nielsen.
- [Fix] [Efficiency] Fixed a bug in `KDTree` construction that results in faster construction and querying times. #11556 by Jake VanderPlas
- [Fix] Fixed a bug in *neighbors.KDTree* and *neighbors.BallTree* where pickled tree objects would change their type to the super class `BinaryTree`. #11774 by Nicolas Hug.

sklearn.neural_network

- [Feature] Add `n_iter_no_change` parameter in `neural_network.BaseMultilayerPerceptron`, *neural_network.MLPRegressor*, and *neural_network.MLPClassifier* to give control over maximum number of epochs to not meet `tol` improvement. #9456 by Nicholas Nadeau.

- [FIX] Fixed a bug in `neural_network.BaseMultilayerPerceptron`, *neural_network.MLPRegressor*, and *neural_network.MLPClassifier* with new `n_iter_no_change` parameter now at 10 from previously hardcoded 2. #9456 by Nicholas Nadeau.
- [FIX] Fixed a bug in *neural_network.MLPRegressor* where fitting quit unexpectedly early due to local minima or fluctuations. #9456 by Nicholas Nadeau

sklearn.pipeline

- [FEATURE] The `predict` method of *pipeline.Pipeline* now passes keyword arguments on to the pipeline's last estimator, enabling the use of parameters such as `return_std` in a pipeline with caution. #9304 by Breno Freitas.
- [API CHANGE] *pipeline.FeatureUnion* now supports `'drop'` as a transformer to drop features. #11144 by Thomas Fan.

sklearn.preprocessing

- [MAJOR FEATURE] Expanded *preprocessing.OneHotEncoder* to allow to encode categorical string features as a numeric array using a one-hot (or dummy) encoding scheme, and added *preprocessing.OrdinalEncoder* to convert to ordinal integers. Those two classes now handle encoding of all feature types (also handles string-valued features) and derives the categories based on the unique values in the features instead of the maximum value in the features. #9151 and #10521 by Vighnesh Birodkar and Joris Van den Bossche.
- [MAJOR FEATURE] Added *preprocessing.KBinsDiscretizer* for turning continuous features into categorical or one-hot encoded features. #7668, #9647, #10195, #10192, #11272, #11467 and #11505. by Henry Lin, Hanmin Qin, Tom Dupre la Tour and Giovanni Giuseppe Costa.
- [MAJOR FEATURE] Added *preprocessing.PowerTransformer*, which implements the Yeo-Johnson and Box-Cox power transformations. Power transformations try to find a set of feature-wise parametric transformations to approximately map data to a Gaussian distribution centered at zero and with unit variance. This is useful as a variance-stabilizing transformation in situations where normality and homoscedasticity are desirable. #10210 by Eric Chang and Maniteja Nandana, and #11520 by Nicolas Hug.
- [MAJOR FEATURE] NaN values are ignored and handled in the following preprocessing methods: *preprocessing.MaxAbsScaler*, *preprocessing.MinMaxScaler*, *preprocessing.RobustScaler*, *preprocessing.StandardScaler*, *preprocessing.PowerTransformer*, *preprocessing.QuantileTransformer* classes and *preprocessing.maxabs_scale*, *preprocessing.minmax_scale*, *preprocessing.robust_scale*, *preprocessing.scale*, *preprocessing.power_transform*, *preprocessing.quantile_transform* functions respectively addressed in issues #11011, #11005, #11308, #11206, #11306, and #10437. By Lucija Gregov and Guillaume Lemaitre.
- [FEATURE] *preprocessing.PolynomialFeatures* now supports sparse input. #10452 by Aman Dalmia and Joel Nothman.
- [FEATURE] *preprocessing.RobustScaler* and *preprocessing.robust_scale* can be fitted using sparse matrices. #11308 by Guillaume Lemaitre.
- [FEATURE] *preprocessing.OneHotEncoder* now supports the *get_feature_names* method to obtain the transformed feature names. #10181 by Nirvan Anjirbag and Joris Van den Bossche.
- [FEATURE] A parameter `check_inverse` was added to *preprocessing.FunctionTransformer* to ensure that `func` and `inverse_func` are the inverse of each other. #9399 by Guillaume Lemaitre.

- [FEATURE] The `transform` method of *sklearn.preprocessing.MultiLabelBinarizer* now ignores any unknown classes. A warning is raised stating the unknown classes classes found which are ignored. #10913 by Rodrigo Agundez.
- [FIX] Fixed bugs in *preprocessing.LabelEncoder* which would sometimes throw errors when `transform` or `inverse_transform` was called with empty arrays. #10458 by Mayur Kulkarni.
- [FIX] Fix ValueError in *preprocessing.LabelEncoder* when using `inverse_transform` on unseen labels. #9816 by Charlie Newey.
- [FIX] Fix bug in *preprocessing.OneHotEncoder* which discarded the `dtype` when returning a sparse matrix output. #11042 by Daniel Morales.
- [FIX] Fix `fit` and `partial_fit` in *preprocessing.StandardScaler* in the rare case when `with_mean=False` and `with_std=False` which was crashing by calling `fit` more than once and giving inconsistent results for `mean_` whether the input was a sparse or a dense matrix. `mean_` will be set to `None` with both sparse and dense inputs. `n_samples_seen_` will be also reported for both input types. #11235 by Guillaume Lemaitre.
- [API CHANGE] Deprecate `n_values` and `categorical_features` parameters and `active_features_`, `feature_indices_` and `n_values_` attributes of *preprocessing.OneHotEncoder*. The `n_values` parameter can be replaced with the new `categories` parameter, and the attributes with the new `categories_` attribute. Selecting the categorical features with the `categorical_features` parameter is now better supported using the *compose.ColumnTransformer*. #10521 by Joris Van den Bossche.
- [API CHANGE] Deprecate `preprocessing.Imputer` and move the corresponding module to *impute.SimpleImputer*. #9726 by Kumar Ashutosh.
- [API CHANGE] The `axis` parameter that was in `preprocessing.Imputer` is no longer present in *impute.SimpleImputer*. The behavior is equivalent to `axis=0` (impute along columns). Row-wise imputation can be performed with FunctionTransformer (e.g., `FunctionTransformer(lambda X: SimpleImputer().fit_transform(X.T).T)`). #10829 by Guillaume Lemaitre and Gilberto Olimpio.
- [API CHANGE] The NaN marker for the missing values has been changed between the `preprocessing.Imputer` and the *impute.SimpleImputer*. `missing_values='NaN'` should now be `missing_values=np.nan`. #11211 by Jeremie du Boisberranger.
- [API CHANGE] In *preprocessing.FunctionTransformer*, the default of `validate` will be from `True` to `False` in 0.22. #10655 by Guillaume Lemaitre.

sklearn.svm

- [FIX] Fixed a bug in *svm.SVC* where when the argument `kernel` is unicode in Python2, the `predict_proba` method was raising an unexpected TypeError given dense inputs. #10412 by Jiongyan Zhang.
- [API CHANGE] Deprecate `random_state` parameter in *svm.OneClassSVM* as the underlying implementation is not random. #9497 by Albert Thomas.
- [API CHANGE] The default value of `gamma` parameter of *svm.SVC*, *NuSVC*, *SVR*, *NuSVR*, *OneClassSVM* will change from `'auto'` to `'scale'` in version 0.22 to account better for unscaled features. #8361 by Gaurav Dhingra and Ting Neo.

sklearn.tree

- [ENHANCEMENT] Although private (and hence not assured API stability), `tree._criterion.`

`ClassificationCriterion` and `tree._criterion.RegressionCriterion` may now be cimported and extended. #10325 by Camil Staps.

- [FIX] Fixed a bug in `tree.BaseDecisionTree` with `splitter="best"` where split threshold could become infinite when values in X were near infinite. #10536 by Jonathan Ohayon.
- [FIX] Fixed a bug in `tree.MAE` to ensure sample weights are being used during the calculation of tree MAE impurity. Previous behaviour could cause suboptimal splits to be chosen since the impurity calculation considered all samples to be of equal weight importance. #11464 by John Stott.

`sklearn.utils`

- [FEATURE] *`utils.check_array`* and *`utils.check_X_y`* now have `accept_large_sparse` to control whether scipy.sparse matrices with 64-bit indices should be rejected. #11327 by Karan Dhingra and Joel Nothman.
- [EFFICIENCY] [FIX] Avoid copying the data in *`utils.check_array`* when the input data is a memmap (and `copy=False`). #10663 by Arthur Mensch and Loïc Estève.
- [API CHANGE] *`utils.check_array`* yield a `FutureWarning` indicating that arrays of bytes/strings will be interpreted as decimal numbers beginning in version 0.22. #10229 by Ryan Lee

Multiple modules

- [FEATURE] [API CHANGE] More consistent outlier detection API: Add a `score_samples` method in *`svm.OneClassSVM`*, *`ensemble.IsolationForest`*, *`neighbors.LocalOutlierFactor`*, *`covariance.EllipticEnvelope`*. It allows to access raw score functions from original papers. A new `offset_` parameter allows to link `score_samples` and `decision_function` methods. The `contamination` parameter of *`ensemble.IsolationForest`* and *`neighbors.LocalOutlierFactor`* `decision_function` methods is used to define this `offset_` such that outliers (resp. inliers) have negative (resp. positive) `decision_function` values. By default, `contamination` is kept unchanged to 0.1 for a deprecation period. In 0.22, it will be set to "auto", thus using method-specific score offsets. In *`covariance.EllipticEnvelope`* `decision_function` method, the `raw_values` parameter is deprecated as the shifted Mahalanobis distance will be always returned in 0.22. #9015 by Nicolas Goix.
- [FEATURE] [API CHANGE] A `behaviour` parameter has been introduced in *`ensemble.IsolationForest`* to ensure backward compatibility. In the old behaviour, the `decision_function` is independent of the `contamination` parameter. A threshold attribute depending on the `contamination` parameter is thus used. In the new behaviour the `decision_function` is dependent on the `contamination` parameter, in such a way that 0 becomes its natural threshold to detect outliers. Setting behaviour to "old" is deprecated and will not be possible in version 0.22. Beside, the behaviour parameter will be removed in 0.24. #11553 by Nicolas Goix.
- [API CHANGE] Added convergence warning to *`svm.LinearSVC`* and *`linear_model.LogisticRegression`* when `verbose` is set to 0. #10881 by Alexandre Sevin.
- [API CHANGE] Changed warning type from `UserWarning` to *`exceptions.ConvergenceWarning`* for failing convergence in *`linear_model.logistic_regression_path`*, *`linear_model.RANSACRegressor`*, *`linear_model.ridge_regression`*, *`gaussian_process.GaussianProcessRegressor`*, *`gaussian_process.GaussianProcessClassifier`*, *`decomposition.fastica`*, *`cross_decomposition.PLSCanonical`*, *`cluster.AffinityPropagation`*, and *`cluster.Birch`*. #10306 by Jonathan Siebert.

Miscellaneous

- [MAJOR FEATURE] A new configuration parameter, `working_memory` was added to control memory consumption limits in chunked operations, such as the new *`metrics.pairwise_distances_chunked`*. See *Limiting Working Memory*. #10280 by Joel Nothman and Aman Dalmia.
- [FEATURE] The version of `joblib` bundled with Scikit-learn is now 0.12. This uses a new default multiprocessing implementation, named loky. While this may incur some memory and communication overhead, it should provide greater cross-platform stability than relying on Python standard library multiprocessing. #11741 by the Joblib developers, especially Thomas Moreau and Olivier Grisel.
- [FEATURE] An environment variable to use the site joblib instead of the vendored one was added (*Environment variables*). The main API of joblib is now exposed in *`sklearn.utils`*. #11166 by Gael Varoquaux.
- [FEATURE] Add almost complete PyPy 3 support. Known unsupported functionalities are *`datasets.load_svmlight_file`*, *`feature_extraction.FeatureHasher`* and *`feature_extraction.text.HashingVectorizer`*. For running on PyPy, PyPy3-v5.10+, Numpy 1.14.0+, and scipy 1.1.0+ are required. #11010 by Ronan Lamy and Roman Yurchak.
- [FEATURE] A utility method *`sklearn.show_versions`* was added to print out information relevant for debugging. It includes the user system, the Python executable, the version of the main libraries and BLAS binding information. #11596 by Alexandre Boucaud
- [FIX] Fixed a bug when setting parameters on meta-estimator, involving both a wrapped estimator and its parameter. #9999 by Marcus Voss and Joel Nothman.
- [FIX] Fixed a bug where calling *`sklearn.base.clone`* was not thread safe and could result in a "pop from empty list" error. #9569 by Andreas Müller.
- [API CHANGE] The default value of `n_jobs` is changed from `1` to `None` in all related functions and classes. `n_jobs=None` means `unset`. It will generally be interpreted as `n_jobs=1`, unless the current `joblib.Parallel` backend context specifies otherwise (See *Glossary* for additional information). Note that this change happens immediately (i.e., without a deprecation cycle). #11741 by Olivier Grisel.
- [FIX] Fixed a bug in validation helpers where passing a Dask DataFrame results in an error. #12462 by Zachariah Miller

Changes to estimator checks

These changes mostly affect library developers.

- Checks for transformers now apply if the estimator implements *transform*, regardless of whether it inherits from *`sklearn.base.TransformerMixin`*. #10474 by Joel Nothman.
- Classifiers are now checked for consistency between *decision_function* and categorical predictions. #10500 by Narine Kokhlikyan.
- Allow tests in *`utils.estimator_checks.check_estimator`* to test functions that accept pairwise data. #9701 by Kyle Johnson
- Allow *`utils.estimator_checks.check_estimator`* to check that there is no private settings apart from parameters during estimator initialization. #9378 by Herilalaina Rakotoarison
- The set of checks in *`utils.estimator_checks.check_estimator`* now includes a `check_set_params` test which checks that `set_params` is equivalent to passing parameters in `__init__` and warns if it encounters parameter validation. #7738 by Alvin Chiang
- Add invariance tests for clustering metrics. #8102 by Ankita Sinha and Guillaume Lemaitre.

- Add `check_methods_subset_invariance` to *check_estimator*, which checks that estimator methods are invariant if applied to a data subset. #10428 by Jonathan Ohayon
- Add tests in *utils.estimator_checks.check_estimator* to check that an estimator can handle read-only memmap input data. #10663 by Arthur Mensch and Loïc Estève.
- `check_sample_weights_pandas_series` now uses 8 rather than 6 samples to accommodate for the default number of clusters in *cluster.KMeans*. #10933 by Johannes Hansen.
- Estimators are now checked for whether `sample_weight=None` equates to `sample_weight=np.ones(...)`. #11558 by Sergul Aydore.

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.19, including:

1.7.13 Version 0.19.2

July, 2018

This release is exclusively in order to support Python 3.7.

Related changes

- `n_iter_` may vary from previous releases in *`linear_model.LogisticRegression`* with `solver='lbfgs'` and *`linear_model.HuberRegressor`*. For Scipy <= 1.0.0, the optimizer could perform more than the requested maximum number of iterations. Now both estimators will report at most `max_iter` iterations even if more were performed. #10723 by Joel Nothman.

1.7.14 Version 0.19.1

October 23, 2017

This is a bug-fix release with some minor documentation improvements and enhancements to features released in 0.19.0.

Note there may be minor differences in TSNE output in this release (due to #9623), in the case where multiple samples have equal distance to some sample.

Changelog

API changes

- Reverted the addition of `metrics.ndcg_score` and `metrics.dcg_score` which had been merged into version 0.19.0 by error. The implementations were broken and undocumented.
- `return_train_score` which was added to *`model_selection.GridSearchCV`*, *`model_selection.RandomizedSearchCV`* and *`model_selection.cross_validate`* in version 0.19.0 will be changing its default value from True to False in version 0.21. We found that calculating training score could have a great effect on cross validation runtime in some cases. Users should explicitly set `return_train_score` to False if prediction or scoring functions are slow, resulting in a deleterious effect on CV runtime, or to True if they wish to use the calculated scores. #9677 by Kumar Ashutosh and Joel Nothman.
- `correlation_models` and `regression_models` from the legacy gaussian processes implementation have been belatedly deprecated. #9717 by Kumar Ashutosh.

Bug fixes

- Avoid integer overflows in *metrics.matthews_corrcoef*. #9693 by Sam Steingold.
- Fixed a bug in the objective function for *manifold.TSNE* (both exact and with the Barnes-Hut approximation) when `n_components >= 3`. #9711 by @goncalo-rodrigues.
- Fix regression in *model_selection.cross_val_predict* where it raised an error with `method='predict_proba'` for some probabilistic classifiers. #9641 by James Bourbeau.
- Fixed a bug where *datasets.make_classification* modified its input `weights`. #9865 by Sachin Kelkar.
- *model_selection.StratifiedShuffleSplit* now works with multioutput multiclass or multilabel data with more than 1000 columns. #9922 by Charlie Brummitt.
- Fixed a bug with nested and conditional parameter setting, e.g. setting a pipeline step and its parameter at the same time. #9945 by Andreas Müller and Joel Nothman.

Regressions in 0.19.0 fixed in 0.19.1:

- Fixed a bug where parallelised prediction in random forests was not thread-safe and could (rarely) result in arbitrary errors. #9830 by Joel Nothman.
- Fix regression in *model_selection.cross_val_predict* where it no longer accepted `X` as a list. #9600 by Rasul Kerimov.
- Fixed handling of `cross_val_predict` for binary classification with `method='decision_function'`. #9593 by Reiichiro Nakano and core devs.
- Fix regression in *pipeline.Pipeline* where it no longer accepted `steps` as a tuple. #9604 by Joris Van den Bossche.
- Fix bug where `n_iter` was not properly deprecated, leaving `n_iter` unavailable for interim use in *linear_model.SGDClassifier*, *linear_model.SGDRegressor*, *linear_model.PassiveAggressiveClassifier*, *linear_model.PassiveAggressiveRegressor* and *linear_model.Perceptron*. #9558 by Andreas Müller.
- Dataset fetchers make sure temporary files are closed before removing them, which caused errors on Windows. #9847 by Joan Massich.
- Fixed a regression in *manifold.TSNE* where it no longer supported metrics other than 'euclidean' and 'precomputed'. #9623 by Oli Blum.

Enhancements

- Our test suite and `utils.estimator_checks.check_estimators` can now be run without Nose installed. #9697 by Joan Massich.
- To improve usability of version 0.19's *pipeline.Pipeline* caching, `memory` now allows `joblib.Memory` instances. This make use of the new *utils.validation.check_memory* helper. issue:`9584` by Kumar Ashutosh
- Some fixes to examples: #9750, #9788, #9815
- Made a FutureWarning in SGD-based estimators less verbose. #9802 by Vrishank Bhardwaj.

1.7.15 Version 0.19

August 12, 2017

Highlights

We are excited to release a number of great new features including *neighbors.LocalOutlierFactor* for anomaly detection, *preprocessing.QuantileTransformer* for robust feature transformation, and the *multioutput.ClassifierChain* meta-estimator to simply account for dependencies between classes in multilabel problems. We have some new algorithms in existing estimators, such as multiplicative update in *decomposition.NMF* and multinomial *linear_model.LogisticRegression* with L1 loss (use `solver='saga'`).

Cross validation is now able to return the results from multiple metric evaluations. The new *model_selection.cross_validate* can return many scores on the test data as well as training set performance and timings, and we have extended the `scoring` and `refit` parameters for grid/randomized search *to handle multiple metrics*.

You can also learn faster. For instance, the *new option to cache transformations* in *pipeline.Pipeline* makes grid search over pipelines including slow transformations much more efficient. And you can predict faster: if you're sure you know what you're doing, you can turn off validating that the input is finite using *config_context*.

We've made some important fixes too. We've fixed a longstanding implementation error in *metrics.average_precision_score*, so please be cautious with prior results reported from that function. A number of errors in the *manifold.TSNE* implementation have been fixed, particularly in the default Barnes-Hut approximation. *semi_supervised.LabelSpreading* and *semi_supervised.LabelPropagation* have had substantial fixes. LabelPropagation was previously broken. LabelSpreading should now correctly respect its alpha parameter.

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- *cluster.KMeans* with sparse X and initial centroids given (bug fix)
- *cross_decomposition.PLSRegression* with `scale=True` (bug fix)
- *ensemble.GradientBoostingClassifier* and *ensemble.GradientBoostingRegressor* where `min_impurity_split` is used (bug fix)
- gradient boosting `loss='quantile'` (bug fix)
- *ensemble.IsolationForest* (bug fix)
- *feature_selection.SelectFdr* (bug fix)
- *linear_model.RANSACRegressor* (bug fix)

- *linear_model.LassoLars* (bug fix)
- *linear_model.LassoLarsIC* (bug fix)
- *manifold.TSNE* (bug fix)
- *neighbors.NearestCentroid* (bug fix)
- *semi_supervised.LabelSpreading* (bug fix)
- *semi_supervised.LabelPropagation* (bug fix)
- tree based models where `min_weight_fraction_leaf` is used (enhancement)
- *model_selection.StratifiedKFold* with `shuffle=True` (this change, due to #7823 was not mentioned in the release notes at the time)

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

Changelog

New features

Classifiers and regressors

- Added *multioutput.ClassifierChain* for multi-label classification. By Adam Kleczewski.
- Added solver `'saga'` that implements the improved version of Stochastic Average Gradient, in *linear_model.LogisticRegression* and *linear_model.Ridge*. It allows the use of L1 penalty with multinomial logistic loss, and behaves marginally better than 'sag' during the first epochs of ridge and logistic regression. #8446 by Arthur Mensch.

Other estimators

- Added the *neighbors.LocalOutlierFactor* class for anomaly detection based on nearest neighbors. #5279 by Nicolas Goix and Alexandre Gramfort.
- Added *preprocessing.QuantileTransformer* class and *preprocessing.quantile_transform* function for features normalization based on quantiles. #8363 by Denis Engemann, Guillaume Lemaitre, Olivier Grisel, Raghav RV, Thierry Guillemot, and Gael Varoquaux.
- The new solver `'mu'` implements a Multiplicate Update in *decomposition.NMF*, allowing the optimization of all beta-divergences, including the Frobenius norm, the generalized Kullback-Leibler divergence and the Itakura-Saito divergence. #5295 by Tom Dupre la Tour.

Model selection and evaluation

- *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV* now support simultaneous evaluation of multiple metrics. Refer to the *Specifying multiple metrics for evaluation* section of the user guide for more information. #7388 by Raghav RV
- Added the *model_selection.cross_validate* which allows evaluation of multiple metrics. This function returns a dict with more useful information from cross-validation such as the train scores, fit times and score times. Refer to *The cross_validate function and multiple metric evaluation* section of the userguide for more information. #7388 by Raghav RV
- Added *metrics.mean_squared_log_error*, which computes the mean square error of the logarithmic transformation of targets, particularly useful for targets with an exponential trend. #7655 by Karan Desai.
- Added *metrics.dcg_score* and *metrics.ndcg_score*, which compute Discounted cumulative gain (DCG) and Normalized discounted cumulative gain (NDCG). #7739 by David Gasquez.

- Added the *model_selection.RepeatedKFold* and *model_selection.RepeatedStratifiedKFold*. #8120 by Neeraj Gangwar.

Miscellaneous

- Validation that input data contains no NaN or inf can now be suppressed using *config_context*, at your own risk. This will save on runtime, and may be particularly useful for prediction time. #7548 by Joel Nothman.
- Added a test to ensure parameter listing in docstrings match the function/class signature. #9206 by Alexandre Gramfort and Raghav RV.

Enhancements

Trees and ensembles

- The `min_weight_fraction_leaf` constraint in tree construction is now more efficient, taking a fast path to declare a node a leaf if its weight is less than 2 * the minimum. Note that the constructed tree will be different from previous versions where `min_weight_fraction_leaf` is used. #7441 by Nelson Liu.
- *ensemble.GradientBoostingClassifier* and *ensemble.GradientBoostingRegressor* now support sparse input for prediction. #6101 by Ibraim Ganiev.
- *ensemble.VotingClassifier* now allows changing estimators by using *ensemble.VotingClassifier.set_params*. An estimator can also be removed by setting it to `None`. #7674 by Yichuan Liu.
- *tree.export_graphviz* now shows configurable number of decimal places. #8698 by Guillaume Lemaitre.
- Added `flatten_transform` parameter to *ensemble.VotingClassifier* to change output shape of `transform` method to 2 dimensional. #7794 by Ibraim Ganiev and Herilalaina Rakotoarison.

Linear, kernelized and related models

- *linear_model.SGDClassifier*, *linear_model.SGDRegressor*, *linear_model.PassiveAggressiveClassifier*, *linear_model.PassiveAggressiveRegressor* and *linear_model.Perceptron* now expose `max_iter` and `tol` parameters, to handle convergence more precisely. `n_iter` parameter is deprecated, and the fitted estimator exposes a `n_iter_` attribute, with actual number of iterations before convergence. #5036 by Tom Dupre la Tour.
- Added `average` parameter to perform weight averaging in *linear_model.PassiveAggressiveClassifier*. #4939 by Andrea Esuli.
- *linear_model.RANSACRegressor* no longer throws an error when calling `fit` if no inliers are found in its first iteration. Furthermore, causes of skipped iterations are tracked in newly added attributes, `n_skips_*`. #7914 by Michael Horrell.
- In *gaussian_process.GaussianProcessRegressor*, method `predict` is a lot faster with `return_std=True`. #8591 by Hadrien Bertrand.
- Added `return_std` to `predict` method of *linear_model.ARDRegression* and *linear_model.BayesianRidge*. #7838 by Sergey Feldman.
- Memory usage enhancements: Prevent cast from float32 to float64 in: *linear_model.MultiTaskElasticNet*; *linear_model.LogisticRegression* when using newton-cg solver; and *linear_model.Ridge* when using svd, sparse_cg, cholesky or lsqr solvers. #8835, #8061 by Joan Massich and Nicolas Cordier and Thierry Guillemot.

Other predictors

- Custom metrics for the `neighbors` binary trees now have fewer constraints: they must take two 1d-arrays and return a float. #6288 by Jake Vanderplas.
- `algorithm='auto` in `neighbors` estimators now chooses the most appropriate algorithm for all input types and metrics. #9145 by Herilalaina Rakotoarison and Reddy Chinthala.

Decomposition, manifold learning and clustering

- *`cluster.MiniBatchKMeans`* and *`cluster.KMeans`* now use significantly less memory when assigning data points to their nearest cluster center. #7721 by Jon Crall.
- *`decomposition.PCA`*, *`decomposition.IncrementalPCA`* and *`decomposition.TruncatedSVD`* now expose the singular values from the underlying SVD. They are stored in the attribute `singular_values_`, like in *`decomposition.IncrementalPCA`*. #7685 by Tommy Löfstedt
- *`decomposition.NMF`* now faster when `beta_loss=0`. #9277 by @hongkahjun.
- Memory improvements for method `barnes_hut` in *`manifold.TSNE`* #7089 by Thomas Moreau and Olivier Grisel.
- Optimization schedule improvements for Barnes-Hut *`manifold.TSNE`* so the results are closer to the one from the reference implementation lvdmaaten/bhtsne by Thomas Moreau and Olivier Grisel.
- Memory usage enhancements: Prevent cast from float32 to float64 in *`decomposition.PCA`* and `decomposition.randomized_svd_low_rank`. #9067 by Raghav RV.

Preprocessing and feature selection

- Added `norm_order` parameter to *`feature_selection.SelectFromModel`* to enable selection of the norm order when `coef_` is more than 1D. #6181 by Antoine Wendlinger.
- Added ability to use sparse matrices in *`feature_selection.f_regression`* with `center=True`. #8065 by Daniel LeJeune.
- Small performance improvement to n-gram creation in `feature_extraction.text` by binding methods for loops and special-casing unigrams. #7567 by Jaye Doepke
- Relax assumption on the data for the *`kernel_approximation.SkewedChi2Sampler`*. Since the Skewed-Chi2 kernel is defined on the open interval $(-skewedness; +\infty)^d$, the transform function should not check whether `X < 0` but whether `X < -self.skewedness`. #7573 by Romain Brault.
- Made default kernel parameters kernel-dependent in *`kernel_approximation.Nystroem`*. #5229 by Saurabh Bansod and Andreas Müller.

Model evaluation and meta-estimators

- *`pipeline.Pipeline`* is now able to cache transformers within a pipeline by using the `memory` constructor parameter. #7990 by Guillaume Lemaitre.
- *`pipeline.Pipeline`* steps can now be accessed as attributes of its `named_steps` attribute. #8586 by Herilalaina Rakotoarison.
- Added `sample_weight` parameter to *`pipeline.Pipeline.score`*. #7723 by Mikhail Korobov.
- Added ability to set `n_jobs` parameter to *`pipeline.make_union`*. A `TypeError` will be raised for any other kwargs. #8028 by Alexander Booth.
- *`model_selection.GridSearchCV`*, *`model_selection.RandomizedSearchCV`* and *`model_selection.cross_val_score`* now allow estimators with callable kernels which were previously prohibited. #8005 by Andreas Müller .
- *`model_selection.cross_val_predict`* now returns output of the correct shape for all values of the argument `method`. #7863 by Aman Dalmia.

- Added `shuffle` and `random_state` parameters to shuffle training data before taking prefixes of it based on training sizes in *model_selection.learning_curve*. #7506 by Narine Kokhlikyan.
- *model_selection.StratifiedShuffleSplit* now works with multioutput multiclass (or multilabel) data. #9044 by Vlad Niculae.
- Speed improvements to *model_selection.StratifiedShuffleSplit*. #5991 by Arthur Mensch and Joel Nothman.
- Add `shuffle` parameter to *model_selection.train_test_split*. #8845 by themrmax
- *multioutput.MultiOutputRegressor* and *multioutput.MultiOutputClassifier* now support online learning using `partial_fit`. :issue: `8053` by Peng Yu.
- Add `max_train_size` parameter to *model_selection.TimeSeriesSplit* #8282 by Aman Dalmia.
- More clustering metrics are now available through *metrics.get_scorer* and `scoring` parameters. #8117 by Raghav RV.
- A scorer based on *metrics.explained_variance_score* is also available. #9259 by Hanmin Qin.

Metrics

- *metrics.matthews_corrcoef* now support multiclass classification. #8094 by Jon Crall.
- Add `sample_weight` parameter to *metrics.cohen_kappa_score*. #8335 by Victor Poughon.

Miscellaneous

- `utils.check_estimator` now attempts to ensure that methods transform, predict, etc. do not set attributes on the estimator. #7533 by Ekaterina Krivich.
- Added type checking to the `accept_sparse` parameter in `utils.validation` methods. This parameter now accepts only boolean, string, or list/tuple of strings. `accept_sparse=None` is deprecated and should be replaced by `accept_sparse=False`. #7880 by Josh Karnofsky.
- Make it possible to load a chunk of an svmlight formatted file by passing a range of bytes to *datasets.load_svmlight_file*. #935 by Olivier Grisel.
- *dummy.DummyClassifier* and *dummy.DummyRegressor* now accept non-finite features. #8931 by @Attractadore.

Bug fixes

Trees and ensembles

- Fixed a memory leak in trees when using trees with `criterion='mae'`. #8002 by Raghav RV.
- Fixed a bug where *ensemble.IsolationForest* uses an an incorrect formula for the average path length #8549 by Peter Wang.
- Fixed a bug where *ensemble.AdaBoostClassifier* throws `ZeroDivisionError` while fitting data with single class labels. #7501 by Dominik Krzeminski.
- Fixed a bug in *ensemble.GradientBoostingClassifier* and *ensemble.GradientBoostingRegressor* where a float being compared to `0.0` using `==` caused a divide by zero error. #7970 by He Chen.
- Fix a bug where *ensemble.GradientBoostingClassifier* and *ensemble.GradientBoostingRegressor* ignored the `min_impurity_split` parameter. #8006 by Sebastian Pölsterl.
- Fixed `oob_score` in *ensemble.BaggingClassifier*. #8936 by Michael Lewis

- Fixed excessive memory usage in prediction for random forests estimators. #8672 by Mike Benfield.
- Fixed a bug where `sample_weight` as a list broke random forests in Python 2 #8068 by @xor.
- Fixed a bug where *ensemble.IsolationForest* fails when `max_features` is less than 1. #5732 by Ishank Gulati.
- Fix a bug where gradient boosting with `loss='quantile'` computed negative errors for negative values of `ytrue - ypred` leading to wrong values when calling `__call__`. #8087 by Alexis Mignon
- Fix a bug where *ensemble.VotingClassifier* raises an error when a numpy array is passed in for weights. #7983 by Vincent Pham.
- Fixed a bug where *tree.export_graphviz* raised an error when the length of features_names does not match n_features in the decision tree. #8512 by Li Li.

Linear, kernelized and related models

- Fixed a bug where *linear_model.RANSACRegressor.fit* may run until `max_iter` if it finds a large inlier group early. #8251 by @aivision2020.
- Fixed a bug where *naive_bayes.MultinomialNB* and *naive_bayes.BernoulliNB* failed when `alpha=0`. #5814 by Yichuan Liu and Herilalaina Rakotoarison.
- Fixed a bug where *linear_model.LassoLars* does not give the same result as the LassoLars implementation available in R (lars library). #7849 by Jair Montoya Martinez.
- Fixed a bug in `linear_model.RandomizedLasso`, *linear_model.Lars*, *linear_model.LassoLars*, *linear_model.LarsCV* and *linear_model.LassoLarsCV*, where the parameter `precompute` was not used consistently across classes, and some values proposed in the docstring could raise errors. #5359 by Tom Dupre la Tour.
- Fix inconsistent results between *linear_model.RidgeCV* and *linear_model.Ridge* when using `normalize=True`. #9302 by Alexandre Gramfort.
- Fix a bug where *linear_model.LassoLars.fit* sometimes left `coef_` as a list, rather than an ndarray. #8160 by CJ Carey.
- Fix *linear_model.BayesianRidge.fit* to return ridge parameter `alpha_` and `lambda_` consistent with calculated coefficients `coef_` and `intercept_`. #8224 by Peter Gedeck.
- Fixed a bug in *svm.OneClassSVM* where it returned floats instead of integer classes. #8676 by Vathsala Achar.
- Fix AIC/BIC criterion computation in *linear_model.LassoLarsIC*. #9022 by Alexandre Gramfort and Mehmet Basbug.
- Fixed a memory leak in our LibLinear implementation. #9024 by Sergei Lebedev
- Fix bug where stratified CV splitters did not work with *linear_model.LassoCV*. #8973 by Paulo Haddad.
- Fixed a bug in *gaussian_process.GaussianProcessRegressor* when the standard deviation and covariance predicted without fit would fail with a unmeaningful error by default. #6573 by Quazi Marufur Rahman and Manoj Kumar.

Other predictors

- Fix `semi_supervised.BaseLabelPropagation` to correctly implement `LabelPropagation` and `LabelSpreading` as done in the referenced papers. #9239 by Andre Ambrosio Boechat, Utkarsh Upadhyay, and Joel Nothman.

Decomposition, manifold learning and clustering

- Fixed the implementation of *manifold.TSNE*:

- `early_exageration` parameter had no effect and is now used for the first 250 optimization iterations.
- Fixed the `AssertionError: Tree consistency failed` exception reported in #8992.
- Improve the learning schedule to match the one from the reference implementation lvdmaaten/bhtsne. by Thomas Moreau and Olivier Grisel.
- Fix a bug in *decomposition.LatentDirichletAllocation* where the `perplexity` method was returning incorrect results because the `transform` method returns normalized document topic distributions as of version 0.18. #7954 by Gary Foreman.
- Fix output shape and bugs with n_jobs > 1 in *decomposition.SparseCoder* transform and *decomposition.sparse_encode* for one-dimensional data and one component. This also impacts the output shape of *decomposition.DictionaryLearning*. #8086 by Andreas Müller.
- Fixed the implementation of `explained_variance_` in *decomposition.PCA*, `decomposition.RandomizedPCA` and *decomposition.IncrementalPCA*. #9105 by Hanmin Qin.
- Fixed the implementation of `noise_variance_` in *decomposition.PCA*. #9108 by Hanmin Qin.
- Fixed a bug where *cluster.DBSCAN* gives incorrect result when input is a precomputed sparse matrix with initial rows all zero. #8306 by Akshay Gupta
- Fix a bug regarding fitting *cluster.KMeans* with a sparse array X and initial centroids, where X's means were unnecessarily being subtracted from the centroids. #7872 by Josh Karnofsky.
- Fixes to the input validation in *covariance.EllipticEnvelope*. #8086 by Andreas Müller.
- Fixed a bug in *covariance.MinCovDet* where inputting data that produced a singular covariance matrix would cause the helper method `_c_step` to throw an exception. #3367 by Jeremy Steward
- Fixed a bug in *manifold.TSNE* affecting convergence of the gradient descent. #8768 by David DeTomaso.
- Fixed a bug in *manifold.TSNE* where it stored the incorrect `kl_divergence_`. #6507 by Sebastian Saeger.
- Fixed improper scaling in *cross_decomposition.PLSRegression* with `scale=True`. #7819 by jayzed82.
- `cluster.bicluster.SpectralCoclustering` and `cluster.bicluster.SpectralBiclustering` `fit` method conforms with API by accepting `y` and returning the object. #6126, #7814 by Laurent Direr and Maniteja Nandana.
- Fix bug where `mixture` `sample` methods did not return as many samples as requested. #7702 by Levi John Wolf.
- Fixed the shrinkage implementation in *neighbors.NearestCentroid*. #9219 by Hanmin Qin.

Preprocessing and feature selection

- For sparse matrices, *preprocessing.normalize* with `return_norm=True` will now raise a `NotImplementedError` with 'l1' or 'l2' norm and with norm 'max' the norms returned will be the same as for dense matrices. #7771 by Ang Lu.
- Fix a bug where *feature_selection.SelectFdr* did not exactly implement Benjamini-Hochberg procedure. It formerly may have selected fewer features than it should. #7490 by Peng Meng.
- Fixed a bug where `linear_model.RandomizedLasso` and `linear_model.RandomizedLogisticRegression` breaks for sparse input. #8259 by Aman Dalmia.
- Fix a bug where *feature_extraction.FeatureHasher* mandatorily applied a sparse random projection to the hashed features, preventing the use of *feature_extraction.text.HashingVectorizer* in a pipeline with *feature_extraction.text.TfidfTransformer*. #7565 by Roman Yurchak.

- Fix a bug where *feature_selection.mutual_info_regression* did not correctly use n_neighbors. #8181 by Guillaume Lemaitre.

Model evaluation and meta-estimators

- Fixed a bug where model_selection.BaseSearchCV.inverse_transform returns self.best_estimator_.transform() instead of self.best_estimator_.inverse_transform(). #8344 by Akshay Gupta and Rasmus Eriksson.
- Added classes_ attribute to *model_selection.GridSearchCV*, *model_selection.RandomizedSearchCV*, grid_search.GridSearchCV, and grid_search.RandomizedSearchCV that matches the classes_ attribute of best_estimator_. #7661 and #8295 by Alyssa Batula, Dylan Werner-Meier, and Stephen Hoover.
- Fixed a bug where *model_selection.validation_curve* reused the same estimator for each parameter value. #7365 by Aleksandr Sandrovskii.
- *model_selection.permutation_test_score* now works with Pandas types. #5697 by Stijn Tonk.
- Several fixes to input validation in *multiclass.OutputCodeClassifier* #8086 by Andreas Müller.
- *multiclass.OneVsOneClassifier*'s partial_fit now ensures all classes are provided up-front. #6250 by Asish Panda.
- Fix *multioutput.MultiOutputClassifier.predict_proba* to return a list of 2d arrays, rather than a 3d array. In the case where different target columns had different numbers of classes, a ValueError would be raised on trying to stack matrices with different dimensions. #8093 by Peter Bull.
- Cross validation now works with Pandas datatypes that that have a read-only index. #9507 by Loic Esteve.

Metrics

- *metrics.average_precision_score* no longer linearly interpolates between operating points, and instead weighs precisions by the change in recall since the last operating point, as per the Wikipedia entry. (#7356). By Nick Dingwall and Gael Varoquaux.
- Fix a bug in metrics.classification._check_targets which would return 'binary' if y_true and y_pred were both 'binary' but the union of y_true and y_pred was 'multiclass'. #8377 by Loic Esteve.
- Fixed an integer overflow bug in *metrics.confusion_matrix* and hence *metrics.cohen_kappa_score*. #8354, #7929 by Joel Nothman and Jon Crall.
- Fixed passing of gamma parameter to the chi2 kernel in *metrics.pairwise.pairwise_kernels* #5211 by Nick Rhinehart, Saurabh Bansod and Andreas Müller.

Miscellaneous

- Fixed a bug when *datasets.make_classification* fails when generating more than 30 features. #8159 by Herilalaina Rakotoarison.
- Fixed a bug where *datasets.make_moons* gives an incorrect result when n_samples is odd. #8198 by Josh Levy.
- Some fetch_ functions in datasets were ignoring the download_if_missing keyword. #7944 by Ralf Gommers.
- Fix estimators to accept a sample_weight parameter of type pandas.Series in their fit function. #7825 by Kathleen Chen.
- Fix a bug in cases where numpy.cumsum may be numerically unstable, raising an exception if instability is identified. #7376 and #7331 by Joel Nothman and @yangarbiter.

- Fix a bug where `base.BaseEstimator.__getstate__` obstructed pickling customizations of child-classes, when used in a multiple inheritance context. #8316 by Holger Peters.
- Update Sphinx-Gallery from 0.1.4 to 0.1.7 for resolving links in documentation build with Sphinx>1.5 #8010, #7986 by Oscar Najera
- Add `data_home` parameter to *`sklearn.datasets.fetch_kddcup99`*. #9289 by Loic Esteve.
- Fix dataset loaders using Python 3 version of makedirs to also work in Python 2. #9284 by Sebastin Santy.
- Several minor issues were fixed with thanks to the alerts of lgtm.com. #9278 by Jean Helie, among others.

API changes summary

Trees and ensembles

- Gradient boosting base models are no longer estimators. By Andreas Müller.
- All tree based estimators now accept a `min_impurity_decrease` parameter in lieu of the `min_impurity_split`, which is now deprecated. The `min_impurity_decrease` helps stop splitting the nodes in which the weighted impurity decrease from splitting is no longer at least `min_impurity_decrease`. #8449 by Raghav RV.

Linear, kernelized and related models

- `n_iter` parameter is deprecated in *`linear_model.SGDClassifier`*, *`linear_model.SGDRegressor`*, *`linear_model.PassiveAggressiveClassifier`*, *`linear_model.PassiveAggressiveRegressor`* and *`linear_model.Perceptron`*. By Tom Dupre la Tour.

Other predictors

- `neighbors.LSHForest` has been deprecated and will be removed in 0.21 due to poor performance. #9078 by Laurent Direr.
- *`neighbors.NearestCentroid`* no longer purports to support `metric='precomputed'` which now raises an error. #8515 by Sergul Aydore.
- The `alpha` parameter of *`semi_supervised.LabelPropagation`* now has no effect and is deprecated to be removed in 0.21. #9239 by Andre Ambrosio Boechat, Utkarsh Upadhyay, and Joel Nothman.

Decomposition, manifold learning and clustering

- Deprecate the `doc_topic_distr` argument of the `perplexity` method in *`decomposition.LatentDirichletAllocation`* because the user no longer has access to the unnormalized document topic distribution needed for the perplexity calculation. #7954 by Gary Foreman.
- The `n_topics` parameter of *`decomposition.LatentDirichletAllocation`* has been renamed to `n_components` and will be removed in version 0.21. #8922 by @Attractadore.
- *`decomposition.SparsePCA.transform`*'s `ridge_alpha` parameter is deprecated in preference for class parameter. #8137 by Naoya Kanai.
- *`cluster.DBSCAN`* now has a `metric_params` parameter. #8139 by Naoya Kanai.

Preprocessing and feature selection

- *`feature_selection.SelectFromModel`* now has a `partial_fit` method only if the underlying estimator does. By Andreas Müller.
- *`feature_selection.SelectFromModel`* now validates the `threshold` parameter and sets the `threshold_` attribute during the call to `fit`, and no longer during the call to `transform`. By Andreas Müller.

- The non_negative parameter in *feature_extraction.FeatureHasher* has been deprecated, and replaced with a more principled alternative, alternate_sign. #7565 by Roman Yurchak.
- linear_model.RandomizedLogisticRegression, and linear_model.RandomizedLasso have been deprecated and will be removed in version 0.21. #8995 by Ramana.S.

Model evaluation and meta-estimators

- Deprecate the fit_params constructor input to the *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV* in favor of passing keyword parameters to the fit methods of those classes. Data-dependent parameters needed for model training should be passed as keyword arguments to fit, and conforming to this convention will allow the hyperparameter selection classes to be used with tools such as *model_selection.cross_val_predict*. #2879 by Stephen Hoover.
- In version 0.21, the default behavior of splitters that use the test_size and train_size parameter will change, such that specifying train_size alone will cause test_size to be the remainder. #7459 by Nelson Liu.
- *multiclass.OneVsRestClassifier* now has partial_fit, decision_function and predict_proba methods only when the underlying estimator does. #7812 by Andreas Müller and Mikhail Korobov.
- *multiclass.OneVsRestClassifier* now has a partial_fit method only if the underlying estimator does. By Andreas Müller.
- The decision_function output shape for binary classification in *multiclass.OneVsRestClassifier* and *multiclass.OneVsOneClassifier* is now (n_samples,) to conform to scikit-learn conventions. #9100 by Andreas Müller.
- The *multioutput.MultiOutputClassifier.predict_proba* function used to return a 3d array (n_samples, n_classes, n_outputs). In the case where different target columns had different numbers of classes, a ValueError would be raised on trying to stack matrices with different dimensions. This function now returns a list of arrays where the length of the list is n_outputs, and each array is (n_samples, n_classes) for that particular output. #8093 by Peter Bull.
- Replace attribute named_steps dict to utils.Bunch in *pipeline.Pipeline* to enable tab completion in interactive environment. In the case conflict value on named_steps and dict attribute, dict behavior will be prioritized. #8481 by Herilalaina Rakotoarison.

Miscellaneous

- Deprecate the y parameter in transform and inverse_transform. The method should not accept y parameter, as it's used at the prediction time. #8174 by Tahar Zanouda, Alexandre Gramfort and Raghav RV.
- SciPy >= 0.13.3 and NumPy >= 1.8.2 are now the minimum supported versions for scikit-learn. The following backported functions in utils have been removed or deprecated accordingly. #8854 and #8874 by Naoya Kanai
- The store_covariances and covariances_ parameters of *discriminant_analysis.QuadraticDiscriminantAnalysis* has been renamed to store_covariance and covariance_ to be consistent with the corresponding parameter names of the *discriminant_analysis.LinearDiscriminantAnalysis*. They will be removed in version 0.21. #7998 by Jiacheng

  Removed in 0.19:

  - utils.fixes.argpartition
  - utils.fixes.array_equal
  - utils.fixes.astype
  - utils.fixes.bincount

  - `utils.fixes.expit`
  - `utils.fixes.frombuffer_empty`
  - `utils.fixes.in1d`
  - `utils.fixes.norm`
  - `utils.fixes.rankdata`
  - `utils.fixes.safe_copy`

  Deprecated in 0.19, to be removed in 0.21:

  - `utils.arpack.eigs`
  - `utils.arpack.eigsh`
  - `utils.arpack.svds`
  - `utils.extmath.fast_dot`
  - `utils.extmath.logsumexp`
  - `utils.extmath.norm`
  - `utils.extmath.pinvh`
  - `utils.graph.graph_laplacian`
  - `utils.random.choice`
  - `utils.sparsetools.connected_components`
  - `utils.stats.rankdata`

- Estimators with both methods `decision_function` and `predict_proba` are now required to have a monotonic relation between them. The method `check_decision_proba_consistency` has been added in **utils.estimator_checks** to check their consistency. #7578 by Shubham Bhardwaj
- All checks in `utils.estimator_checks`, in particular *`utils.estimator_checks.check_estimator`* now accept estimator instances. Most other checks do not accept estimator classes any more. #9019 by Andreas Müller.
- Ensure that estimators' attributes ending with _ are not set in the constructor but only in the `fit` method. Most notably, ensemble estimators (deriving from `ensemble.BaseEnsemble`) now only have `self.estimators_` available after `fit`. #7464 by Lars Buitinck and Loic Esteve.

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.18, including:

Joel Nothman, Loic Esteve, Andreas Mueller, Guillaume Lemaitre, Olivier Grisel, Hanmin Qin, Raghav RV, Alexandre Gramfort, themrmax, Aman Dalmia, Gael Varoquaux, Naoya Kanai, Tom Dupré la Tour, Rishikesh, Nelson Liu, Taehoon Lee, Nelle Varoquaux, Aashil, Mikhail Korobov, Sebastin Santy, Joan Massich, Roman Yurchak, RAKOTOARISON Herilalaina, Thierry Guillemot, Alexandre Abadie, Carol Willing, Balakumaran Manoharan, Josh Karnofsky, Vlad Niculae, Utkarsh Upadhyay, Dmitry Petrov, Minghui Liu, Srivatsan, Vincent Pham, Albert Thomas, Jake VanderPlas, Attractadore, JC Liu, alexandercbooth, chkoar, Óscar Nájera, Aarshay Jain, Kyle Gilliam, Ramana Subramanyam, CJ Carey, Clement Joudet, David Robles, He Chen, Joris Van den Bossche, Karan Desai, Katie Luangkote, Leland McInnes, Maniteja Nandana, Michele Lacchia, Sergei Lebedev, Shubham Bhardwaj, akshay0724, omtcyfz, rickiepark, waterponey, Vathsala Achar, jbDelafosse, Ralf Gommers, Ekaterina Krivich, Vivek Kumar, Ishank Gulati, Dave Elliott, ldirer, Reiichiro Nakano, Levi John Wolf, Mathieu Blondel, Sid Kapur, Dougal J. 1.7.16 Version 0.18.2

June 20, 2017

Last release with Python 2.6 support

Scikit-learn 0.18 is the last major release of scikit-learn to support Python 2.6. Later versions of scikit-learn will require Python 2.7 or above.

Changelog

- Fixes for compatibility with NumPy 1.13.0: #7946 #8355 by Loic Esteve.
- Minor compatibility changes in the examples #9010 #8040 #9149.

Code Contributors

Aman Dalmia, Loic Esteve, Nate Guerin, Sergei Lebedev

1.7.17 Version 0.18.1

November 11, 2016

Changelog

Enhancements

- Improved `sample_without_replacement` speed by utilizing numpy.random.permutation for most cases. As a result, samples may differ in this release for a fixed random state. Affected estimators:
  - *ensemble.BaggingClassifier*
  - *ensemble.BaggingRegressor*
  - *linear_model.RANSACRegressor*
  - *model_selection.RandomizedSearchCV*
  - *random_projection.SparseRandomProjection*

  This also affects the *datasets.make_classification* method.

Bug fixes

- Fix issue where `min_grad_norm` and `n_iter_without_progress` parameters were not being utilised by *manifold.TSNE*. #6497 by Sebastian Säger
- Fix bug for svm's decision values when `decision_function_shape` is `ovr` in *svm.SVC*. *svm.SVC*'s decision_function was incorrect from versions 0.17.0 through 0.18.0. #7724 by Bing Tian Dai
- Attribute `explained_variance_ratio` of *discriminant_analysis.LinearDiscriminantAnalysis* calculated with SVD and Eigen solver are now of the same length. #7632 by JPFrancoia
- Fixes issue in *Univariate feature selection* where score functions were not accepting multi-label targets. #7676 by Mohammed Affan
- Fixed setting parameters when calling `fit` multiple times on *feature_selection.SelectFromModel*. #7756 by Andreas Müller
- Fixes issue in `partial_fit` method of *multiclass.OneVsRestClassifier* when number of classes used in `partial_fit` was less than the total number of classes in the data. #7786 by Srivatsan Ramesh
- Fixes issue in *calibration.CalibratedClassifierCV* where the sum of probabilities of each class for a data was not 1, and `CalibratedClassifierCV` now handles the case where the training set has less number of classes than the total data. #7799 by Srivatsan Ramesh
- Fix a bug where *sklearn.feature_selection.SelectFdr* did not exactly implement Benjamini-Hochberg procedure. It formerly may have selected fewer features than it should. #7490 by Peng Meng.
- *sklearn.manifold.LocallyLinearEmbedding* now correctly handles integer inputs. #6282 by Jake Vanderplas.
- The `min_weight_fraction_leaf` parameter of tree-based classifiers and regressors now assumes uniform sample weights by default if the `sample_weight` argument is not passed to the `fit` function. Previously, the parameter was silently ignored. #7301 by Nelson Liu.
- Numerical issue with *linear_model.RidgeCV* on centered data when `n_features > n_samples`. #6178 by Bertrand Thirion

- Tree splitting criterion classes' cloning/pickling is now memory safe #7680 by Ibraim Ganiev.
- Fixed a bug where *decomposition.NMF* sets its n_iters_ attribute in transform(). #7553 by Ekaterina Krivich.
- *sklearn.linear_model.LogisticRegressionCV* now correctly handles string labels. #5874 by Raghav RV.
- Fixed a bug where *sklearn.model_selection.train_test_split* raised an error when stratify is a list of string labels. #7593 by Raghav RV.
- Fixed a bug where *sklearn.model_selection.GridSearchCV* and *sklearn.model_selection.RandomizedSearchCV* were not pickleable because of a pickling bug in np.ma.MaskedArray. #7594 by Raghav RV.
- All cross-validation utilities in *sklearn.model_selection* now permit one time cross-validation splitters for the cv parameter. Also non-deterministic cross-validation splitters (where multiple calls to split produce dissimilar splits) can be used as cv parameter. The *sklearn.model_selection.GridSearchCV* will cross-validate each parameter setting on the split produced by the first split call to the cross-validation splitter. #7660 by Raghav RV.
- Fix bug where *preprocessing.MultiLabelBinarizer.fit_transform* returned an invalid CSR matrix. #7750 by CJ Carey.
- Fixed a bug where *metrics.pairwise.cosine_distances* could return a small negative distance. #7732 by Artsion.

API changes summary

Trees and forests

- The min_weight_fraction_leaf parameter of tree-based classifiers and regressors now assumes uniform sample weights by default if the sample_weight argument is not passed to the fit function. Previously, the parameter was silently ignored. #7301 by Nelson Liu.
- Tree splitting criterion classes' cloning/pickling is now memory safe. #7680 by Ibraim Ganiev.

Linear, kernelized and related models

- Length of explained_variance_ratio of *discriminant_analysis.LinearDiscriminantAnalysis* changed for both Eigen and SVD solvers. The attribute has now a length of min(n_components, n_classes - 1). #7632 by JPFrancoia
- Numerical issue with *linear_model.RidgeCV* on centered data when n_features > n_samples. #6178 by Bertrand Thirion

1.7.18 Version 0.18

September 28, 2016

Last release with Python 2.6 support

Scikit-learn 0.18 will be the last version of scikit-learn to support Python 2.6. Later versions of scikit-learn will require Python 2.7 or above.

Model Selection Enhancements and API Changes

- **The model_selection module**

  The new module *sklearn.model_selection*, which groups together the functionalities of formerly sklearn.cross_validation, sklearn.grid_search and sklearn.learning_curve, introduces new possibilities such as nested cross-validation and better manipulation of parameter searches with Pandas.

  Many things will stay the same but there are some key differences. Read below to know more about the changes.

- **Data-independent CV splitters enabling nested cross-validation**

  The new cross-validation splitters, defined in the *sklearn.model_selection*, are no longer initialized with any data-dependent parameters such as y. Instead they expose a split method that takes in the data and yields a generator for the different splits.

  This change makes it possible to use the cross-validation splitters to perform nested cross-validation, facilitated by *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV* utilities.

- **The enhanced cv_results_ attribute**

  The new cv_results_ attribute (of *model_selection.GridSearchCV* and *model_selection.RandomizedSearchCV*) introduced in lieu of the grid_scores_ attribute is a dict of 1D arrays with elements in each array corresponding to the parameter settings (i.e. search candidates).

  The cv_results_ dict can be easily imported into pandas as a DataFrame for exploring the search results.

  The cv_results_ arrays include scores for each cross-validation split (with keys such as 'split0_test_score'), as well as their mean ('mean_test_score') and standard deviation ('std_test_score').

  The ranks for the search candidates (based on their mean cross-validation score) is available at cv_results_['rank_test_score'].

  The parameter values for each parameter is stored separately as numpy masked object arrays. The value, for that search candidate, is masked if the corresponding parameter is not applicable. Additionally a list of all the parameter dicts are stored at cv_results_['params'].

- **Parameters n_folds and n_iter renamed to n_splits**

  Some parameter names have changed: The n_folds parameter in new *model_selection.KFold*, *model_selection.GroupKFold* (see below for the name change), and *model_selection.StratifiedKFold* is now renamed to n_splits. The n_iter parameter in *model_selection.ShuffleSplit*, the new class *model_selection.GroupShuffleSplit* and *model_selection.StratifiedShuffleSplit* is now renamed to n_splits.

- **Rename of splitter classes which accepts group labels along with data**

  The cross-validation splitters LabelKFold, LabelShuffleSplit, LeaveOneLabelOut and LeavePLabelOut have been renamed to *model_selection.GroupKFold*, *model_selection.GroupShuffleSplit*, *model_selection.LeaveOneGroupOut* and *model_selection.LeavePGroupsOut* respectively.

  Note the change from singular to plural form in *model_selection.LeavePGroupsOut*.

- **Fit parameter labels renamed to groups**

  The labels parameter in the split method of the newly renamed splitters *model_selection.GroupKFold*, *model_selection.LeaveOneGroupOut*, *model_selection.LeavePGroupsOut*, *model_selection.GroupShuffleSplit* is renamed to groups following the new nomenclature of their class names.

- **Parameter n_labels renamed to n_groups**

  The parameter `n_labels` in the newly renamed *model_selection.LeavePGroupsOut* is changed to `n_groups`.

- Training scores and Timing information

  `cv_results_` also includes the training scores for each cross-validation split (with keys such as `'split0_train_score'`), as well as their mean (`'mean_train_score'`) and standard deviation (`'std_train_score'`). To avoid the cost of evaluating training score, set `return_train_score=False`.

  Additionally the mean and standard deviation of the times taken to split, train and score the model across all the cross-validation splits is available at the key `'mean_time'` and `'std_time'` respectively.

Changelog

New features

Classifiers and Regressors

- The Gaussian Process module has been reimplemented and now offers classification and regression estimators through *gaussian_process.GaussianProcessClassifier* and *gaussian_process.GaussianProcessRegressor*. Among other things, the new implementation supports kernel engineering, gradient-based hyperparameter optimization or sampling of functions from GP prior and GP posterior. Extensive documentation and examples are provided. By Jan Hendrik Metzen.
- Added new supervised learning algorithm: *Multi-layer Perceptron* #3204 by Issam H. Laradji
- Added *linear_model.HuberRegressor*, a linear model robust to outliers. #5291 by Manoj Kumar.
- Added the *multioutput.MultiOutputRegressor* meta-estimator. It converts single output regressors to multi-output regressors by fitting one regressor per output. By Tim Head.

Other estimators

- New *mixture.GaussianMixture* and *mixture.BayesianGaussianMixture* replace former mixture models, employing faster inference for sounder results. #7295 by Wei Xue and Thierry Guillemot.
- Class `decomposition.RandomizedPCA` is now factored into *decomposition.PCA* and it is available calling with parameter `svd_solver='randomized'`. The default number of `n_iter` for `'randomized'` has changed to 4. The old behavior of PCA is recovered by `svd_solver='full'`. An additional solver calls `arpack` and performs truncated (non-randomized) SVD. By default, the best solver is selected depending on the size of the input and the number of components requested. #5299 by Giorgio Patrini.
- Added two functions for mutual information estimation: *feature_selection.mutual_info_classif* and *feature_selection.mutual_info_regression*. These functions can be used in *feature_selection.SelectKBest* and *feature_selection.SelectPercentile* as score functions. By Andrea Bravi and Nikolay Mayorov.
- Added the *ensemble.IsolationForest* class for anomaly detection based on random forests. By Nicolas Goix.
- Added `algorithm="elkan"` to *cluster.KMeans* implementing Elkan's fast K-Means algorithm. By Andreas Müller.

Model selection and evaluation

- Added `metrics.cluster.fowlkes_mallows_score`, the Fowlkes Mallows Index which measures the similarity of two clusterings of a set of points By Arnaud Fouchet and Thierry Guillemot.

- Added *metrics.calinski_harabaz_score*, which computes the Calinski and Harabaz score to evaluate the resulting clustering of a set of points. By Arnaud Fouchet and Thierry Guillemot.
- Added new cross-validation splitter *model_selection.TimeSeriesSplit* to handle time series data. #6586 by YenChen Lin
- The cross-validation iterators are replaced by cross-validation splitters available from *sklearn.model_selection*, allowing for nested cross-validation. See *Model Selection Enhancements and API Changes* for more information. #4294 by Raghav RV.

Enhancements

Trees and ensembles

- Added a new splitting criterion for *tree.DecisionTreeRegressor*, the mean absolute error. This criterion can also be used in *ensemble.ExtraTreesRegressor*, *ensemble.RandomForestRegressor*, and the gradient boosting estimators. #6667 by Nelson Liu.
- Added weighted impurity-based early stopping criterion for decision tree growth. #6954 by Nelson Liu
- The random forest, extra tree and decision tree estimators now has a method `decision_path` which returns the decision path of samples in the tree. By Arnaud Joly.
- A new example has been added unveiling the decision tree structure. By Arnaud Joly.
- Random forest, extra trees, decision trees and gradient boosting estimator accept the parameter `min_samples_split` and `min_samples_leaf` provided as a percentage of the training samples. By yelite and Arnaud Joly.
- Gradient boosting estimators accept the parameter `criterion` to specify to splitting criterion used in built decision trees. #6667 by Nelson Liu.
- The memory footprint is reduced (sometimes greatly) for `ensemble.bagging.BaseBagging` and classes that inherit from it, i.e, *ensemble.BaggingClassifier*, *ensemble.BaggingRegressor*, and *ensemble.IsolationForest*, by dynamically generating attribute `estimators_samples_` only when it is needed. By David Staub.
- Added `n_jobs` and `sample_weight` parameters for *ensemble.VotingClassifier* to fit underlying estimators in parallel. #5805 by Ibraim Ganiev.

Linear, kernelized and related models

- In *linear_model.LogisticRegression*, the SAG solver is now available in the multinomial case. #5251 by Tom Dupre la Tour.
- *linear_model.RANSACRegressor*, *svm.LinearSVC* and *svm.LinearSVR* now support `sample_weight`. By Imaculate.
- Add parameter `loss` to *linear_model.RANSACRegressor* to measure the error on the samples for every trial. By Manoj Kumar.
- Prediction of out-of-sample events with Isotonic Regression (*isotonic.IsotonicRegression*) is now much faster (over 1000x in tests with synthetic data). By Jonathan Arfa.
- Isotonic regression (*isotonic.IsotonicRegression*) now uses a better algorithm to avoid `O(n^2)` behavior in pathological cases, and is also generally faster (##6691). By Antony Lee.
- *naive_bayes.GaussianNB* now accepts data-independent class-priors through the parameter `priors`. By Guillaume Lemaitre.

- *linear_model.ElasticNet* and *linear_model.Lasso* now works with `np.float32` input data without converting it into `np.float64`. This allows to reduce the memory consumption. #6913 by YenChen Lin.
- *semi_supervised.LabelPropagation* and *semi_supervised.LabelSpreading* now accept arbitrary kernel functions in addition to strings `knn` and `rbf`. #5762 by Utkarsh Upadhyay.

Decomposition, manifold learning and clustering

- Added `inverse_transform` function to *decomposition.NMF* to compute data matrix of original shape. By Anish Shah.
- *cluster.KMeans* and *cluster.MiniBatchKMeans* now works with `np.float32` and `np.float64` input data without converting it. This allows to reduce the memory consumption by using `np.float32`. #6846 by Sebastian Säger and YenChen Lin.

Preprocessing and feature selection

- *preprocessing.RobustScaler* now accepts `quantile_range` parameter. #5929 by Konstantin Podshumok.
- *feature_extraction.FeatureHasher* now accepts string values. #6173 by Ryad Zenine and Devashish Deshpande.
- Keyword arguments can now be supplied to `func` in *preprocessing.FunctionTransformer* by means of the `kw_args` parameter. By Brian McFee.
- *feature_selection.SelectKBest* and *feature_selection.SelectPercentile* now accept score functions that take X, y as input and return only the scores. By Nikolay Mayorov.

Model evaluation and meta-estimators

- *multiclass.OneVsOneClassifier* and *multiclass.OneVsRestClassifier* now support `partial_fit`. By Asish Panda and Philipp Dowling.
- Added support for substituting or disabling *pipeline.Pipeline* and *pipeline.FeatureUnion* components using the `set_params` interface that powers `sklearn.grid_search`. See *Selecting dimensionality reduction with Pipeline and GridSearchCV* By Joel Nothman and Robert McGibbon.
- The new `cv_results_` attribute of *model_selection.GridSearchCV* (and *model_selection.RandomizedSearchCV*) can be easily imported into pandas as a `DataFrame`. Ref *Model Selection Enhancements and API Changes* for more information. #6697 by Raghav RV.
- Generalization of *model_selection.cross_val_predict*. One can pass method names such as `predict_proba` to be used in the cross validation framework instead of the default `predict`. By Ori Ziv and Sears Merritt.
- The training scores and time taken for training followed by scoring for each search candidate are now available at the `cv_results_` dict. See *Model Selection Enhancements and API Changes* for more information. #7325 by Eugene Chen and Raghav RV.

Metrics

- Added `labels` flag to *metrics.log_loss* to explicitly provide the labels when the number of classes in `y_true` and `y_pred` differ. #7239 by Hong Guangguo with help from Mads Jensen and Nelson Liu.
- Support sparse contingency matrices in cluster evaluation (`metrics.cluster.supervised`) to scale to a large number of clusters. #7419 by Gregory Stupp and Joel Nothman.
- Add `sample_weight` parameter to *metrics.matthews_corrcoef*. By Jatin Shah and Raghav RV.
- Speed up *metrics.silhouette_score* by using vectorized operations. By Manoj Kumar.
- Add `sample_weight` parameter to *metrics.confusion_matrix*. By Bernardo Stein.

Miscellaneous

- Added `n_jobs` parameter to *`feature_selection.RFECV`* to compute the score on the test folds in parallel. By Manoj Kumar
- Codebase does not contain C/C++ cython generated files: they are generated during build. Distribution packages will still contain generated C/C++ files. By Arthur Mensch.
- Reduce the memory usage for 32-bit float input arrays of `utils.sparse_func.mean_variance_axis` and `utils.sparse_func.incr_mean_variance_axis` by supporting cython fused types. By YenChen Lin.
- The `ignore_warnings` now accept a category argument to ignore only the warnings of a specified type. By Thierry Guillemot.
- Added parameter `return_X_y` and return type `(data, target) : tuple` option to `load_iris` dataset #7049, `load_breast_cancer` dataset #7152, `load_digits` dataset, `load_diabetes` dataset, `load_linnerud` dataset, `load_boston` dataset #7154 by Manvendra Singh.
- Simplification of the `clone` function, deprecate support for estimators that modify parameters in `__init__`. #5540 by Andreas Müller.
- When unpickling a scikit-learn estimator in a different version than the one the estimator was trained with, a `UserWarning` is raised, see *the documentation on model persistence* for more details. (#7248) By Andreas Müller.

Bug fixes

Trees and ensembles

- Random forest, extra trees, decision trees and gradient boosting won't accept anymore `min_samples_split=1` as at least 2 samples are required to split a decision tree node. By Arnaud Joly
- *`ensemble.VotingClassifier`* now raises `NotFittedError` if `predict`, `transform` or `predict_proba` are called on the non-fitted estimator. by Sebastian Raschka.
- Fix bug where *`ensemble.AdaBoostClassifier`* and *`ensemble.AdaBoostRegressor`* would perform poorly if the `random_state` was fixed (#7411). By Joel Nothman.
- Fix bug in ensembles with randomization where the ensemble would not set `random_state` on base estimators in a pipeline or similar nesting. (#7411). Note, results for *`ensemble.BaggingClassifier`* *`ensemble.BaggingRegressor`*, *`ensemble.AdaBoostClassifier`* and *`ensemble.AdaBoostRegressor`* will now differ from previous versions. By Joel Nothman.

Linear, kernelized and related models

- Fixed incorrect gradient computation for `loss='squared_epsilon_insensitive'` in *`linear_model.SGDClassifier`* and *`linear_model.SGDRegressor`* (#6764). By Wenhua Yang.
- Fix bug in *`linear_model.LogisticRegressionCV`* where `solver='liblinear'` did not accept `class_weights='balanced`. (#6817). By Tom Dupre la Tour.
- Fix bug in *`neighbors.RadiusNeighborsClassifier`* where an error occurred when there were outliers being labelled and a weight function specified (#6902). By LeonieBorne.
- Fix *`linear_model.ElasticNet`* sparse decision function to match output with dense in the multioutput case.

Decomposition, manifold learning and clustering

- `decomposition.RandomizedPCA` default number of `iterated_power` is 4 instead of 3. #5141 by Giorgio Patrini.
- *`utils.extmath.randomized_svd`* performs 4 power iterations by default, instead or 0. In practice this is enough for obtaining a good approximation of the true eigenvalues/vectors in the presence of noise. When `n_components` is small (`< .1 * min(X.shape)`) `n_iter` is set to 7, unless the user specifies a higher number. This improves precision with few components. #5299 by Giorgio Patrini.
- Whiten/non-whiten inconsistency between components of *`decomposition.PCA`* and `decomposition.RandomizedPCA` (now factored into PCA, see the New features) is fixed. `components_` are stored with no whitening. #5299 by Giorgio Patrini.
- Fixed bug in *`manifold.spectral_embedding`* where diagonal of unnormalized Laplacian matrix was incorrectly set to 1. #4995 by Peter Fischer.
- Fixed incorrect initialization of `utils.arpack.eigsh` on all occurrences. Affects `cluster.bicluster.SpectralBiclustering`, *`decomposition.KernelPCA`*, *`manifold.LocallyLinearEmbedding`*, and *`manifold.SpectralEmbedding`* (#5012). By Peter Fischer.
- Attribute `explained_variance_ratio_` calculated with the SVD solver of *`discriminant_analysis.LinearDiscriminantAnalysis`* now returns correct results. By JPFrancoia

Preprocessing and feature selection

- `preprocessing.data._transform_selected` now always passes a copy of `X` to transform function when `copy=True` (#7194). By Caio Oliveira.

Model evaluation and meta-estimators

- *`model_selection.StratifiedKFold`* now raises error if all n_labels for individual classes is less than n_folds. #6182 by Devashish Deshpande.
- Fixed bug in *`model_selection.StratifiedShuffleSplit`* where train and test sample could overlap in some edge cases, see #6121 for more details. By Loic Esteve.
- Fix in *`sklearn.model_selection.StratifiedShuffleSplit`* to return splits of size `train_size` and `test_size` in all cases (#6472). By Andreas Müller.
- Cross-validation of `OneVsOneClassifier` and `OneVsRestClassifier` now works with precomputed kernels. #7350 by Russell Smith.
- Fix incomplete `predict_proba` method delegation from *`model_selection.GridSearchCV`* to *`linear_model.SGDClassifier`* (#7159) by Yichuan Liu.

Metrics

- Fix bug in *`metrics.silhouette_score`* in which clusters of size 1 were incorrectly scored. They should get a score of 0. By Joel Nothman.
- Fix bug in *`metrics.silhouette_samples`* so that it now works with arbitrary labels, not just those ranging from 0 to n_clusters - 1.
- Fix bug where expected and adjusted mutual information were incorrect if cluster contingency cells exceeded `2**16`. By Joel Nothman.
- `metrics.pairwise.pairwise_distances` now converts arrays to boolean arrays when required in `scipy.spatial.distance`. #5460 by Tom Dupre la Tour.
- Fix sparse input support in *`metrics.silhouette_score`* as well as example examples/text/document_clustering.py. By YenChen Lin.
- *`metrics.roc_curve`* and *`metrics.precision_recall_curve`* no longer round `y_score` values when creating ROC curves; this was causing problems for users with very small differences in scores (#7353).

Miscellaneous

- `model_selection.tests._search._check_param_grid` now works correctly with all types that extends/implements `Sequence` (except string), including range (Python 3.x) and xrange (Python 2.x). #7323 by Viacheslav Kovalevskyi.
- *`utils.extmath.randomized_range_finder`* is more numerically stable when many power iterations are requested, since it applies LU normalization by default. If `n_iter<2` numerical issues are unlikely, thus no normalization is applied. Other normalization options are available: `'none', 'LU'` and `'QR'`. #5141 by Giorgio Patrini.
- Fix a bug where some formats of `scipy.sparse` matrix, and estimators with them as parameters, could not be passed to *`base.clone`*. By Loic Esteve.
- *`datasets.load_svmlight_file`* now is able to read long int QID values. #7101 by Ibraim Ganiev.

API changes summary

Linear, kernelized and related models

- `residual_metric` has been deprecated in *`linear_model.RANSACRegressor`*. Use `loss` instead. By Manoj Kumar.
- Access to public attributes `.X_` and `.y_` has been deprecated in *`isotonic.IsotonicRegression`*. By Jonathan Arfa.

Decomposition, manifold learning and clustering

- The old `mixture.DPGMM` is deprecated in favor of the new *`mixture.BayesianGaussianMixture`* (with the parameter `weight_concentration_prior_type='dirichlet_process'`). The new class solves the computational problems of the old class and computes the Gaussian mixture with a Dirichlet process prior faster than before. #7295 by Wei Xue and Thierry Guillemot.
- The old `mixture.VBGMM` is deprecated in favor of the new *`mixture.BayesianGaussianMixture`* (with the parameter `weight_concentration_prior_type='dirichlet_distribution'`). The new class solves the computational problems of the old class and computes the Variational Bayesian Gaussian mixture faster than before. #6651 by Wei Xue and Thierry Guillemot.
- The old `mixture.GMM` is deprecated in favor of the new *`mixture.GaussianMixture`*. The new class computes the Gaussian mixture faster than before and some of computational problems have been solved. #6666 by Wei Xue and Thierry Guillemot.

Model evaluation and meta-estimators

- The `sklearn.cross_validation`, `sklearn.grid_search` and `sklearn.learning_curve` have been deprecated and the classes and functions have been reorganized into the *`sklearn.model_selection`* module. Ref *Model Selection Enhancements and API Changes* for more information. #4294 by Raghav RV.
- The `grid_scores_` attribute of *`model_selection.GridSearchCV`* and *`model_selection.RandomizedSearchCV`* is deprecated in favor of the attribute `cv_results_`. Ref *Model Selection Enhancements and API Changes* for more information. #6697 by Raghav RV.
- The parameters `n_iter` or `n_folds` in old CV splitters are replaced by the new parameter `n_splits` since it can provide a consistent and unambiguous interface to represent the number of train-test splits. #7187 by YenChen Lin.
- `classes` parameter was renamed to `labels` in *`metrics.hamming_loss`*. #7260 by Sebastián Vanrell.

- The splitter classes `LabelKFold`, `LabelShuffleSplit`, `LeaveOneLabelOut` and `LeavePLabelsOut` are renamed to *model_selection.GroupKFold*, *model_selection.GroupShuffleSplit*, *model_selection.LeaveOneGroupOut* and *model_selection.LeavePGroupsOut* respectively. Also the parameter `labels` in the `split` method of the newly renamed splitters *model_selection.LeaveOneGroupOut* and *model_selection.LeavePGroupsOut* is renamed to `groups`. Additionally in *model_selection.LeavePGroupsOut*, the parameter `n_labels` is renamed to `n_groups`. #6660 by Raghav RV.
- Error and loss names for `scoring` parameters are now prefixed by `'neg_'`, such as `neg_mean_squared_error`. The unprefixed versions are deprecated and will be removed in version 0.20. #7261 by Tim Head.

1.7.19 Version 0.17.1

February 18, 2016

Changelog

Bug fixes

- Upgrade vendored joblib to version 0.9.4 that fixes an important bug in `joblib.Parallel` that can silently yield to wrong results when working on datasets larger than 1MB: https://github.com/joblib/joblib/blob/0.9.4/CHANGES.rst
- Fixed reading of Bunch pickles generated with scikit-learn version <= 0.16. This can affect users who have already downloaded a dataset with scikit-learn 0.16 and are loading it with scikit-learn 0.17. See #6196 for how this affected *datasets.fetch_20newsgroups*. By Loic Esteve.
- Fixed a bug that prevented using ROC AUC score to perform grid search on several CPU / cores on large arrays. See #6147 By Olivier Grisel.
- Fixed a bug that prevented to properly set the `presort` parameter in *ensemble.GradientBoostingRegressor*. See #5857 By Andrew McCulloh.
- Fixed a joblib error when evaluating the perplexity of a *decomposition.LatentDirichletAllocation* model. See #6258 By Chyi-Kwei Yau.

1.7.20 Version 0.17

November 5, 2015

Changelog

New features

- All the Scaler classes but *preprocessing.RobustScaler* can be fitted online by calling `partial_fit`. By Giorgio Patrini.
- The new class *ensemble.VotingClassifier* implements a "majority rule" / "soft voting" ensemble classifier to combine estimators for classification. By Sebastian Raschka.
- The new class *preprocessing.RobustScaler* provides an alternative to *preprocessing.StandardScaler* for feature-wise centering and range normalization that is robust to outliers. By Thomas Unterthiner.
- The new class *preprocessing.MaxAbsScaler* provides an alternative to *preprocessing.MinMaxScaler* for feature-wise range normalization when the data is already centered or sparse. By Thomas Unterthiner.
- The new class *preprocessing.FunctionTransformer* turns a Python function into a `Pipeline`-compatible transformer object. By Joe Jevnik.
- The new classes `cross_validation.LabelKFold` and `cross_validation.LabelShuffleSplit` generate train-test folds, respectively similar to `cross_validation.KFold` and `cross_validation.ShuffleSplit`, except that the folds are conditioned on a label array. By Brian McFee, Jean Kossaifi and Gilles Louppe.

- *decomposition.LatentDirichletAllocation* implements the Latent Dirichlet Allocation topic model with online variational inference. By Chyi-Kwei Yau, with code based on an implementation by Matt Hoffman. (#3659)
- The new solver `sag` implements a Stochastic Average Gradient descent and is available in both *linear_model.LogisticRegression* and *linear_model.Ridge*. This solver is very efficient for large datasets. By Danny Sullivan and Tom Dupre la Tour. (#4738)
- The new solver `cd` implements a Coordinate Descent in *decomposition.NMF*. Previous solver based on Projected Gradient is still available setting new parameter `solver` to `pg`, but is deprecated and will be removed in 0.19, along with `decomposition.ProjectedGradientNMF` and parameters `sparseness`, `eta`, `beta` and `nls_max_iter`. New parameters `alpha` and `l1_ratio` control L1 and L2 regularization, and `shuffle` adds a shuffling step in the `cd` solver. By Tom Dupre la Tour and Mathieu Blondel.

Enhancements

- *manifold.TSNE* now supports approximate optimization via the Barnes-Hut method, leading to much faster fitting. By Christopher Erick Moody. (#4025)
- `cluster.mean_shift_.MeanShift` now supports parallel execution, as implemented in the `mean_shift` function. By Martino Sorbaro.
- *naive_bayes.GaussianNB* now supports fitting with `sample_weight`. By Jan Hendrik Metzen.
- *dummy.DummyClassifier* now supports a prior fitting strategy. By Arnaud Joly.
- Added a `fit_predict` method for `mixture.GMM` and subclasses. By Cory Lorenz.
- Added the *metrics.label_ranking_loss* metric. By Arnaud Joly.
- Added the *metrics.cohen_kappa_score* metric.
- Added a `warm_start` constructor parameter to the bagging ensemble models to increase the size of the ensemble. By Tim Head.
- Added option to use multi-output regression metrics without averaging. By Konstantin Shmelkov and Michael Eickenberg.
- Added `stratify` option to `cross_validation.train_test_split` for stratified splitting. By Miroslav Batchkarov.
- The *tree.export_graphviz* function now supports aesthetic improvements for *tree.DecisionTreeClassifier* and *tree.DecisionTreeRegressor*, including options for coloring nodes by their majority class or impurity, showing variable names, and using node proportions instead of raw sample counts. By Trevor Stephens.
- Improved speed of `newton-cg` solver in *linear_model.LogisticRegression*, by avoiding loss computation. By Mathieu Blondel and Tom Dupre la Tour.
- The `class_weight="auto"` heuristic in classifiers supporting `class_weight` was deprecated and replaced by the `class_weight="balanced"` option, which has a simpler formula and interpretation. By Hanna Wallach and Andreas Müller.
- Add `class_weight` parameter to automatically weight samples by class frequency for *linear_model.PassiveAggressiveClassifier*. By Trevor Stephens.
- Added backlinks from the API reference pages to the user guide. By Andreas Müller.
- The `labels` parameter to *sklearn.metrics.f1_score*, *sklearn.metrics.fbeta_score*, *sklearn.metrics.recall_score* and *sklearn.metrics.precision_score* has been ex-

tended. It is now possible to ignore one or more labels, such as where a multiclass problem has a majority class to ignore. By Joel Nothman.

- Add `sample_weight` support to *linear_model.RidgeClassifier*. By Trevor Stephens.
- Provide an option for sparse output from *sklearn.metrics.pairwise.cosine_similarity*. By Jaidev Deshpande.
- Add `minmax_scale` to provide a function interface for `MinMaxScaler`. By Thomas Unterthiner.
- `dump_svmlight_file` now handles multi-label datasets. By Chih-Wei Chang.
- RCV1 dataset loader (*sklearn.datasets.fetch_rcv1*). By Tom Dupre la Tour.
- The "Wisconsin Breast Cancer" classical two-class classification dataset is now included in scikit-learn, available with `sklearn.dataset.load_breast_cancer`.
- Upgraded to joblib 0.9.3 to benefit from the new automatic batching of short tasks. This makes it possible for scikit-learn to benefit from parallelism when many very short tasks are executed in parallel, for instance by the `grid_search.GridSearchCV` meta-estimator with `n_jobs > 1` used with a large grid of parameters on a small dataset. By Vlad Niculae, Olivier Grisel and Loic Esteve.
- For more details about changes in joblib 0.9.3 see the release notes: https://github.com/joblib/joblib/blob/master/CHANGES.rst#release-093
- Improved speed (3 times per iteration) of `decomposition.DictLearning` with coordinate descent method from *linear_model.Lasso*. By Arthur Mensch.
- Parallel processing (threaded) for queries of nearest neighbors (using the ball-tree) by Nikolay Mayorov.
- Allow *datasets.make_multilabel_classification* to output a sparse `y`. By Kashif Rasul.
- *cluster.DBSCAN* now accepts a sparse matrix of precomputed distances, allowing memory-efficient distance precomputation. By Joel Nothman.
- *tree.DecisionTreeClassifier* now exposes an `apply` method for retrieving the leaf indices samples are predicted as. By Daniel Galvez and Gilles Louppe.
- Speed up decision tree regressors, random forest regressors, extra trees regressors and gradient boosting estimators by computing a proxy of the impurity improvement during the tree growth. The proxy quantity is such that the split that maximizes this value also maximizes the impurity improvement. By Arnaud Joly, Jacob Schreiber and Gilles Louppe.
- Speed up tree based methods by reducing the number of computations needed when computing the impurity measure taking into account linear relationship of the computed statistics. The effect is particularly visible with extra trees and on datasets with categorical or sparse features. By Arnaud Joly.
- *ensemble.GradientBoostingRegressor* and *ensemble.GradientBoostingClassifier* now expose an `apply` method for retrieving the leaf indices each sample ends up in under each try. By Jacob Schreiber.
- Add `sample_weight` support to *linear_model.LinearRegression*. By Sonny Hu. (##4881)
- Add `n_iter_without_progress` to *manifold.TSNE* to control the stopping criterion. By Santi Villalba. (#5186)
- Added optional parameter `random_state` in *linear_model.Ridge* , to set the seed of the pseudo random generator used in `sag` solver. By Tom Dupre la Tour.
- Added optional parameter `warm_start` in *linear_model.LogisticRegression*. If set to True, the solvers `lbfgs`, `newton-cg` and `sag` will be initialized with the coefficients computed in the previous fit. By Tom Dupre la Tour.

- Added `sample_weight` support to *linear_model.LogisticRegression* for the `lbfgs`, `newton-cg`, and `sag` solvers. By Valentin Stolbunov. Support added to the `liblinear` solver. By Manoj Kumar.
- Added optional parameter `presort` to *ensemble.GradientBoostingRegressor* and *ensemble.GradientBoostingClassifier*, keeping default behavior the same. This allows gradient boosters to turn off presorting when building deep trees or using sparse data. By Jacob Schreiber.
- Altered *metrics.roc_curve* to drop unnecessary thresholds by default. By Graham Clenaghan.
- Added *feature_selection.SelectFromModel* meta-transformer which can be used along with estimators that have `coef_` or `feature_importances_` attribute to select important features of the input data. By Maheshakya Wijewardena, Joel Nothman and Manoj Kumar.
- Added *metrics.pairwise.laplacian_kernel*. By Clyde Fare.
- `covariance.GraphLasso` allows separate control of the convergence criterion for the Elastic-Net subproblem via the `enet_tol` parameter.
- Improved verbosity in *decomposition.DictionaryLearning*.
- *ensemble.RandomForestClassifier* and *ensemble.RandomForestRegressor* no longer explicitly store the samples used in bagging, resulting in a much reduced memory footprint for storing random forest models.
- Added `positive` option to *linear_model.Lars* and *linear_model.lars_path* to force coefficients to be positive. (#5131)
- Added the `X_norm_squared` parameter to *metrics.pairwise.euclidean_distances* to provide precomputed squared norms for `X`.
- Added the `fit_predict` method to *pipeline.Pipeline*.
- Added the `preprocessing.min_max_scale` function.

Bug fixes

- Fixed non-determinism in *dummy.DummyClassifier* with sparse multi-label output. By Andreas Müller.
- Fixed the output shape of *linear_model.RANSACRegressor* to `(n_samples, )`. By Andreas Müller.
- Fixed bug in `decomposition.DictLearning` when `n_jobs < 0`. By Andreas Müller.
- Fixed bug where `grid_search.RandomizedSearchCV` could consume a lot of memory for large discrete grids. By Joel Nothman.
- Fixed bug in *linear_model.LogisticRegressionCV* where `penalty` was ignored in the final fit. By Manoj Kumar.
- Fixed bug in `ensemble.forest.ForestClassifier` while computing oob_score and X is a sparse.csc_matrix. By Ankur Ankan.
- All regressors now consistently handle and warn when given `y` that is of shape `(n_samples, 1)`. By Andreas Müller and Henry Lin. (#5431)
- Fix in *cluster.KMeans* cluster reassignment for sparse input by Lars Buitinck.
- Fixed a bug in `lda.LDA` that could cause asymmetric covariance matrices when using shrinkage. By Martin Billinger.
- Fixed `cross_validation.cross_val_predict` for estimators with sparse predictions. By Buddha Prakash.

- Fixed the `predict_proba` method of *linear_model.LogisticRegression* to use soft-max instead of one-vs-rest normalization. By Manoj Kumar. (#5182)
- Fixed the `partial_fit` method of *linear_model.SGDClassifier* when called with `average=True`. By Andrew Lamb. (#5282)
- Dataset fetchers use different filenames under Python 2 and Python 3 to avoid pickling compatibility issues. By Olivier Grisel. (#5355)
- Fixed a bug in *naive_bayes.GaussianNB* which caused classification results to depend on scale. By Jake Vanderplas.
- Fixed temporarily *linear_model.Ridge*, which was incorrect when fitting the intercept in the case of sparse data. The fix automatically changes the solver to 'sag' in this case. #5360 by Tom Dupre la Tour.
- Fixed a performance bug in `decomposition.RandomizedPCA` on data with a large number of features and fewer samples. (#4478) By Andreas Müller, Loic Esteve and Giorgio Patrini.
- Fixed bug in `cross_decomposition.PLS` that yielded unstable and platform dependent output, and failed on `fit_transform`. By Arthur Mensch.
- Fixes to the `Bunch` class used to store datasets.
- Fixed `ensemble.plot_partial_dependence` ignoring the `percentiles` parameter.
- Providing a `set` as vocabulary in `CountVectorizer` no longer leads to inconsistent results when pickling.
- Fixed the conditions on when a precomputed Gram matrix needs to be recomputed in *linear_model.LinearRegression*, *linear_model.OrthogonalMatchingPursuit*, *linear_model.Lasso* and *linear_model.ElasticNet*.
- Fixed inconsistent memory layout in the coordinate descent solver that affected `linear_model.DictionaryLearning` and `covariance.GraphLasso`. (#5337) By Olivier Grisel.
- *manifold.LocallyLinearEmbedding* no longer ignores the `reg` parameter.
- Nearest Neighbor estimators with custom distance metrics can now be pickled. (#4362)
- Fixed a bug in *pipeline.FeatureUnion* where `transformer_weights` were not properly handled when performing grid-searches.
- Fixed a bug in *linear_model.LogisticRegression* and *linear_model.LogisticRegressionCV* when using `class_weight='balanced'` or `class_weight='auto'`. By Tom Dupre la Tour.
- Fixed bug #5495 when doing OVR(SVC(decision_function_shape="ovr")). Fixed by Elvis Dohmatob.

API changes summary

- Attribute `data_min`, `data_max` and `data_range` in *preprocessing.MinMaxScaler* are deprecated and won't be available from 0.19. Instead, the class now exposes `data_min_`, `data_max_` and `data_range_`. By Giorgio Patrini.
- All Scaler classes now have an `scale_` attribute, the feature-wise rescaling applied by their `transform` methods. The old attribute `std_` in *preprocessing.StandardScaler* is deprecated and superseded by `scale_`; it won't be available in 0.19. By Giorgio Patrini.
- `svm.SVC`` and *svm.NuSVC* now have an `decision_function_shape` parameter to make their decision function of shape `(n_samples, n_classes)` by setting `decision_function_shape='ovr'`. This will be the default behavior starting in 0.19. By Andreas Müller.

- Passing 1D data arrays as input to estimators is now deprecated as it caused confusion in how the array elements should be interpreted as features or as samples. All data arrays are now expected to be explicitly shaped `(n_samples, n_features)`. By Vighnesh Birodkar.
- `lda.LDA` and `qda.QDA` have been moved to *discriminant_analysis.LinearDiscriminantAnalysis* and *discriminant_analysis.QuadraticDiscriminantAnalysis*.
- The `store_covariance` and `tol` parameters have been moved from the fit method to the constructor in *discriminant_analysis.LinearDiscriminantAnalysis* and the `store_covariances` and `tol` parameters have been moved from the fit method to the constructor in *discriminant_analysis.QuadraticDiscriminantAnalysis*.
- Models inheriting from `_LearntSelectorMixin` will no longer support the transform methods. (i.e, RandomForests, GradientBoosting, LogisticRegression, DecisionTrees, SVMs and SGD related models). Wrap these models around the metatransfomer *feature_selection.SelectFromModel* to remove features (according to `coefs_` or `feature_importances_`) which are below a certain threshold value instead.
- *cluster.KMeans* re-runs cluster-assignments in case of non-convergence, to ensure consistency of `predict(X)` and `labels_`. By Vighnesh Birodkar.
- Classifier and Regressor models are now tagged as such using the `_estimator_type` attribute.
- Cross-validation iterators always provide indices into training and test set, not boolean masks.
- The `decision_function` on all regressors was deprecated and will be removed in 0.19. Use `predict` instead.
- `datasets.load_lfw_pairs` is deprecated and will be removed in 0.19. Use *datasets.fetch_lfw_pairs* instead.
- The deprecated `hmm` module was removed.
- The deprecated `Bootstrap` cross-validation iterator was removed.
- The deprecated `Ward` and `WardAgglomerative` classes have been removed. Use `clustering.AgglomerativeClustering` instead.
- `cross_validation.check_cv` is now a public function.
- The property `residues_` of *linear_model.LinearRegression* is deprecated and will be removed in 0.19.
- The deprecated `n_jobs` parameter of *linear_model.LinearRegression* has been moved to the constructor.
- Removed deprecated `class_weight` parameter from *linear_model.SGDClassifier*'s `fit` method. Use the construction parameter instead.
- The deprecated support for the sequence of sequences (or list of lists) multilabel format was removed. To convert to and from the supported binary indicator matrix format, use *MultiLabelBinarizer*.
- The behavior of calling the `inverse_transform` method of `Pipeline.pipeline` will change in 0.19. It will no longer reshape one-dimensional input to two-dimensional input.
- The deprecated attributes `indicator_matrix_`, `multilabel_` and `classes_` of *preprocessing.LabelBinarizer* were removed.
- Using `gamma=0` in *svm.SVC* and *svm.SVR* to automatically set the gamma to `1. / n_features` is deprecated and will be removed in 0.19. Use `gamma="auto"` instead.

1.7.21 Version 0.16.1

April 14, 2015

Changelog

Bug fixes

- Allow input data larger than `block_size` in *covariance.LedoitWolf* by Andreas Müller.
- Fix a bug in *isotonic.IsotonicRegression* deduplication that caused unstable result in *calibration.CalibratedClassifierCV* by Jan Hendrik Metzen.
- Fix sorting of labels in func:`preprocessing.label_binarize` by Michael Heilman.
- Fix several stability and convergence issues in *cross_decomposition.CCA* and *cross_decomposition.PLSCanonical* by Andreas Müller
- Fix a bug in *cluster.KMeans* when `precompute_distances=False` on fortran-ordered data.
- Fix a speed regression in *ensemble.RandomForestClassifier*'s `predict` and `predict_proba` by Andreas Müller.
- Fix a regression where `utils.shuffle` converted lists and dataframes to arrays, by Olivier Grisel

1.7.22 Version 0.16

March 26, 2015

Highlights

- Speed improvements (notably in *cluster.DBSCAN*), reduced memory requirements, bug-fixes and better default settings.
- Multinomial Logistic regression and a path algorithm in *linear_model.LogisticRegressionCV*.
- Out-of core learning of PCA via *decomposition.IncrementalPCA*.
- Probability callibration of classifiers using *calibration.CalibratedClassifierCV*.
- *cluster.Birch* clustering method for large-scale datasets.
- Scalable approximate nearest neighbors search with Locality-sensitive hashing forests in `neighbors.LSHForest`.
- Improved error messages and better validation when using malformed input data.
- More robust integration with pandas dataframes.

Changelog

New features

- The new `neighbors.LSHForest` implements locality-sensitive hashing for approximate nearest neighbors search. By Maheshakya Wijewardena.
- Added *svm.LinearSVR*. This class uses the liblinear implementation of Support Vector Regression which is much faster for large sample sizes than *svm.SVR* with linear kernel. By Fabian Pedregosa and Qiang Luo.
- Incremental fit for *GaussianNB*.
- Added `sample_weight` support to *dummy.DummyClassifier* and *dummy.DummyRegressor*. By Arnaud Joly.
- Added the *metrics.label_ranking_average_precision_score* metrics. By Arnaud Joly.
- Add the *metrics.coverage_error* metrics. By Arnaud Joly.
- Added *linear_model.LogisticRegressionCV*. By Manoj Kumar, Fabian Pedregosa, Gael Varoquaux and Alexandre Gramfort.
- Added `warm_start` constructor parameter to make it possible for any trained forest model to grow additional trees incrementally. By Laurent Direr.
- Added `sample_weight` support to *ensemble.GradientBoostingClassifier* and *ensemble.GradientBoostingRegressor*. By Peter Prettenhofer.
- Added *decomposition.IncrementalPCA*, an implementation of the PCA algorithm that supports out-of-core learning with a `partial_fit` method. By Kyle Kastner.
- Averaged SGD for *SGDClassifier* and *SGDRegressor* By Danny Sullivan.
- Added `cross_val_predict` function which computes cross-validated estimates. By Luis Pedro Coelho
- Added *linear_model.TheilSenRegressor*, a robust generalized-median-based estimator. By Florian Wilhelm.
- Added *metrics.median_absolute_error*, a robust metric. By Gael Varoquaux and Florian Wilhelm.
- Add *cluster.Birch*, an online clustering algorithm. By Manoj Kumar, Alexandre Gramfort and Joel Nothman.

- Added shrinkage support to *discriminant_analysis.LinearDiscriminantAnalysis* using two new solvers. By Clemens Brunner and Martin Billinger.
- Added *kernel_ridge.KernelRidge*, an implementation of kernelized ridge regression. By Mathieu Blondel and Jan Hendrik Metzen.
- All solvers in *linear_model.Ridge* now support `sample_weight`. By Mathieu Blondel.
- Added `cross_validation.PredefinedSplit` cross-validation for fixed user-provided cross-validation folds. By Thomas Unterthiner.
- Added *calibration.CalibratedClassifierCV*, an approach for calibrating the predicted probabilities of a classifier. By Alexandre Gramfort, Jan Hendrik Metzen, Mathieu Blondel and Balazs Kegl.

Enhancements

- Add option `return_distance` in `hierarchical.ward_tree` to return distances between nodes for both structured and unstructured versions of the algorithm. By Matteo Visconti di Oleggio Castello. The same option was added in `hierarchical.linkage_tree`. By Manoj Kumar
- Add support for sample weights in scorer objects. Metrics with sample weight support will automatically benefit from it. By Noel Dawe and Vlad Niculae.
- Added `newton-cg` and `lbfgs` solver support in *linear_model.LogisticRegression*. By Manoj Kumar.
- Add `selection="random"` parameter to implement stochastic coordinate descent for *linear_model.Lasso*, *linear_model.ElasticNet* and related. By Manoj Kumar.
- Add `sample_weight` parameter to *metrics.jaccard_similarity_score* and *metrics.log_loss*. By Jatin Shah.
- Support sparse multilabel indicator representation in *preprocessing.LabelBinarizer* and *multiclass.OneVsRestClassifier* (by Hamzeh Alsalhi with thanks to Rohit Sivaprasad), as well as evaluation metrics (by Joel Nothman).
- Add `sample_weight` parameter to `metrics.jaccard_similarity_score`. By `Jatin Shah`.
- Add support for multiclass in `metrics.hinge_loss`. Added `labels=None` as optional parameter. By `Saurabh Jha`.
- Add `sample_weight` parameter to `metrics.hinge_loss`. By `Saurabh Jha`.
- Add `multi_class="multinomial"` option in *linear_model.LogisticRegression* to implement a Logistic Regression solver that minimizes the cross-entropy or multinomial loss instead of the default One-vs-Rest setting. Supports `lbfgs` and `newton-cg` solvers. By Lars Buitinck and Manoj Kumar. Solver option `newton-cg` by Simon Wu.
- `DictVectorizer` can now perform `fit_transform` on an iterable in a single pass, when giving the option `sort=False`. By Dan Blanchard.
- `GridSearchCV` and `RandomizedSearchCV` can now be configured to work with estimators that may fail and raise errors on individual folds. This option is controlled by the `error_score` parameter. This does not affect errors raised on re-fit. By Michal Romaniuk.
- Add `digits` parameter to `metrics.classification_report` to allow report to show different precision of floating point numbers. By Ian Gilmore.
- Add a quantile prediction strategy to the *dummy.DummyRegressor*. By Aaron Staple.
- Add `handle_unknown` option to *preprocessing.OneHotEncoder* to handle unknown categorical features more gracefully during transform. By Manoj Kumar.

- Added support for sparse input data to decision trees and their ensembles. By Fares Hedyati and Arnaud Joly.
- Optimized *cluster.AffinityPropagation* by reducing the number of memory allocations of large temporary data-structures. By Antony Lee.
- Parellization of the computation of feature importances in random forest. By Olivier Grisel and Arnaud Joly.
- Add `n_iter_` attribute to estimators that accept a `max_iter` attribute in their constructor. By Manoj Kumar.
- Added decision function for *multiclass.OneVsOneClassifier* By Raghav RV and Kyle Beauchamp.
- *neighbors.kneighbors_graph* and `radius_neighbors_graph` support non-Euclidean metrics. By Manoj Kumar
- Parameter `connectivity` in *cluster.AgglomerativeClustering* and family now accept callables that return a connectivity matrix. By Manoj Kumar.
- Sparse support for `paired_distances`. By Joel Nothman.
- *cluster.DBSCAN* now supports sparse input and sample weights and has been optimized: the inner loop has been rewritten in Cython and radius neighbors queries are now computed in batch. By Joel Nothman and Lars Buitinck.
- Add `class_weight` parameter to automatically weight samples by class frequency for *ensemble.RandomForestClassifier*, *tree.DecisionTreeClassifier*, *ensemble.ExtraTreesClassifier* and *tree.ExtraTreeClassifier*. By Trevor Stephens.
- `grid_search.RandomizedSearchCV` now does sampling without replacement if all parameters are given as lists. By Andreas Müller.
- Parallelized calculation of `pairwise_distances` is now supported for scipy metrics and custom callables. By Joel Nothman.
- Allow the fitting and scoring of all clustering algorithms in *pipeline.Pipeline*. By Andreas Müller.
- More robust seeding and improved error messages in *cluster.MeanShift* by Andreas Müller.
- Make the stopping criterion for `mixture.GMM`, `mixture.DPGMM` and `mixture.VBGMM` less dependent on the number of samples by thresholding the average log-likelihood change instead of its sum over all samples. By Hervé Bredin.
- The outcome of *manifold.spectral_embedding* was made deterministic by flipping the sign of eigenvectors. By Hasil Sharma.
- Significant performance and memory usage improvements in *preprocessing.PolynomialFeatures*. By Eric Martin.
- Numerical stability improvements for *preprocessing.StandardScaler* and *preprocessing.scale*. By Nicolas Goix
- *svm.SVC* fitted on sparse input now implements `decision_function`. By Rob Zinkov and Andreas Müller.
- `cross_validation.train_test_split` now preserves the input type, instead of converting to numpy arrays.

Documentation improvements

- Added example of using `FeatureUnion` for heterogeneous input. By Matt Terry
- Documentation on scorers was improved, to highlight the handling of loss functions. By Matt Pico.
- A discrepancy between liblinear output and scikit-learn's wrappers is now noted. By Manoj Kumar.

- Improved documentation generation: examples referring to a class or function are now shown in a gallery on the class/function's API reference page. By Joel Nothman.
- More explicit documentation of sample generators and of data transformation. By Joel Nothman.
- *sklearn.neighbors.BallTree* and *sklearn.neighbors.KDTree* used to point to empty pages stating that they are aliases of BinaryTree. This has been fixed to show the correct class docs. By Manoj Kumar.
- Added silhouette plots for analysis of KMeans clustering using *metrics.silhouette_samples* and *metrics.silhouette_score*. See *Selecting the number of clusters with silhouette analysis on KMeans clustering*

Bug fixes

- Metaestimators now support ducktyping for the presence of `decision_function`, `predict_proba` and other methods. This fixes behavior of `grid_search.GridSearchCV`, `grid_search.RandomizedSearchCV`, *pipeline.Pipeline*, *feature_selection.RFE*, *feature_selection.RFECV* when nested. By Joel Nothman
- The `scoring` attribute of grid-search and cross-validation methods is no longer ignored when a `grid_search.GridSearchCV` is given as a base estimator or the base estimator doesn't have predict.
- The function `hierarchical.ward_tree` now returns the children in the same order for both the structured and unstructured versions. By Matteo Visconti di Oleggio Castello.
- *feature_selection.RFECV* now correctly handles cases when `step` is not equal to 1. By Nikolay Mayorov
- The *decomposition.PCA* now undoes whitening in its `inverse_transform`. Also, its `components_` now always have unit length. By Michael Eickenberg.
- Fix incomplete download of the dataset when `datasets.download_20newsgroups` is called. By Manoj Kumar.
- Various fixes to the Gaussian processes subpackage by Vincent Dubourg and Jan Hendrik Metzen.
- Calling `partial_fit` with `class_weight=='auto'` throws an appropriate error message and suggests a work around. By Danny Sullivan.
- *RBFSampler* with `gamma=g` formerly approximated *rbf_kernel* with `gamma=g/2.`; the definition of `gamma` is now consistent, which may substantially change your results if you use a fixed value. (If you cross-validated over `gamma`, it probably doesn't matter too much.) By Dougal Sutherland.
- Pipeline object delegate the `classes_` attribute to the underlying estimator. It allows, for instance, to make bagging of a pipeline object. By Arnaud Joly
- *neighbors.NearestCentroid* now uses the median as the centroid when metric is set to `manhattan`. It was using the mean before. By Manoj Kumar
- Fix numerical stability issues in *linear_model.SGDClassifier* and *linear_model.SGDRegressor* by clipping large gradients and ensuring that weight decay rescaling is always positive (for large l2 regularization and large learning rate values). By Olivier Grisel
- When `compute_full_tree` is set to "auto", the full tree is built when n_clusters is high and is early stopped when n_clusters is low, while the behavior should be vice-versa in *cluster.AgglomerativeClustering* (and friends). This has been fixed By Manoj Kumar
- Fix lazy centering of data in *linear_model.enet_path* and *linear_model.lasso_path*. It was centered around one. It has been changed to be centered around the origin. By Manoj Kumar

- Fix handling of precomputed affinity matrices in *cluster.AgglomerativeClustering* when using connectivity constraints. By Cathy Deng
- Correct `partial_fit` handling of `class_prior` for *sklearn.naive_bayes.MultinomialNB* and *sklearn.naive_bayes.BernoulliNB*. By Trevor Stephens.
- Fixed a crash in *metrics.precision_recall_fscore_support* when using unsorted `labels` in the multi-label setting. By Andreas Müller.
- Avoid skipping the first nearest neighbor in the methods `radius_neighbors`, `kneighbors`, `kneighbors_graph` and `radius_neighbors_graph` in *sklearn.neighbors.NearestNeighbors* and family, when the query data is not the same as fit data. By Manoj Kumar.
- Fix log-density calculation in the `mixture.GMM` with tied covariance. By Will Dawson
- Fixed a scaling error in *feature_selection.SelectFdr* where a factor `n_features` was missing. By Andrew Tulloch
- Fix zero division in *neighbors.KNeighborsRegressor* and related classes when using distance weighting and having identical data points. By Garret-R.
- Fixed round off errors with non positive-definite covariance matrices in GMM. By Alexis Mignon.
- Fixed a error in the computation of conditional probabilities in *naive_bayes.BernoulliNB*. By Hanna Wallach.
- Make the method `radius_neighbors` of *neighbors.NearestNeighbors* return the samples lying on the boundary for `algorithm='brute'`. By Yan Yi.
- Flip sign of `dual_coef_` of *svm.SVC* to make it consistent with the documentation and `decision_function`. By Artem Sobolev.
- Fixed handling of ties in *isotonic.IsotonicRegression*. We now use the weighted average of targets (secondary method). By Andreas Müller and Michael Bommarito.

API changes summary

- `GridSearchCV` and `cross_val_score` and other meta-estimators don't convert pandas DataFrames into arrays any more, allowing DataFrame specific operations in custom estimators.
- `multiclass.fit_ovr`, `multiclass.predict_ovr`, `predict_proba_ovr`, `multiclass.fit_ovo`, `multiclass.predict_ovo`, `multiclass.fit_ecoc` and `multiclass.predict_ecoc` are deprecated. Use the underlying estimators instead.
- Nearest neighbors estimators used to take arbitrary keyword arguments and pass these to their distance metric. This will no longer be supported in scikit-learn 0.18; use the `metric_params` argument instead.
- **`n_jobs` parameter of the fit method shifted to the constructor of the** LinearRegression class.
- The `predict_proba` method of *multiclass.OneVsRestClassifier* now returns two probabilities per sample in the multiclass case; this is consistent with other estimators and with the method's documentation, but previous versions accidentally returned only the positive probability. Fixed by Will Lamond and Lars Buitinck.
- Change default value of precompute in `ElasticNet` and `Lasso` to False. Setting precompute to "auto" was found to be slower when n_samples > n_features since the computation of the Gram matrix is computationally expensive and outweighs the benefit of fitting the Gram for just one alpha. `precompute="auto"` is now deprecated and will be removed in 0.18 By Manoj Kumar.
- Expose `positive` option in *linear_model.enet_path* and *linear_model.enet_path* which constrains coefficients to be positive. By Manoj Kumar.

- Users should now supply an explicit `average` parameter to *sklearn.metrics.f1_score*, *sklearn.metrics.fbeta_score*, *sklearn.metrics.recall_score* and *sklearn.metrics.precision_score* when performing multiclass or multilabel (i.e. not binary) classification. By Joel Nothman.
- `scoring` parameter for cross validation now accepts `'f1_micro'`, `'f1_macro'` or `'f1_weighted'`. `'f1'` is now for binary classification only. Similar changes apply to `'precision'` and `'recall'`. By Joel Nothman.
- The `fit_intercept`, `normalize` and `return_models` parameters in *linear_model.enet_path* and *linear_model.lasso_path* have been removed. They were deprecated since 0.14
- From now onwards, all estimators will uniformly raise `NotFittedError` (`utils.validation.NotFittedError`), when any of the `predict` like methods are called before the model is fit. By Raghav RV.
- Input data validation was refactored for more consistent input validation. The `check_arrays` function was replaced by `check_array` and `check_X_y`. By Andreas Müller.
- Allow `X=None` in the methods `radius_neighbors`, `kneighbors`, `kneighbors_graph` and `radius_neighbors_graph` in *sklearn.neighbors.NearestNeighbors* and family. If set to None, then for every sample this avoids setting the sample itself as the first nearest neighbor. By Manoj Kumar.
- Add parameter `include_self` in *neighbors.kneighbors_graph* and *neighbors.radius_neighbors_graph* which has to be explicitly set by the user. If set to True, then the sample itself is considered as the first nearest neighbor.
- `thresh` parameter is deprecated in favor of new `tol` parameter in `GMM`, `DPGMM` and `VBGMM`. See `Enhancements` section for details. By Hervé Bredin.
- Estimators will treat input with dtype object as numeric when possible. By Andreas Müller
- Estimators now raise `ValueError` consistently when fitted on empty data (less than 1 sample or less than 1 feature for 2D input). By Olivier Grisel.
- The `shuffle` option of *linear_model.SGDClassifier*, *linear_model.SGDRegressor*, *linear_model.Perceptron*, *linear_model.PassiveAggressiveClassifier* and *linear_model.PassiveAggressiveRegressor* now defaults to `True`.
- *cluster.DBSCAN* now uses a deterministic initialization. The `random_state` parameter is deprecated. By Erich Schubert.

1.7.23 Version 0.15.2

September 4, 2014

Bug fixes

- Fixed handling of the `p` parameter of the Minkowski distance that was previously ignored in nearest neighbors models. By Nikolay Mayorov.
- Fixed duplicated alphas in *`linear_model.LassoLars`* with early stopping on 32 bit Python. By Olivier Grisel and Fabian Pedregosa.
- Fixed the build under Windows when scikit-learn is built with MSVC while NumPy is built with MinGW. By Olivier Grisel and Federico Vaggi.
- Fixed an array index overflow bug in the coordinate descent solver. By Gael Varoquaux.
- Better handling of numpy 1.9 deprecation warnings. By Gael Varoquaux.
- Removed unnecessary data copy in *`cluster.KMeans`*. By Gael Varoquaux.
- Explicitly close open files to avoid `ResourceWarnings` under Python 3. By Calvin Giles.
- The `transform` of *`discriminant_analysis.LinearDiscriminantAnalysis`* now projects the input on the most discriminant directions. By Martin Billinger.
- Fixed potential overflow in `_tree.safe_realloc` by Lars Buitinck.
- Performance optimization in *`isotonic.IsotonicRegression`*. By Robert Bradshaw.
- `nose` is non-longer a runtime dependency to import `sklearn`, only for running the tests. By Joel Nothman.
- Many documentation and website fixes by Joel Nothman, Lars Buitinck Matt Pico, and others.

1.7.24 Version 0.15.1

August 1, 2014

Bug fixes

- Made `cross_validation.cross_val_score` use `cross_validation.KFold` instead of `cross_validation.StratifiedKFold` on multi-output classification problems. By Nikolay Mayorov.
- Support unseen labels *`preprocessing.LabelBinarizer`* to restore the default behavior of 0.14.1 for backward compatibility. By Hamzeh Alsalhi.
- Fixed the *`cluster.KMeans`* stopping criterion that prevented early convergence detection. By Edward Raff and Gael Varoquaux.

- Fixed the behavior of *multiclass.OneVsOneClassifier*. in case of ties at the per-class vote level by computing the correct per-class sum of prediction scores. By Andreas Müller.
- Made `cross_validation.cross_val_score` and `grid_search.GridSearchCV` accept Python lists as input data. This is especially useful for cross-validation and model selection of text processing pipelines. By Andreas Müller.
- Fixed data input checks of most estimators to accept input data that implements the NumPy `__array__` protocol. This is the case for for `pandas.Series` and `pandas.DataFrame` in recent versions of pandas. By Gael Varoquaux.
- Fixed a regression for *linear_model.SGDClassifier* with `class_weight="auto"` on data with non-contiguous labels. By Olivier Grisel.

1.7.25 Version 0.15

July 15, 2014

Highlights

- Many speed and memory improvements all across the code
- Huge speed and memory improvements to random forests (and extra trees) that also benefit better from parallel computing.
- Incremental fit to *BernoulliRBM*
- Added *cluster.AgglomerativeClustering* for hierarchical agglomerative clustering with average linkage, complete linkage and ward strategies.
- Added *linear_model.RANSACRegressor* for robust regression models.
- Added dimensionality reduction with *manifold.TSNE* which can be used to visualize high-dimensional data.

Changelog

New features

- Added *ensemble.BaggingClassifier* and *ensemble.BaggingRegressor* meta-estimators for ensembling any kind of base estimator. See the *Bagging* section of the user guide for details and examples. By Gilles Louppe.
- New unsupervised feature selection algorithm *feature_selection.VarianceThreshold*, by Lars Buitinck.
- Added *linear_model.RANSACRegressor* meta-estimator for the robust fitting of regression models. By Johannes Schönberger.
- Added *cluster.AgglomerativeClustering* for hierarchical agglomerative clustering with average linkage, complete linkage and ward strategies, by Nelle Varoquaux and Gael Varoquaux.
- Shorthand constructors *pipeline.make_pipeline* and *pipeline.make_union* were added by Lars Buitinck.
- Shuffle option for `cross_validation.StratifiedKFold`. By Jeffrey Blackburne.
- Incremental learning (`partial_fit`) for Gaussian Naive Bayes by Imran Haque.
- Added `partial_fit` to *BernoulliRBM* By Danny Sullivan.

- Added `learning_curve` utility to chart performance with respect to training size. See *Plotting Learning Curves*. By Alexander Fabisch.
- Add positive option in *LassoCV* and *ElasticNetCV*. By Brian Wignall and Alexandre Gramfort.
- Added *linear_model.MultiTaskElasticNetCV* and *linear_model.MultiTaskLassoCV*. By Manoj Kumar.
- Added *manifold.TSNE*. By Alexander Fabisch.

Enhancements

- Add sparse input support to *ensemble.AdaBoostClassifier* and *ensemble.AdaBoostRegressor* meta-estimators. By Hamzeh Alsalhi.
- Memory improvements of decision trees, by Arnaud Joly.
- Decision trees can now be built in best-first manner by using `max_leaf_nodes` as the stopping criteria. Refactored the tree code to use either a stack or a priority queue for tree building. By Peter Prettenhofer and Gilles Louppe.
- Decision trees can now be fitted on fortran- and c-style arrays, and non-continuous arrays without the need to make a copy. If the input array has a different dtype than `np.float32`, a fortran- style copy will be made since fortran-style memory layout has speed advantages. By Peter Prettenhofer and Gilles Louppe.
- Speed improvement of regression trees by optimizing the the computation of the mean square error criterion. This lead to speed improvement of the tree, forest and gradient boosting tree modules. By Arnaud Joly
- The `img_to_graph` and `grid_tograph` functions in *sklearn.feature_extraction.image* now return `np.ndarray` instead of `np.matrix` when `return_as=np.ndarray`. See the Notes section for more information on compatibility.
- Changed the internal storage of decision trees to use a struct array. This fixed some small bugs, while improving code and providing a small speed gain. By Joel Nothman.
- Reduce memory usage and overhead when fitting and predicting with forests of randomized trees in parallel with `n_jobs != 1` by leveraging new threading backend of joblib 0.8 and releasing the GIL in the tree fitting Cython code. By Olivier Grisel and Gilles Louppe.
- Speed improvement of the `sklearn.ensemble.gradient_boosting` module. By Gilles Louppe and Peter Prettenhofer.
- Various enhancements to the `sklearn.ensemble.gradient_boosting` module: a `warm_start` argument to fit additional trees, a `max_leaf_nodes` argument to fit GBM style trees, a `monitor` fit argument to inspect the estimator during training, and refactoring of the verbose code. By Peter Prettenhofer.
- Faster `sklearn.ensemble.ExtraTrees` by caching feature values. By Arnaud Joly.
- Faster depth-based tree building algorithm such as decision tree, random forest, extra trees or gradient tree boosting (with depth based growing strategy) by avoiding trying to split on found constant features in the sample subset. By Arnaud Joly.
- Add `min_weight_fraction_leaf` pre-pruning parameter to tree-based methods: the minimum weighted fraction of the input samples required to be at a leaf node. By Noel Dawe.
- Added *metrics.pairwise_distances_argmin_min*, by Philippe Gervais.
- Added predict method to *cluster.AffinityPropagation* and *cluster.MeanShift*, by Mathieu Blondel.
- Vector and matrix multiplications have been optimised throughout the library by Denis Engemann, and Alexandre Gramfort. In particular, they should take less memory with older NumPy versions (prior to 1.7.2).

- Precision-recall and ROC examples now use train_test_split, and have more explanation of why these metrics are useful. By Kyle Kastner
- The training algorithm for *decomposition.NMF* is faster for sparse matrices and has much lower memory complexity, meaning it will scale up gracefully to large datasets. By Lars Buitinck.
- Added svd_method option with default value to "randomized" to *decomposition.FactorAnalysis* to save memory and significantly speedup computation by Denis Engemann, and Alexandre Gramfort.
- Changed `cross_validation.StratifiedKFold` to try and preserve as much of the original ordering of samples as possible so as not to hide overfitting on datasets with a non-negligible level of samples dependency. By Daniel Nouri and Olivier Grisel.
- Add multi-output support to `gaussian_process.GaussianProcess` by John Novak.
- Support for precomputed distance matrices in nearest neighbor estimators by Robert Layton and Joel Nothman.
- Norm computations optimized for NumPy 1.6 and later versions by Lars Buitinck. In particular, the k-means algorithm no longer needs a temporary data structure the size of its input.
- *dummy.DummyClassifier* can now be used to predict a constant output value. By Manoj Kumar.
- *dummy.DummyRegressor* has now a strategy parameter which allows to predict the mean, the median of the training set or a constant output value. By Maheshakya Wijewardena.
- Multi-label classification output in multilabel indicator format is now supported by *metrics.roc_auc_score* and *metrics.average_precision_score* by Arnaud Joly.
- Significant performance improvements (more than 100x speedup for large problems) in *isotonic.IsotonicRegression* by Andrew Tulloch.
- Speed and memory usage improvements to the SGD algorithm for linear models: it now uses threads, not separate processes, when `n_jobs>1`. By Lars Buitinck.
- Grid search and cross validation allow NaNs in the input arrays so that preprocessors such as `preprocessing.Imputer` can be trained within the cross validation loop, avoiding potentially skewed results.
- Ridge regression can now deal with sample weights in feature space (only sample space until then). By Michael Eickenberg. Both solutions are provided by the Cholesky solver.
- Several classification and regression metrics now support weighted samples with the new `sample_weight` argument: *metrics.accuracy_score*, *metrics.zero_one_loss*, *metrics.precision_score*, *metrics.average_precision_score*, *metrics.f1_score*, *metrics.fbeta_score*, *metrics.recall_score*, *metrics.roc_auc_score*, *metrics.explained_variance_score*, *metrics.mean_squared_error*, *metrics.mean_absolute_error*, *metrics.r2_score*. By Noel Dawe.
- Speed up of the sample generator *datasets.make_multilabel_classification*. By Joel Nothman.

Documentation improvements

- The *Working With Text Data* tutorial has now been worked in to the main documentation's tutorial section. Includes exercises and skeletons for tutorial presentation. Original tutorial created by several authors including Olivier Grisel, Lars Buitinck and many others. Tutorial integration into the scikit-learn documentation by Jaques Grobler
- Added *Computational Performance* documentation. Discussion and examples of prediction latency / throughput and different factors that have influence over speed. Additional tips for building faster models and choosing a relevant compromise between speed and predictive power. By Eustache Diemert.

Bug fixes

- Fixed bug in *decomposition.MiniBatchDictionaryLearning* : `partial_fit` was not working properly.
- Fixed bug in `linear_model.stochastic_gradient` : `l1_ratio` was used as `(1.0 - l1_ratio)` .
- Fixed bug in *multiclass.OneVsOneClassifier* with string labels
- Fixed a bug in *LassoCV* and *ElasticNetCV*: they would not pre-compute the Gram matrix with `precompute=True` or `precompute="auto"` and `n_samples > n_features`. By Manoj Kumar.
- Fixed incorrect estimation of the degrees of freedom in *feature_selection.f_regression* when variates are not centered. By Virgile Fritsch.
- Fixed a race condition in parallel processing with `pre_dispatch != "all"` (for instance, in `cross_val_score`). By Olivier Grisel.
- Raise error in *cluster.FeatureAgglomeration* and `cluster.WardAgglomeration` when no samples are given, rather than returning meaningless clustering.
- Fixed bug in `gradient_boosting.GradientBoostingRegressor` with `loss='huber'`: `gamma` might have not been initialized.
- Fixed feature importances as computed with a forest of randomized trees when fit with `sample_weight != None` and/or with `bootstrap=True`. By Gilles Louppe.

API changes summary

- `sklearn.hmm` is deprecated. Its removal is planned for the 0.17 release.
- Use of `covariance.EllipticEnvelop` has now been removed after deprecation. Please use *covariance.EllipticEnvelope* instead.
- `cluster.Ward` is deprecated. Use *cluster.AgglomerativeClustering* instead.
- `cluster.WardClustering` is deprecated. Use
- *cluster.AgglomerativeClustering* instead.
- `cross_validation.Bootstrap` is deprecated. `cross_validation.KFold` or `cross_validation.ShuffleSplit` are recommended instead.
- Direct support for the sequence of sequences (or list of lists) multilabel format is deprecated. To convert to and from the supported binary indicator matrix format, use *MultiLabelBinarizer*. By Joel Nothman.
- Add score method to *PCA* following the model of probabilistic PCA and deprecate `ProbabilisticPCA` model whose score implementation is not correct. The computation now also exploits the matrix inversion lemma for faster computation. By Alexandre Gramfort.
- The score method of *FactorAnalysis* now returns the average log-likelihood of the samples. Use score_samples to get log-likelihood of each sample. By Alexandre Gramfort.
- Generating boolean masks (the setting `indices=False`) from cross-validation generators is deprecated. Support for masks will be removed in 0.17. The generators have produced arrays of indices by default since 0.10. By Joel Nothman.
- 1-d arrays containing strings with `dtype=object` (as used in Pandas) are now considered valid classification targets. This fixes a regression from version 0.13 in some classifiers. By Joel Nothman.
- Fix wrong `explained_variance_ratio_` attribute in `RandomizedPCA`. By Alexandre Gramfort.

- Fit alphas for each `l1_ratio` instead of `mean_l1_ratio` in *linear_model.ElasticNetCV* and *linear_model.LassoCV*. This changes the shape of `alphas_` from `(n_alphas,)` to `(n_l1_ratio, n_alphas)` if the `l1_ratio` provided is a 1-D array like object of length greater than one. By Manoj Kumar.
- Fix *linear_model.ElasticNetCV* and *linear_model.LassoCV* when fitting intercept and input data is sparse. The automatic grid of alphas was not computed correctly and the scaling with normalize was wrong. By Manoj Kumar.
- Fix wrong maximal number of features drawn (`max_features`) at each split for decision trees, random forests and gradient tree boosting. Previously, the count for the number of drawn features started only after one non constant features in the split. This bug fix will affect computational and generalization performance of those algorithms in the presence of constant features. To get back previous generalization performance, you should modify the value of `max_features`. By Arnaud Joly.
- Fix wrong maximal number of features drawn (`max_features`) at each split for *ensemble.ExtraTreesClassifier* and *ensemble.ExtraTreesRegressor*. Previously, only non constant features in the split was counted as drawn. Now constant features are counted as drawn. Furthermore at least one feature must be non constant in order to make a valid split. This bug fix will affect computational and generalization performance of extra trees in the presence of constant features. To get back previous generalization performance, you should modify the value of `max_features`. By Arnaud Joly.
- Fix `utils.compute_class_weight` when `class_weight=="auto"`. Previously it was broken for input of non-integer `dtype` and the weighted array that was returned was wrong. By Manoj Kumar.
- Fix `cross_validation.Bootstrap` to return `ValueError` when `n_train + n_test > n`. By Ronald Phlypo.

1.7.26 Version 0.14

August 7, 2013

Changelog

- Missing values with sparse and dense matrices can be imputed with the transformer `preprocessing.Imputer` by Nicolas Trésegnie.
- The core implementation of decisions trees has been rewritten from scratch, allowing for faster tree induction and lower memory consumption in all tree-based estimators. By Gilles Louppe.
- Added *ensemble.AdaBoostClassifier* and *ensemble.AdaBoostRegressor*, by Noel Dawe and Gilles Louppe. See the *AdaBoost* section of the user guide for details and examples.
- Added `grid_search.RandomizedSearchCV` and `grid_search.ParameterSampler` for randomized hyperparameter optimization. By Andreas Müller.
- Added *biclustering* algorithms (`sklearn.cluster.bicluster.SpectralCoclustering` and `sklearn.cluster.bicluster.SpectralBiclustering`), data generation methods (*sklearn.datasets.make_biclusters* and *sklearn.datasets.make_checkerboard*), and scoring metrics (*sklearn.metrics.consensus_score*). By Kemal Eren.
- Added *Restricted Boltzmann Machines* (*neural_network.BernoulliRBM*). By Yann Dauphin.
- Python 3 support by Justin Vincent, Lars Buitinck, Subhodeep Moitra and Olivier Grisel. All tests now pass under Python 3.3.
- Ability to pass one penalty (alpha value) per target in *linear_model.Ridge*, by @eickenberg and Mathieu Blondel.
- Fixed `sklearn.linear_model.stochastic_gradient.py` L2 regularization issue (minor practical significance). By Norbert Crombach and Mathieu Blondel .
- Added an interactive version of Andreas Müller's Machine Learning Cheat Sheet (for scikit-learn) to the documentation. See *Choosing the right estimator*. By Jaques Grobler.
- `grid_search.GridSearchCV` and `cross_validation.cross_val_score` now support the use of advanced scoring function such as area under the ROC curve and f-beta scores. See *The scoring parameter: defining model evaluation rules* for details. By Andreas Müller and Lars Buitinck. Passing a function from *sklearn.metrics* as `score_func` is deprecated.
- Multi-label classification output is now supported by *metrics.accuracy_score*, *metrics.zero_one_loss*, *metrics.f1_score*, *metrics.fbeta_score*, *metrics.classification_report*, *metrics.precision_score* and *metrics.recall_score* by Arnaud Joly.
- Two new metrics *metrics.hamming_loss* and *metrics.jaccard_similarity_score* are added with multi-label support by Arnaud Joly.
- Speed and memory usage improvements in *feature_extraction.text.CountVectorizer* and *feature_extraction.text.TfidfVectorizer*, by Jochen Wersdörfer and Roman Sinayev.
- The `min_df` parameter in *feature_extraction.text.CountVectorizer* and *feature_extraction.text.TfidfVectorizer*, which used to be 2, has been reset to 1 to avoid unpleasant surprises (empty vocabularies) for novice users who try it out on tiny document collections. A value of at least 2 is still recommended for practical use.

- *svm.LinearSVC*, *linear_model.SGDClassifier* and *linear_model.SGDRegressor* now have a sparsify method that converts their coef_ into a sparse matrix, meaning stored models trained using these estimators can be made much more compact.
- *linear_model.SGDClassifier* now produces multiclass probability estimates when trained under log loss or modified Huber loss.
- Hyperlinks to documentation in example code on the website by Martin Luessi.
- Fixed bug in *preprocessing.MinMaxScaler* causing incorrect scaling of the features for non-default feature_range settings. By Andreas Müller.
- max_features in *tree.DecisionTreeClassifier*, *tree.DecisionTreeRegressor* and all derived ensemble estimators now supports percentage values. By Gilles Louppe.
- Performance improvements in *isotonic.IsotonicRegression* by Nelle Varoquaux.
- *metrics.accuracy_score* has an option normalize to return the fraction or the number of correctly classified sample by Arnaud Joly.
- Added *metrics.log_loss* that computes log loss, aka cross-entropy loss. By Jochen Wersdörfer and Lars Buitinck.
- A bug that caused *ensemble.AdaBoostClassifier*'s to output incorrect probabilities has been fixed.
- Feature selectors now share a mixin providing consistent transform, inverse_transform and get_support methods. By Joel Nothman.
- A fitted grid_search.GridSearchCV or grid_search.RandomizedSearchCV can now generally be pickled. By Joel Nothman.
- Refactored and vectorized implementation of *metrics.roc_curve* and *metrics.precision_recall_curve*. By Joel Nothman.
- The new estimator *sklearn.decomposition.TruncatedSVD* performs dimensionality reduction using SVD on sparse matrices, and can be used for latent semantic analysis (LSA). By Lars Buitinck.
- Added self-contained example of out-of-core learning on text data *Out-of-core classification of text documents*. By Eustache Diemert.
- The default number of components for sklearn.decomposition.RandomizedPCA is now correctly documented to be n_features. This was the default behavior, so programs using it will continue to work as they did.
- *sklearn.cluster.KMeans* now fits several orders of magnitude faster on sparse data (the speedup depends on the sparsity). By Lars Buitinck.
- Reduce memory footprint of FastICA by Denis Engemann and Alexandre Gramfort.
- Verbose output in sklearn.ensemble.gradient_boosting now uses a column format and prints progress in decreasing frequency. It also shows the remaining time. By Peter Prettenhofer.
- sklearn.ensemble.gradient_boosting provides out-of-bag improvement oob_improvement_ rather than the OOB score for model selection. An example that shows how to use OOB estimates to select the number of trees was added. By Peter Prettenhofer.
- Most metrics now support string labels for multiclass classification by Arnaud Joly and Lars Buitinck.
- New OrthogonalMatchingPursuitCV class by Alexandre Gramfort and Vlad Niculae.
- Fixed a bug in sklearn.covariance.GraphLassoCV: the 'alphas' parameter now works as expected when given a list of values. By Philippe Gervais.

- Fixed an important bug in `sklearn.covariance.GraphLassoCV` that prevented all folds provided by a CV object to be used (only the first 3 were used). When providing a CV object, execution time may thus increase significantly compared to the previous version (bug results are correct now). By Philippe Gervais.
- `cross_validation.cross_val_score` and the `grid_search` module is now tested with multi-output data by Arnaud Joly.
- *`datasets.make_multilabel_classification`* can now return the output in label indicator multilabel format by Arnaud Joly.
- K-nearest neighbors, *`neighbors.KNeighborsRegressor`* and *`neighbors.RadiusNeighborsRegressor`*, and radius neighbors, *`neighbors.RadiusNeighborsRegressor`* and *`neighbors.RadiusNeighborsClassifier`* support multioutput data by Arnaud Joly.
- Random state in LibSVM-based estimators (*`svm.SVC`*, `NuSVC`, `OneClassSVM`, *`svm.SVR`*, *`svm.NuSVR`*) can now be controlled. This is useful to ensure consistency in the probability estimates for the classifiers trained with `probability=True`. By Vlad Niculae.
- Out-of-core learning support for discrete naive Bayes classifiers *`sklearn.naive_bayes.MultinomialNB`* and *`sklearn.naive_bayes.BernoulliNB`* by adding the `partial_fit` method by Olivier Grisel.
- New website design and navigation by Gilles Louppe, Nelle Varoquaux, Vincent Michel and Andreas Müller.
- Improved documentation on *multi-class, multi-label and multi-output classification* by Yannick Schwartz and Arnaud Joly.
- Better input and error handling in the `metrics` module by Arnaud Joly and Joel Nothman.
- Speed optimization of the `hmm` module by Mikhail Korobov
- Significant speed improvements for *`sklearn.cluster.DBSCAN`* by cleverless

API changes summary

- The `auc_score` was renamed `roc_auc_score`.
- Testing scikit-learn with `sklearn.test()` is deprecated. Use `nosetests sklearn` from the command line.
- Feature importances in *`tree.DecisionTreeClassifier`*, *`tree.DecisionTreeRegressor`* and all derived ensemble estimators are now computed on the fly when accessing the `feature_importances_` attribute. Setting `compute_importances=True` is no longer required. By Gilles Louppe.
- *`linear_model.lasso_path`* and *`linear_model.enet_path`* can return its results in the same format as that of *`linear_model.lars_path`*. This is done by setting the `return_models` parameter to `False`. By Jaques Grobler and Alexandre Gramfort
- `grid_search.IterGrid` was renamed to `grid_search.ParameterGrid`.
- Fixed bug in `KFold` causing imperfect class balance in some cases. By Alexandre Gramfort and Tadej Janež.
- *`sklearn.neighbors.BallTree`* has been refactored, and a *`sklearn.neighbors.KDTree`* has been added which shares the same interface. The Ball Tree now works with a wide variety of distance metrics. Both classes have many new methods, including single-tree and dual-tree queries, breadth-first and depth-first searching, and more advanced queries such as kernel density estimation and 2-point correlation functions. By Jake Vanderplas
- Support for scipy.spatial.cKDTree within neighbors queries has been removed, and the functionality replaced with the new `KDTree` class.

- *sklearn.neighbors.KernelDensity* has been added, which performs efficient kernel density estimation with a variety of kernels.
- *sklearn.decomposition.KernelPCA* now always returns output with n_components components, unless the new parameter remove_zero_eig is set to True. This new behavior is consistent with the way kernel PCA was always documented; previously, the removal of components with zero eigenvalues was tacitly performed on all data.
- gcv_mode="auto" no longer tries to perform SVD on a densified sparse matrix in *sklearn.linear_model.RidgeCV*.
- Sparse matrix support in sklearn.decomposition.RandomizedPCA is now deprecated in favor of the new TruncatedSVD.
- cross_validation.KFold and cross_validation.StratifiedKFold now enforce n_folds >= 2 otherwise a ValueError is raised. By Olivier Grisel.
- *datasets.load_files*'s charset and charset_errors parameters were renamed encoding and decode_errors.
- Attribute oob_score_ in *sklearn.ensemble.GradientBoostingRegressor* and *sklearn.ensemble.GradientBoostingClassifier* is deprecated and has been replaced by oob_improvement_ .
- Attributes in OrthogonalMatchingPursuit have been deprecated (copy_X, Gram, ...) and precompute_gram renamed precompute for consistency. See #2224.
- *sklearn.preprocessing.StandardScaler* now converts integer input to float, and raises a warning. Previously it rounded for dense integer input.
- *sklearn.multiclass.OneVsRestClassifier* now has a decision_function method. This will return the distance of each sample from the decision boundary for each class, as long as the underlying estimators implement the decision_function method. By Kyle Kastner.
- Better input validation, warning on unexpected shapes for y.

1.7.27 Version 0.13.1

February 23, 2013

The 0.13.1 release only fixes some bugs and does not add any new functionality.

Changelog

- Fixed a testing error caused by the function `cross_validation.train_test_split` being interpreted as a test by Yaroslav Halchenko.
- Fixed a bug in the reassignment of small clusters in the *`cluster.MiniBatchKMeans`* by Gael Varoquaux.
- Fixed default value of `gamma` in *`decomposition.KernelPCA`* by Lars Buitinck.
- Updated joblib to `0.7.0d` by Gael Varoquaux.
- Fixed scaling of the deviance in *`ensemble.GradientBoostingClassifier`* by Peter Prettenhofer.
- Better tie-breaking in *`multiclass.OneVsOneClassifier`* by Andreas Müller.
- Other small improvements to tests and documentation.

1.7.28 Version 0.13

January 21, 2013

New Estimator Classes

- `dummy.DummyClassifier` and `dummy.DummyRegressor`, two data-independent predictors by Mathieu Blondel. Useful to sanity-check your estimators. See *Dummy estimators* in the user guide. Multioutput support added by Arnaud Joly.
- `decomposition.FactorAnalysis`, a transformer implementing the classical factor analysis, by Christian Osendorfer and Alexandre Gramfort. See *Factor Analysis* in the user guide.
- `feature_extraction.FeatureHasher`, a transformer implementing the "hashing trick" for fast, low-memory feature extraction from string fields by Lars Buitinck and `feature_extraction.text.HashingVectorizer` for text documents by Olivier Grisel See *Feature hashing* and *Vectorizing a large text corpus with the hashing trick* for the documentation and sample usage.
- `pipeline.FeatureUnion`, a transformer that concatenates results of several other transformers by Andreas Müller. See *FeatureUnion: composite feature spaces* in the user guide.
- `random_projection.GaussianRandomProjection`, `random_projection.SparseRandomProjection` and the function `random_projection.johnson_lindenstrauss_min_dim`. The first two are transformers implementing Gaussian and sparse random projection matrix by Olivier Grisel and Arnaud Joly. See *Random Projection* in the user guide.
- `kernel_approximation.Nystroem`, a transformer for approximating arbitrary kernels by Andreas Müller. See *Nystroem Method for Kernel Approximation* in the user guide.
- `preprocessing.OneHotEncoder`, a transformer that computes binary encodings of categorical features by Andreas Müller. See *Encoding categorical features* in the user guide.
- `linear_model.PassiveAggressiveClassifier` and `linear_model.PassiveAggressiveRegressor`, predictors implementing an efficient stochastic optimization for linear models by Rob Zinkov and Mathieu Blondel. See *Passive Aggressive Algorithms* in the user guide.
- `ensemble.RandomTreesEmbedding`, a transformer for creating high-dimensional sparse representations using ensembles of totally random trees by Andreas Müller. See *Totally Random Trees Embedding* in the user guide.
- `manifold.SpectralEmbedding` and function `manifold.spectral_embedding`, implementing the "laplacian eigenmaps" transformation for non-linear dimensionality reduction by Wei Li. See *Spectral Embedding* in the user guide.
- `isotonic.IsotonicRegression` by Fabian Pedregosa, Alexandre Gramfort and Nelle Varoquaux,

Changelog

- `metrics.zero_one_loss` (formerly `metrics.zero_one`) now has option for normalized output that reports the fraction of misclassifications, rather than the raw number of misclassifications. By Kyle Beauchamp.
- `tree.DecisionTreeClassifier` and all derived ensemble models now support sample weighting, by Noel Dawe and Gilles Louppe.
- Speedup improvement when using bootstrap samples in forests of randomized trees, by Peter Prettenhofer and Gilles Louppe.
- Partial dependence plots for *Gradient Tree Boosting* in `ensemble.partial_dependence.partial_dependence` by Peter Prettenhofer. See *Partial Dependence Plots* for an example.

- The table of contents on the website has now been made expandable by Jaques Grobler.
- *feature_selection.SelectPercentile* now breaks ties deterministically instead of returning all equally ranked features.
- *feature_selection.SelectKBest* and *feature_selection.SelectPercentile* are more numerically stable since they use scores, rather than p-values, to rank results. This means that they might sometimes select different features than they did previously.
- Ridge regression and ridge classification fitting with `sparse_cg` solver no longer has quadratic memory complexity, by Lars Buitinck and Fabian Pedregosa.
- Ridge regression and ridge classification now support a new fast solver called `lsqr`, by Mathieu Blondel.
- Speed up of *metrics.precision_recall_curve* by Conrad Lee.
- Added support for reading/writing svmlight files with pairwise preference attribute (qid in svmlight file format) in *datasets.dump_svmlight_file* and *datasets.load_svmlight_file* by Fabian Pedregosa.
- Faster and more robust *metrics.confusion_matrix* and *Clustering performance evaluation* by Wei Li.
- `cross_validation.cross_val_score` now works with precomputed kernels and affinity matrices, by Andreas Müller.
- LARS algorithm made more numerically stable with heuristics to drop regressors too correlated as well as to stop the path when numerical noise becomes predominant, by Gael Varoquaux.
- Faster implementation of *metrics.precision_recall_curve* by Conrad Lee.
- New kernel `metrics.chi2_kernel` by Andreas Müller, often used in computer vision applications.
- Fix of longstanding bug in *naive_bayes.BernoulliNB* fixed by Shaun Jackman.
- Implemented `predict_proba` in *multiclass.OneVsRestClassifier*, by Andrew Winterman.
- Improve consistency in gradient boosting: estimators *ensemble.GradientBoostingRegressor* and *ensemble.GradientBoostingClassifier* use the estimator *tree.DecisionTreeRegressor* instead of the `tree._tree.Tree` data structure by Arnaud Joly.
- Fixed a floating point exception in the *decision trees* module, by Seberg.
- Fix *metrics.roc_curve* fails when y_true has only one class by Wei Li.
- Add the *metrics.mean_absolute_error* function which computes the mean absolute error. The *metrics.mean_squared_error*, *metrics.mean_absolute_error* and *metrics.r2_score* metrics support multioutput by Arnaud Joly.
- Fixed `class_weight` support in *svm.LinearSVC* and *linear_model.LogisticRegression* by Andreas Müller. The meaning of `class_weight` was reversed as erroneously higher weight meant less positives of a given class in earlier releases.
- Improve narrative documentation and consistency in *sklearn.metrics* for regression and classification metrics by Arnaud Joly.
- Fixed a bug in *sklearn.svm.SVC* when using csr-matrices with unsorted indices by Xinfan Meng and Andreas Müller.
- `MiniBatchKMeans`: Add random reassignment of cluster centers with little observations attached to them, by Gael Varoquaux.

API changes summary

- Renamed all occurrences of `n_atoms` to `n_components` for consistency. This applies to *decomposition.DictionaryLearning*, *decomposition.*

MiniBatchDictionaryLearning, *decomposition.dict_learning*, *decomposition.dict_learning_online*.

- Renamed all occurrences of `max_iters` to `max_iter` for consistency. This applies to *semi_supervised.LabelPropagation* and `semi_supervised.label_propagation.LabelSpreading`.
- Renamed all occurrences of `learn_rate` to `learning_rate` for consistency in `ensemble.BaseGradientBoosting` and *ensemble.GradientBoostingRegressor*.
- The module `sklearn.linear_model.sparse` is gone. Sparse matrix support was already integrated into the "regular" linear models.
- `sklearn.metrics.mean_square_error`, which incorrectly returned the accumulated error, was removed. Use `mean_squared_error` instead.
- Passing `class_weight` parameters to `fit` methods is no longer supported. Pass them to estimator constructors instead.
- GMMs no longer have `decode` and `rvs` methods. Use the `score`, `predict` or `sample` methods instead.
- The `solver` fit option in Ridge regression and classification is now deprecated and will be removed in v0.14. Use the constructor option instead.
- `feature_extraction.text.DictVectorizer` now returns sparse matrices in the CSR format, instead of COO.
- Renamed `k` in `cross_validation.KFold` and `cross_validation.StratifiedKFold` to `n_folds`, renamed `n_bootstraps` to `n_iter` in `cross_validation.Bootstrap`.
- Renamed all occurrences of `n_iterations` to `n_iter` for consistency. This applies to `cross_validation.ShuffleSplit`, `cross_validation.StratifiedShuffleSplit`, `utils.randomized_range_finder` and `utils.randomized_svd`.
- Replaced `rho` in *linear_model.ElasticNet* and *linear_model.SGDClassifier* by `l1_ratio`. The `rho` parameter had different meanings; `l1_ratio` was introduced to avoid confusion. It has the same meaning as previously `rho` in *linear_model.ElasticNet* and `(1-rho)` in *linear_model.SGDClassifier*.
- *linear_model.LassoLars* and *linear_model.Lars* now store a list of paths in the case of multiple targets, rather than an array of paths.
- The attribute `gmm` of `hmm.GMMHMM` was renamed to `gmm_` to adhere more strictly with the API.
- `cluster.spectral_embedding` was moved to *manifold.spectral_embedding*.
- Renamed `eig_tol` in *manifold.spectral_embedding*, *cluster.SpectralClustering* to `eigen_tol`, renamed `mode` to `eigen_solver`.
- Renamed `mode` in *manifold.spectral_embedding* and *cluster.SpectralClustering* to `eigen_solver`.
- `classes_` and `n_classes_` attributes of *tree.DecisionTreeClassifier* and all derived ensemble models are now flat in case of single output problems and nested in case of multi-output problems.
- The `estimators_` attribute of `ensemble.gradient_boosting.GradientBoostingRegressor` and `ensemble.gradient_boosting.GradientBoostingClassifier` is now an array of :class:'tree.DecisionTreeRegressor'.
- Renamed `chunk_size` to `batch_size` in *decomposition.MiniBatchDictionaryLearning* and *decomposition.MiniBatchSparsePCA* for consistency.
- *svm.SVC* and *svm.NuSVC* now provide a `classes_` attribute and support arbitrary dtypes for labels `y`. Also, the dtype returned by `predict` now reflects the dtype of `y` during `fit` (used to be `np.float`).

- Changed default test_size in `cross_validation.train_test_split` to None, added possibility to infer `test_size` from `train_size` in `cross_validation.ShuffleSplit` and `cross_validation.StratifiedShuffleSplit`.
- Renamed function `sklearn.metrics.zero_one` to *`sklearn.metrics.zero_one_loss`*. Be aware that the default behavior in *`sklearn.metrics.zero_one_loss`* is different from `sklearn.metrics.zero_one`: `normalize=False` is changed to `normalize=True`.
- Renamed function `metrics.zero_one_score` to *`metrics.accuracy_score`*.
- *`datasets.make_circles`* now has the same number of inner and outer points.
- In the Naive Bayes classifiers, the `class_prior` parameter was moved from `fit` to `__init__`.

1.7.29 Version 0.12.1

October 8, 2012

The 0.12.1 release is a bug-fix release with no additional features, but is instead a set of bug fixes

Changelog

- Improved numerical stability in spectral embedding by Gael Varoquaux
- Doctest under windows 64bit by Gael Varoquaux
- Documentation fixes for elastic net by Andreas Müller and Alexandre Gramfort
- Proper behavior with fortran-ordered NumPy arrays by Gael Varoquaux
- Make GridSearchCV work with non-CSR sparse matrix by Lars Buitinck
- Fix parallel computing in MDS by Gael Varoquaux
- Fix Unicode support in count vectorizer by Andreas Müller
- Fix MinCovDet breaking with X.shape = (3, 1) by Virgile Fritsch
- Fix clone of SGD objects by Peter Prettenhofer
- Stabilize GMM by Virgile Fritsch

1.7.30 Version 0.12

September 4, 2012

Changelog

- Various speed improvements of the *decision trees* module, by Gilles Louppe.
- *ensemble.GradientBoostingRegressor* and *ensemble.GradientBoostingClassifier* now support feature subsampling via the `max_features` argument, by Peter Prettenhofer.
- Added Huber and Quantile loss functions to *ensemble.GradientBoostingRegressor*, by Peter Prettenhofer.
- *Decision trees* and *forests of randomized trees* now support multi-output classification and regression problems, by Gilles Louppe.
- Added *preprocessing.LabelEncoder*, a simple utility class to normalize labels or transform non-numerical labels, by Mathieu Blondel.
- Added the epsilon-insensitive loss and the ability to make probabilistic predictions with the modified huber loss in *Stochastic Gradient Descent*, by Mathieu Blondel.
- Added *Multi-dimensional Scaling (MDS)*, by Nelle Varoquaux.
- SVMlight file format loader now detects compressed (gzip/bzip2) files and decompresses them on the fly, by Lars Buitinck.
- SVMlight file format serializer now preserves double precision floating point values, by Olivier Grisel.
- A common testing framework for all estimators was added, by Andreas Müller.
- Understandable error messages for estimators that do not accept sparse input by Gael Varoquaux
- Speedups in hierarchical clustering by Gael Varoquaux. In particular building the tree now supports early stopping. This is useful when the number of clusters is not small compared to the number of samples.
- Add MultiTaskLasso and MultiTaskElasticNet for joint feature selection, by Alexandre Gramfort.
- Added `metrics.auc_score` and *metrics.average_precision_score* convenience functions by Andreas Müller.
- Improved sparse matrix support in the *Feature selection* module by Andreas Müller.
- New word boundaries-aware character n-gram analyzer for the *Text feature extraction* module by @kernc.
- Fixed bug in spectral clustering that led to single point clusters by Andreas Müller.
- In *feature_extraction.text.CountVectorizer*, added an option to ignore infrequent words, `min_df` by Andreas Müller.
- Add support for multiple targets in some linear models (ElasticNet, Lasso and OrthogonalMatchingPursuit) by Vlad Niculae and Alexandre Gramfort.
- Fixes in `decomposition.ProbabilisticPCA` score function by Wei Li.
- Fixed feature importance computation in *Gradient Tree Boosting*.

API changes summary

- The old `scikits.learn` package has disappeared; all code should import from `sklearn` instead, which was introduced in 0.9.
- In *metrics.roc_curve*, the `thresholds` array is now returned with it's order reversed, in order to keep it consistent with the order of the returned `fpr` and `tpr`.
- In `hmm` objects, like `hmm.GaussianHMM`, `hmm.MultinomialHMM`, etc., all parameters must be passed to the object when initialising it and not through `fit`. Now `fit` will only accept the data as an input parameter.

- For all SVM classes, a faulty behavior of `gamma` was fixed. Previously, the default gamma value was only computed the first time `fit` was called and then stored. It is now recalculated on every call to `fit`.
- All `Base` classes are now abstract meta classes so that they can not be instantiated.
- *`cluster.ward_tree`* now also returns the parent array. This is necessary for early-stopping in which case the tree is not completely built.
- In *`feature_extraction.text.CountVectorizer`* the parameters `min_n` and `max_n` were joined to the parameter `n_gram_range` to enable grid-searching both at once.
- In *`feature_extraction.text.CountVectorizer`*, words that appear only in one document are now ignored by default. To reproduce the previous behavior, set `min_df=1`.
- Fixed API inconsistency: *`linear_model.SGDClassifier.predict_proba`* now returns 2d array when fit on two classes.
- Fixed API inconsistency: *`discriminant_analysis.QuadraticDiscriminantAnalysis.decision_function`* and *`discriminant_analysis.LinearDiscriminantAnalysis.decision_function`* now return 1d arrays when fit on two classes.
- Grid of alphas used for fitting *`linear_model.LassoCV`* and *`linear_model.ElasticNetCV`* is now stored in the attribute `alphas_` rather than overriding the init parameter `alphas`.
- Linear models when alpha is estimated by cross-validation store the estimated value in the `alpha_` attribute rather than just `alpha` or `best_alpha`.
- *`ensemble.GradientBoostingClassifier`* now supports *`ensemble.GradientBoostingClassifier.staged_predict_proba`*, and *`ensemble.GradientBoostingClassifier.staged_predict`*.
- `svm.sparse.SVC` and other sparse SVM classes are now deprecated. The all classes in the *Support Vector Machines* module now automatically select the sparse or dense representation base on the input.
- All clustering algorithms now interpret the array `X` given to `fit` as input data, in particular *`cluster.SpectralClustering`* and *`cluster.AffinityPropagation`* which previously expected affinity matrices.
- For clustering algorithms that take the desired number of clusters as a parameter, this parameter is now called `n_clusters`.

1.7.31 Version 0.11

May 7, 2012

Changelog

Highlights

- Gradient boosted regression trees (*Gradient Tree Boosting*) for classification and regression by Peter Prettenhofer and Scott White .
- Simple dict-based feature loader with support for categorical variables (`feature_extraction.DictVectorizer`) by Lars Buitinck.
- Added Matthews correlation coefficient (`metrics.matthews_corrcoef`) and added macro and micro average options to `metrics.precision_score`, `metrics.recall_score` and `metrics.f1_score` by Satrajit Ghosh.
- *Out of Bag Estimates* of generalization error for *Ensemble methods* by Andreas Müller.
- Randomized sparse linear models for feature selection, by Alexandre Gramfort and Gael Varoquaux
- *Label Propagation* for semi-supervised learning, by Clay Woolam. **Note** the semi-supervised API is still work in progress, and may change.
- Added BIC/AIC model selection to classical *Gaussian mixture models* and unified the API with the remainder of scikit-learn, by Bertrand Thirion
- Added `sklearn.cross_validation.StratifiedShuffleSplit`, which is a `sklearn.cross_validation.ShuffleSplit` with balanced splits, by Yannick Schwartz.
- `sklearn.neighbors.NearestCentroid` classifier added, along with a `shrink_threshold` parameter, which implements **shrunken centroid classification**, by Robert Layton.

Other changes

- Merged dense and sparse implementations of *Stochastic Gradient Descent* module and exposed utility extension types for sequential datasets `seq_dataset` and weight vectors `weight_vector` by Peter Prettenhofer.
- Added `partial_fit` (support for online/minibatch learning) and warm_start to the *Stochastic Gradient Descent* module by Mathieu Blondel.
- Dense and sparse implementations of *Support Vector Machines* classes and `linear_model.LogisticRegression` merged by Lars Buitinck.
- Regressors can now be used as base estimator in the *Multiclass and multilabel algorithms* module by Mathieu Blondel.
- Added n_jobs option to `metrics.pairwise.pairwise_distances` and `metrics.pairwise.pairwise_kernels` for parallel computation, by Mathieu Blondel.
- *K-means* can now be run in parallel, using the `n_jobs` argument to either *K-means* or `KMeans`, by Robert Layton.
- Improved *Cross-validation: evaluating estimator performance* and *Tuning the hyper-parameters of an estimator* documentation and introduced the new `cross_validation.train_test_split` helper function by Olivier Grisel

- *svm.SVC* members coef_ and intercept_ changed sign for consistency with decision_function; for kernel==linear, coef_ was fixed in the one-vs-one case, by Andreas Müller.
- Performance improvements to efficient leave-one-out cross-validated Ridge regression, esp. for the n_samples > n_features case, in *linear_model.RidgeCV*, by Reuben Fletcher-Costin.
- Refactoring and simplification of the *Text feature extraction* API and fixed a bug that caused possible negative IDF, by Olivier Grisel.
- Beam pruning option in _BaseHMM module has been removed since it is difficult to Cythonize. If you are interested in contributing a Cython version, you can use the python version in the git history as a reference.
- Classes in *Nearest Neighbors* now support arbitrary Minkowski metric for nearest neighbors searches. The metric can be specified by argument p.

API changes summary

- covariance.EllipticEnvelop is now deprecated - Please use *covariance.EllipticEnvelope* instead.
- NeighborsClassifier and NeighborsRegressor are gone in the module *Nearest Neighbors*. Use the classes KNeighborsClassifier, RadiusNeighborsClassifier, KNeighborsRegressor and/or RadiusNeighborsRegressor instead.
- Sparse classes in the *Stochastic Gradient Descent* module are now deprecated.
- In mixture.GMM, mixture.DPGMM and mixture.VBGMM, parameters must be passed to an object when initialising it and not through fit. Now fit will only accept the data as an input parameter.
- methods rvs and decode in GMM module are now deprecated. sample and score or predict should be used instead.
- attribute _scores and _pvalues in univariate feature selection objects are now deprecated. scores_ or pvalues_ should be used instead.
- In LogisticRegression, LinearSVC, SVC and NuSVC, the class_weight parameter is now an initialization parameter, not a parameter to fit. This makes grid searches over this parameter possible.
- LFW data is now always shape (n_samples, n_features) to be consistent with the Olivetti faces dataset. Use images and pairs attribute to access the natural images shapes instead.
- In *svm.LinearSVC*, the meaning of the multi_class parameter changed. Options now are 'ovr' and 'crammer_singer', with 'ovr' being the default. This does not change the default behavior but hopefully is less confusing.
- Class feature_selection.text.Vectorizer is deprecated and replaced by feature_selection.text.TfidfVectorizer.
- The preprocessor / analyzer nested structure for text feature extraction has been removed. All those features are now directly passed as flat constructor arguments to feature_selection.text.TfidfVectorizer and feature_selection.text.CountVectorizer, in particular the following parameters are now used:
- analyzer can be 'word' or 'char' to switch the default analysis scheme, or use a specific python callable (as previously).
- tokenizer and preprocessor have been introduced to make it still possible to customize those steps with the new API.
- input explicitly control how to interpret the sequence passed to fit and predict: filenames, file objects or direct (byte or Unicode) strings.

- charset decoding is explicit and strict by default.
- the `vocabulary`, fitted or not is now stored in the `vocabulary_` attribute to be consistent with the project conventions.
- Class `feature_selection.text.TfidfVectorizer` now derives directly from `feature_selection.text.CountVectorizer` to make grid search trivial.
- methods `rvs` in `_BaseHMM` module are now deprecated. `sample` should be used instead.
- Beam pruning option in `_BaseHMM` module is removed since it is difficult to be Cythonized. If you are interested, you can look in the history codes by git.
- The SVMlight format loader now supports files with both zero-based and one-based column indices, since both occur "in the wild".
- Arguments in class `ShuffleSplit` are now consistent with `StratifiedShuffleSplit`. Arguments `test_fraction` and `train_fraction` are deprecated and renamed to `test_size` and `train_size` and can accept both `float` and `int`.
- Arguments in class `Bootstrap` are now consistent with `StratifiedShuffleSplit`. Arguments `n_test` and `n_train` are deprecated and renamed to `test_size` and `train_size` and can accept both `float` and `int`.
- Argument `p` added to classes in *Nearest Neighbors* to specify an arbitrary Minkowski metric for nearest neighbors searches.

1.7.32 Version 0.10

January 11, 2012

Changelog

- Python 2.5 compatibility was dropped; the minimum Python version needed to use scikit-learn is now 2.6.
- *Sparse inverse covariance* estimation using the graph Lasso, with associated cross-validated estimator, by Gael Varoquaux
- New *Tree* module by Brian Holt, Peter Prettenhofer, Satrajit Ghosh and Gilles Louppe. The module comes with complete documentation and examples.
- Fixed a bug in the RFE module by Gilles Louppe (issue #378).
- Fixed a memory leak in *Support Vector Machines* module by Brian Holt (issue #367).
- Faster tests by Fabian Pedregosa and others.
- Silhouette Coefficient cluster analysis evaluation metric added as `sklearn.metrics.silhouette_score` by Robert Layton.
- Fixed a bug in *K-means* in the handling of the `n_init` parameter: the clustering algorithm used to be run `n_init` times but the last solution was retained instead of the best solution by Olivier Grisel.
- Minor refactoring in *Stochastic Gradient Descent* module; consolidated dense and sparse predict methods; Enhanced test time performance by converting model parameters to fortran-style arrays after fitting (only multiclass).
- Adjusted Mutual Information metric added as `sklearn.metrics.adjusted_mutual_info_score` by Robert Layton.
- Models like SVC/SVR/LinearSVC/LogisticRegression from libsvm/liblinear now support scaling of C regularization parameter by the number of samples by Alexandre Gramfort.
- New *Ensemble Methods* module by Gilles Louppe and Brian Holt. The module comes with the random forest algorithm and the extra-trees method, along with documentation and examples.
- *Novelty and Outlier Detection*: outlier and novelty detection, by Virgile Fritsch.
- *Kernel Approximation*: a transform implementing kernel approximation for fast SGD on non-linear kernels by Andreas Müller.
- Fixed a bug due to atom swapping in *Orthogonal Matching Pursuit (OMP)* by Vlad Niculae.
- *Sparse coding with a precomputed dictionary* by Vlad Niculae.
- *Mini Batch K-Means* performance improvements by Olivier Grisel.
- *K-means* support for sparse matrices by Mathieu Blondel.
- Improved documentation for developers and for the `sklearn.utils` module, by Jake Vanderplas.
- Vectorized 20newsgroups dataset loader (`sklearn.datasets.fetch_20newsgroups_vectorized`) by Mathieu Blondel.
- *Multiclass and multilabel algorithms* by Lars Buitinck.
- Utilities for fast computation of mean and variance for sparse matrices by Mathieu Blondel.
- Make `sklearn.preprocessing.scale` and `sklearn.preprocessing.Scaler` work on sparse matrices by Olivier Grisel
- Feature importances using decision trees and/or forest of trees, by Gilles Louppe.
- Parallel implementation of forests of randomized trees by Gilles Louppe.
- `sklearn.cross_validation.ShuffleSplit` can subsample the train sets as well as the test sets by Olivier Grisel.

- Errors in the build of the documentation fixed by Andreas Müller.

API changes summary

Here are the code migration instructions when upgrading from scikit-learn version 0.9:

- Some estimators that may overwrite their inputs to save memory previously had `overwrite_` parameters; these have been replaced with `copy_` parameters with exactly the opposite meaning.

  This particularly affects some of the estimators in `linear_model`. The default behavior is still to copy everything passed in.

- The SVMlight dataset loader *`sklearn.datasets.load_svmlight_file`* no longer supports loading two files at once; use `load_svmlight_files` instead. Also, the (unused) `buffer_mb` parameter is gone.

- Sparse estimators in the *Stochastic Gradient Descent* module use dense parameter vector `coef_` instead of `sparse_coef_`. This significantly improves test time performance.

- The *Covariance estimation* module now has a robust estimator of covariance, the Minimum Covariance Determinant estimator.

- Cluster evaluation metrics in `metrics.cluster` have been refactored but the changes are backwards compatible. They have been moved to the `metrics.cluster.supervised`, along with `metrics.cluster.unsupervised` which contains the Silhouette Coefficient.

- The `permutation_test_score` function now behaves the same way as `cross_val_score` (i.e. uses the mean score across the folds.)

- Cross Validation generators now use integer indices (`indices=True`) by default instead of boolean masks. This make it more intuitive to use with sparse matrix data.

- The functions used for sparse coding, `sparse_encode` and `sparse_encode_parallel` have been combined into *`sklearn.decomposition.sparse_encode`*, and the shapes of the arrays have been transposed for consistency with the matrix factorization setting, as opposed to the regression setting.

- Fixed an off-by-one error in the SVMlight/LibSVM file format handling; files generated using *`sklearn.datasets.dump_svmlight_file`* should be re-generated. (They should continue to work, but accidentally had one extra column of zeros prepended.)

- `BaseDictionaryLearning` class replaced by `SparseCodingMixin`.

- `sklearn.utils.extmath.fast_svd` has been renamed *`sklearn.utils.extmath.randomized_svd`* and the default oversampling is now fixed to 10 additional random vectors instead of doubling the number of components to extract. The new behavior follows the reference paper.

People

The following people contributed to scikit-learn since last release:

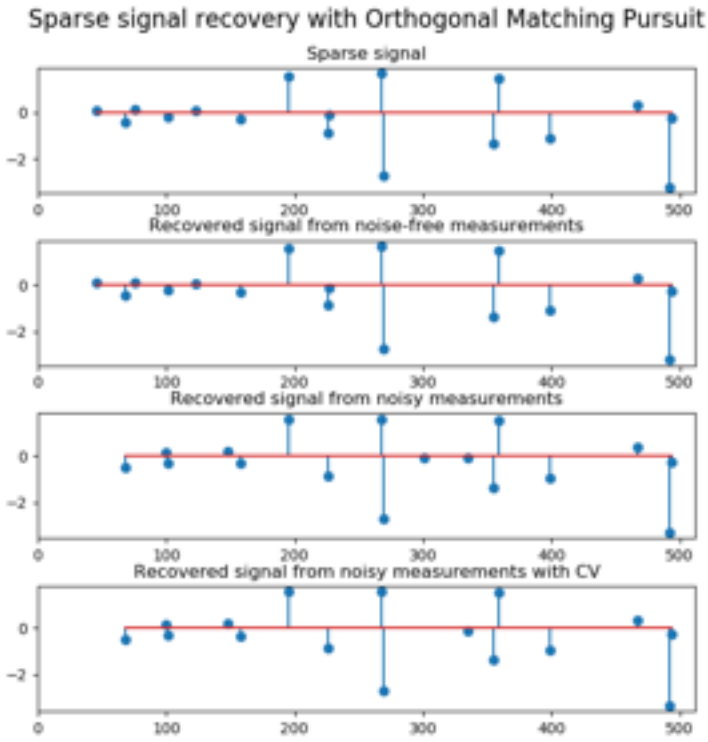
1.7.33 Version 0.9

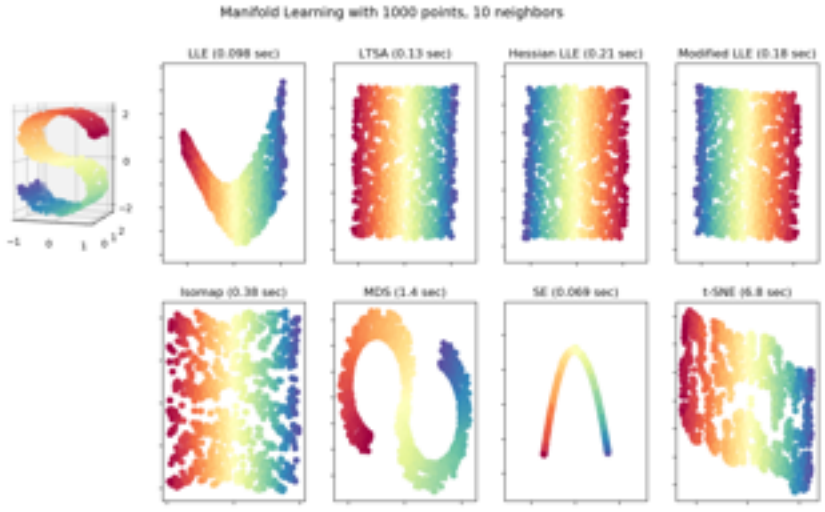
September 21, 2011

scikit-learn 0.9 was released on September 2011, three months after the 0.8 release and includes the new modules *Manifold learning*, *The Dirichlet Process* as well as several new algorithms and documentation improvements.

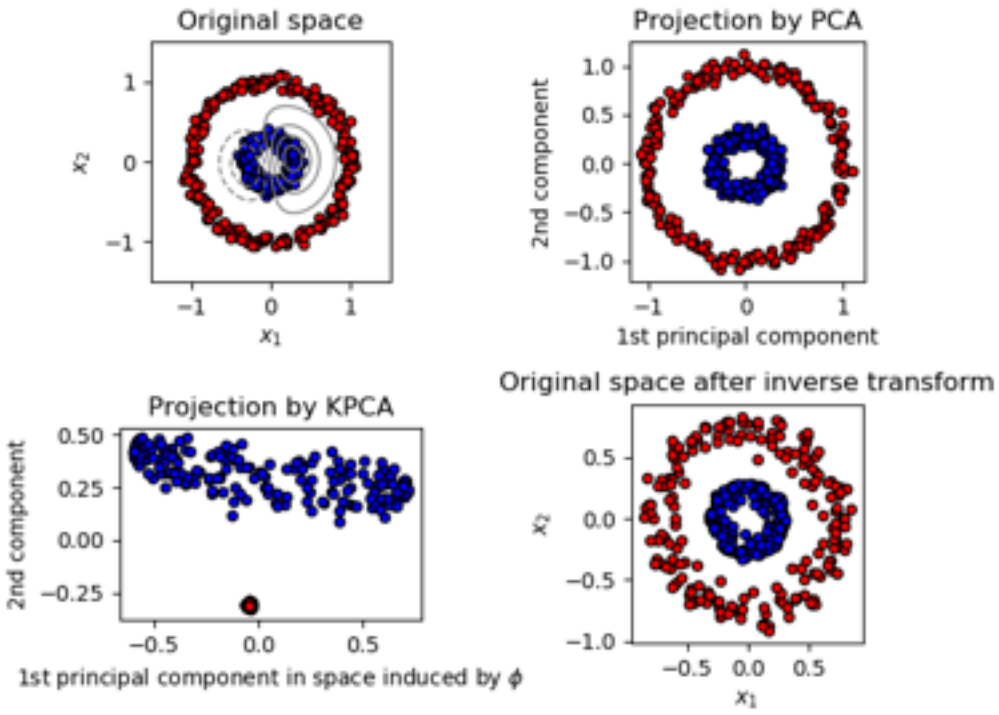
This release also includes the dictionary-learning work developed by Vlad Niculae as part of the Google Summer of Code program.



Sparse signal recovery with Orthogonal Matching Pursuit
Sparse signal
Recovered signal from noise-free measurements
Recovered signal from noisy measurements
Recovered signal from noisy measurements with CV



Manifold Learning with 1000 points, 10 neighbors
LLE (0.098 sec)
LTSA (0.13 sec)
Hessian LLE (0.21 sec)
Modified LLE (0.18 sec)
Isomap (0.38 sec)
MDS (1.4 sec)
SE (0.069 sec)
t-SNE (6.8 sec)



Changelog

- New *Manifold learning* module by Jake Vanderplas and Fabian Pedregosa.
- New *Dirichlet Process* Gaussian Mixture Model by Alexandre Passos
- *Nearest Neighbors* module refactoring by Jake Vanderplas : general refactoring, support for sparse matrices in input, speed and documentation improvements. See the next section for a full list of API changes.
- Improvements on the *Feature selection* module by Gilles Louppe : refactoring of the RFE classes, documentation rewrite, increased efficiency and minor API changes.
- *Sparse principal components analysis (SparsePCA and MiniBatchSparsePCA)* by Vlad Niculae, Gael Varoquaux and Alexandre Gramfort
- Printing an estimator now behaves independently of architectures and Python version thanks to Jean Kossaifi.
- *Loader for libsvm/svmlight format* by Mathieu Blondel and Lars Buitinck
- Documentation improvements: thumbnails in example gallery by Fabian Pedregosa.
- Important bugfixes in *Support Vector Machines* module (segfaults, bad performance) by Fabian Pedregosa.
- Added *Multinomial Naive Bayes* and *Bernoulli Naive Bayes* by Lars Buitinck
- Text feature extraction optimizations by Lars Buitinck
- Chi-Square feature selection (`feature_selection.univariate_selection.chi2`) by Lars Buitinck.
- *Generated datasets* module refactoring by Gilles Louppe
- *Multiclass and multilabel algorithms* by Mathieu Blondel
- Ball tree rewrite by Jake Vanderplas

- Implementation of *DBSCAN* algorithm by Robert Layton
- Kmeans predict and transform by Robert Layton
- Preprocessing module refactoring by Olivier Grisel
- Faster mean shift by Conrad Lee
- New `Bootstrap`, *Random permutations cross-validation a.k.a. Shuffle & Split* and various other improvements in cross validation schemes by Olivier Grisel and Gael Varoquaux
- Adjusted Rand index and V-Measure clustering evaluation metrics by Olivier Grisel
- Added *`Orthogonal Matching Pursuit`* by Vlad Niculae
- Added 2D-patch extractor utilities in the *Feature extraction* module by Vlad Niculae
- Implementation of *`linear_model.LassoLarsCV`* (cross-validated Lasso solver using the Lars algorithm) and *`linear_model.LassoLarsIC`* (BIC/AIC model selection in Lars) by Gael Varoquaux and Alexandre Gramfort
- Scalability improvements to *`metrics.roc_curve`* by Olivier Hervieu
- Distance helper functions `metrics.pairwise.pairwise_distances` and *`metrics.pairwise.pairwise_kernels`* by Robert Layton
- *`Mini-Batch K-Means`* by Nelle Varoquaux and Peter Prettenhofer.
- mldata utilities by Pietro Berkes.
- *The Olivetti faces dataset* by David Warde-Farley.

API changes summary

Here are the code migration instructions when upgrading from scikit-learn version 0.8:

- The `scikits.learn` package was renamed `sklearn`. There is still a `scikits.learn` package alias for backward compatibility.

  Third-party projects with a dependency on scikit-learn 0.9+ should upgrade their codebase. For instance, under Linux / MacOSX just run (make a backup first!):

  ```
  find -name "*.py" | xargs sed -i 's/\bscikits.learn\b/sklearn/g'
  ```

- Estimators no longer accept model parameters as `fit` arguments: instead all parameters must be only be passed as constructor arguments or using the now public `set_params` method inherited from *`base.BaseEstimator`*.

  Some estimators can still accept keyword arguments on the `fit` but this is restricted to data-dependent values (e.g. a Gram matrix or an affinity matrix that are precomputed from the `X` data matrix.

- The `cross_val` package has been renamed to `cross_validation` although there is also a `cross_val` package alias in place for backward compatibility.

  Third-party projects with a dependency on scikit-learn 0.9+ should upgrade their codebase. For instance, under Linux / MacOSX just run (make a backup first!):

  ```
  find -name "*.py" | xargs sed -i 's/\bcross_val\b/cross_validation/g'
  ```

- The `score_func` argument of the `sklearn.cross_validation.cross_val_score` function is now expected to accept `y_test` and `y_predicted` as only arguments for classification and regression tasks or `X_test` for unsupervised estimators.

- `gamma` parameter for support vector machine algorithms is set to `1 / n_features` by default, instead of `1 / n_samples`.
- The `sklearn.hmm` has been marked as orphaned: it will be removed from scikit-learn in version 0.11 unless someone steps up to contribute documentation, examples and fix lurking numerical stability issues.
- `sklearn.neighbors` has been made into a submodule. The two previously available estimators, `NeighborsClassifier` and `NeighborsRegressor` have been marked as deprecated. Their functionality has been divided among five new classes: `NearestNeighbors` for unsupervised neighbors searches, `KNeighborsClassifier` & `RadiusNeighborsClassifier` for supervised classification problems, and `KNeighborsRegressor` & `RadiusNeighborsRegressor` for supervised regression problems.
- `sklearn.ball_tree.BallTree` has been moved to `sklearn.neighbors.BallTree`. Using the former will generate a warning.
- `sklearn.linear_model.LARS()` and related classes (LassoLARS, LassoLARSCV, etc.) have been renamed to `sklearn.linear_model.Lars()`.
- All distance metrics and kernels in `sklearn.metrics.pairwise` now have a Y parameter, which by default is None. If not given, the result is the distance (or kernel similarity) between each sample in Y. If given, the result is the pairwise distance (or kernel similarity) between samples in X to Y.
- `sklearn.metrics.pairwise.l1_distance` is now called `manhattan_distance`, and by default returns the pairwise distance. For the component wise distance, set the parameter `sum_over_features` to `False`.

Backward compatibility package aliases and other deprecated classes and functions will be removed in version 0.11.

1.7.34 Version 0.8

May 11, 2011

scikit-learn 0.8 was released on May 2011, one month after the first "international" scikit-learn coding sprint and is marked by the inclusion of important modules: *Hierarchical clustering*, *Cross decomposition*, *Non-negative matrix factorization (NMF or NNMF)*, initial support for Python 3 and by important enhancements and bug fixes.

Changelog

Several new modules where introduced during this release:

- New *Hierarchical clustering* module by Vincent Michel, Bertrand Thirion, Alexandre Gramfort and Gael Varoquaux.
- *Kernel PCA* implementation by Mathieu Blondel
- *The Labeled Faces in the Wild face recognition dataset* by Olivier Grisel.
- New *Cross decomposition* module by Edouard Duchesnay.
- *Non-negative matrix factorization (NMF or NNMF)* module Vlad Niculae
- Implementation of the *Oracle Approximating Shrinkage* algorithm by Virgile Fritsch in the *Covariance estimation* module.

Some other modules benefited from significant improvements or cleanups.

- Initial support for Python 3: builds and imports cleanly, some modules are usable while others have failing tests by Fabian Pedregosa.
- `decomposition.PCA` is now usable from the Pipeline object by Olivier Grisel.
- Guide *How to optimize for speed* by Olivier Grisel.
- Fixes for memory leaks in libsvm bindings, 64-bit safer BallTree by Lars Buitinck.
- bug and style fixing in *K-means* algorithm by Jan Schlüter.
- Add attribute converged to Gaussian Mixture Models by Vincent Schut.
- Implemented `transform`, `predict_log_proba` in `discriminant_analysis.LinearDiscriminantAnalysis` By Mathieu Blondel.
- Refactoring in the *Support Vector Machines* module and bug fixes by Fabian Pedregosa, Gael Varoquaux and Amit Aides.
- Refactored SGD module (removed code duplication, better variable naming), added interface for sample weight by Peter Prettenhofer.
- Wrapped BallTree with Cython by Thouis (Ray) Jones.
- Added function `svm.l1_min_c` by Paolo Losi.
- Typos, doc style, etc. by Yaroslav Halchenko, Gael Varoquaux, Olivier Grisel, Yann Malet, Nicolas Pinto, Lars Buitinck and Fabian Pedregosa.

1.7.35 Version 0.7

March 2, 2011

scikit-learn 0.7 was released in March 2011, roughly three months after the 0.6 release. This release is marked by the speed improvements in existing algorithms like k-Nearest Neighbors and K-Means algorithm and by the inclusion of an efficient algorithm for computing the Ridge Generalized Cross Validation solution. Unlike the preceding release, no new modules where added to this release.

Changelog

- Performance improvements for Gaussian Mixture Model sampling [Jan Schlüter].
- Implementation of efficient leave-one-out cross-validated Ridge in *linear_model.RidgeCV* [Mathieu Blondel]
- Better handling of collinearity and early stopping in *linear_model.lars_path* [Alexandre Gramfort and Fabian Pedregosa].
- Fixes for liblinear ordering of labels and sign of coefficients [Dan Yamins, Paolo Losi, Mathieu Blondel and Fabian Pedregosa].
- Performance improvements for Nearest Neighbors algorithm in high-dimensional spaces [Fabian Pedregosa].
- Performance improvements for *cluster.KMeans* [Gael Varoquaux and James Bergstra].
- Sanity checks for SVM-based classes [Mathieu Blondel].
- Refactoring of `neighbors.NeighborsClassifier` and *neighbors.kneighbors_graph*: added different algorithms for the k-Nearest Neighbor Search and implemented a more stable algorithm for finding barycenter weights. Also added some developer documentation for this module, see notes_neighbors for more information [Fabian Pedregosa].
- Documentation improvements: Added `pca.RandomizedPCA` and *linear_model.LogisticRegression* to the class reference. Also added references of matrices used for clustering and other fixes [Gael Varoquaux, Fabian Pedregosa, Mathieu Blondel, Olivier Grisel, Virgile Fritsch , Emmanuelle Gouillart]
- Binded decision_function in classes that make use of liblinear, dense and sparse variants, like *svm.LinearSVC* or *linear_model.LogisticRegression* [Fabian Pedregosa].
- Performance and API improvements to `metrics.euclidean_distances` and to `pca.RandomizedPCA` [James Bergstra].
- Fix compilation issues under NetBSD [Kamel Ibn Hassen Derouiche]
- Allow input sequences of different lengths in `hmm.GaussianHMM` [Ron Weiss].

- Fix bug in affinity propagation caused by incorrect indexing [Xinfan Meng]

1.7.36 Version 0.6

December 21, 2010

scikit-learn 0.6 was released on December 2010. It is marked by the inclusion of several new modules and a general renaming of old ones. It is also marked by the inclusion of new example, including applications to real-world datasets.

Changelog

- New stochastic gradient descent module by Peter Prettenhofer. The module comes with complete documentation and examples.
- Improved svm module: memory consumption has been reduced by 50%, heuristic to automatically set class weights, possibility to assign weights to samples (see *SVM: Weighted samples* for an example).
- New *Gaussian Processes* module by Vincent Dubourg. This module also has great documentation and some very neat examples. See example_gaussian_process_plot_gp_regression.py or example_gaussian_process_plot_gp_probabilistic_classification_after_regression.py for a taste of what can be done.
- It is now possible to use liblinear's Multi-class SVC (option multi_class in `svm.LinearSVC`)
- New features and performance improvements of text feature extraction.

- Improved sparse matrix support, both in main classes (`grid_search.GridSearchCV`) as in modules sklearn.svm.sparse and sklearn.linear_model.sparse.
- Lots of cool new examples and a new section that uses real-world datasets was created. These include: *Faces recognition example using eigenfaces and SVMs*, *Species distribution modeling*, *Libsvm GUI*, *Wikipedia principal eigenvector* and others.
- Faster *Least Angle Regression* algorithm. It is now 2x faster than the R version on worst case and up to 10x times faster on some cases.
- Faster coordinate descent algorithm. In particular, the full path version of lasso (*linear_model.lasso_path*) is more than 200x times faster than before.
- It is now possible to get probability estimates from a *linear_model.LogisticRegression* model.
- module renaming: the glm module has been renamed to linear_model, the gmm module has been included into the more general mixture model and the sgd module has been included in linear_model.
- Lots of bug fixes and documentation improvements.

1.7.37 Version 0.5

October 11, 2010

Changelog

New classes

- Support for sparse matrices in some classifiers of modules `svm` and `linear_model` (see `svm.sparse.SVC`, `svm.sparse.SVR`, `svm.sparse.LinearSVC`, `linear_model.sparse.Lasso`, `linear_model.sparse.ElasticNet`)

- New *pipeline.Pipeline* object to compose different estimators.
- Recursive Feature Elimination routines in module *Feature selection*.
- Addition of various classes capable of cross validation in the linear_model module (*linear_model.LassoCV*, *linear_model.ElasticNetCV*, etc.).
- New, more efficient LARS algorithm implementation. The Lasso variant of the algorithm is also implemented. See *linear_model.lars_path*, *linear_model.Lars* and *linear_model.LassoLars*.
- New Hidden Markov Models module (see classes `hmm.GaussianHMM`, `hmm.MultinomialHMM`, `hmm.GMMHMM`)
- New module feature_extraction (see *class reference*)
- New FastICA algorithm in module sklearn.fastica

Documentation

- Improved documentation for many modules, now separating narrative documentation from the class reference. As an example, see documentation for the SVM module and the complete class reference.

Fixes

- API changes: adhere variable names to PEP-8, give more meaningful names.
- Fixes for svm module to run on a shared memory context (multiprocessing).
- It is again possible to generate latex (and thus PDF) from the sphinx docs.

Examples

- new examples using some of the mlcomp datasets: `sphx_glr_auto_examples_mlcomp_sparse_document_classif` `py` (since removed) and *Classification of text documents using sparse features*
- Many more examples. See here the full list of examples.

External dependencies

- Joblib is now a dependency of this package, although it is shipped with (sklearn.externals.joblib).

Removed modules

- Module ann (Artificial Neural Networks) has been removed from the distribution. Users wanting this sort of algorithms should take a look into pybrain.

Misc

- New sphinx theme for the web page.

Authors

The following is a list of authors for this release, preceded by number of commits:

- 262 Fabian Pedregosa
- 240 Gael Varoquaux
- 149 Alexandre Gramfort
- 116 Olivier Grisel
- 40 Vincent Michel
- 38 Ron Weiss
- 23 Matthieu Perrot
- 10 Bertrand Thirion
- 7 Yaroslav Halchenko
- 9 VirgileFritsch
- 6 Edouard Duchesnay
- 4 Mathieu Blondel
- 1 Ariel Rokem
- 1 Matthieu Brucher

1.7.38 Version 0.4

August 26, 2010

Changelog

Major changes in this release include:

- Coordinate Descent algorithm (Lasso, ElasticNet) refactoring & speed improvements (roughly 100x times faster).
- Coordinate Descent Refactoring (and bug fixing) for consistency with R's package GLMNET.
- New metrics module.
- New GMM module contributed by Ron Weiss.
- Implementation of the LARS algorithm (without Lasso variant for now).
- feature_selection module redesign.
- Migration to GIT as version control system.
- Removal of obsolete attrselect module.
- Rename of private compiled extensions (added underscore).
- Removal of legacy unmaintained code.
- Documentation improvements (both docstring and rst).
- Improvement of the build system to (optionally) link with MKL. Also, provide a lite BLAS implementation in case no system-wide BLAS is found.

- Lots of new examples.
- Many, many bug fixes ...

Authors

The committer list for this release is the following (preceded by number of commits):

- 143 Fabian Pedregosa
- 35 Alexandre Gramfort
- 34 Olivier Grisel
- 11 Gael Varoquaux
- 5 Yaroslav Halchenko
- 2 Vincent Michel
- 1 Chris Filo Gorgolewski

1.7.39 Earlier versions

Earlier versions included contributions by Fred Mailhot, David Cooke, David Huard, Dave Morrill, Ed Schofield, Travis Oliphant, Pearu Peterson.

1.8 Roadmap

1.8.1 Purpose of this document

This document list general directions that core contributors are interested to see developed in scikit-learn. The fact that an item is listed here is in no way a promise that it will happen, as resources are limited. Rather, it is an indication that help is welcomed on this topic.

1.8.2 Statement of purpose: Scikit-learn in 2018

Eleven years after the inception of Scikit-learn, much has changed in the world of machine learning. Key changes include:

- Computational tools: The exploitation of GPUs, distributed programming frameworks like Scala/Spark, etc.
- High-level Python libraries for experimentation, processing and data management: Jupyter notebook, Cython, Pandas, Dask, Numba...
- Changes in the focus of machine learning research: artificial intelligence applications (where input structure is key) with deep learning, representation learning, reinforcement learning, domain transfer, etc.

A more subtle change over the last decade is that, due to changing interests in ML, PhD students in machine learning are more likely to contribute to PyTorch, Dask, etc. than to Scikit-learn, so our contributor pool is very different to a decade ago.

Scikit-learn remains very popular in practice for trying out canonical machine learning techniques, particularly for applications in experimental science and in data science. A lot of what we provide is now very mature. But it can be costly to maintain, and we cannot therefore include arbitrary new implementations. Yet Scikit-learn is also essential

in defining an API framework for the development of interoperable machine learning components external to the core library.

Thus our main goals in this era are to:

- continue maintaining a high-quality, well-documented collection of canonical tools for data processing and machine learning within the current scope (i.e. rectangular data largely invariant to column and row order; predicting targets with simple structure)
- improve the ease for users to develop and publish external components
- improve inter-operability with modern data science tools (e.g. Pandas, Dask) and infrastructures (e.g. distributed processing)

Many of the more fine-grained goals can be found under the API tag on the issue tracker.

1.8.3 Architectural / general goals

The list is numbered not as an indication of the order of priority, but to make referring to specific points easier. Please add new entries only at the bottom. Note that the crossed out entries are already done, and we try to keep the document up to date as we work on these issues.

1. Improved handling of Pandas DataFrames
    - document current handling
    - column reordering issue #7242
    - avoiding unnecessary conversion to ndarray #12147
    - returning DataFrames from transformers #5523
    - getting DataFrames from dataset loaders #10733, #13902
    - Sparse currently not considered #12800
2. Improved handling of categorical features
    - Tree-based models should be able to handle both continuous and categorical features #12866 and #15550.
    - In dataset loaders #13902
    - As generic transformers to be used with ColumnTransforms (e.g. ordinal encoding supervised by correlation with target variable) #5853, #11805
    - Handling mixtures of categorical and continuous variables
3. Improved handling of missing data
    - Making sure meta-estimators are lenient towards missing data, #15319
    - Non-trivial imputers #11977, #12852
    - Learners directly handling missing data #13911
    - An amputation sample generator to make parts of a dataset go missing #6284
4. More didactic documentation
    - More and more options have been added to scikit-learn. As a result, the documentation is crowded which makes it hard for beginners to get the big picture. Some work could be done in prioritizing the information.
5. Passing around information that is not (X, y): Sample properties
    - We need to be able to pass sample weights to scorers in cross validation.

- We should have standard/generalised ways of passing sample-wise properties around in meta-estimators. #4497 #7646

6. Passing around information that is not (X, y): Feature properties
   - Feature names or descriptions should ideally be available to fit for, e.g. . #6425 #6424
   - Per-feature handling (e.g. "is this a nominal / ordinal / English language text?") should also not need to be provided to estimator constructors, ideally, but should be available as metadata alongside X. #8480
7. Passing around information that is not (X, y): Target information
   - We have problems getting the full set of classes to all components when the data is split/sampled. #6231 #8100
   - We have no way to handle a mixture of categorical and continuous targets.
8. Make it easier for external users to write Scikit-learn-compatible components
   - More flexible estimator checks that do not select by estimator name #6599 #6715
   - Example of how to develop an estimator or a meta-estimator, #14582
   - More self-sufficient running of scikit-learn-contrib or a similar resource
9. Support resampling and sample reduction
   - Allow subsampling of majority classes (in a pipeline?) #3855
   - Implement random forests with resampling #8732
10. Better interfaces for interactive development
    - __repr__ and HTML visualisations of estimators #6323 and #14180.
    - Include plotting tools, not just as examples. #9173
11. Improved tools for model diagnostics and basic inference
    - alternative feature importances implementations, #13146
    - better ways to handle validation sets when fitting
    - better ways to find thresholds / create decision rules #8614
12. Better tools for selecting hyperparameters with transductive estimators
    - Grid search and cross validation are not applicable to most clustering tasks. Stability-based selection is more relevant.
13. Better support for manual and automatic pipeline building
    - Easier way to construct complex pipelines and valid search spaces #7608 #5082 #8243
    - provide search ranges for common estimators??
    - cf. searchgrid
14. Improved tracking of fitting
    - Verbose is not very friendly and should use a standard logging library #6929, #78
    - Callbacks or a similar system would facilitate logging and early stopping
15. Distributed parallelism
    - Accept data which complies with `__array_function__`
16. A way forward for more out of core

- Dask enables easy out-of-core computation. While the Dask model probably cannot be adaptable to all machine-learning algorithms, most machine learning is on smaller data than ETL, hence we can maybe adapt to very large scale while supporting only a fraction of the patterns.

17. Support for working with pre-trained models
    - Estimator "freezing". In particular, right now it's impossible to clone a `CalibratedClassifierCV` with prefit. #8370. #6451
18. Backwards-compatible de/serialization of some estimators
    - Currently serialization (with pickle) breaks across versions. While we may not be able to get around other limitations of pickle re security etc, it would be great to offer cross-version safety from version 1.0. Note: Gael and Olivier think that this can cause heavy maintenance burden and we should manage the trade-offs. A possible alternative is presented in the following point.
19. Documentation and tooling for model lifecycle management
    - Document good practices for model deployments and lifecycle: before deploying a model: snapshot the code versions (numpy, scipy, scikit-learn, custom code repo), the training script and an alias on how to retrieve historical training data + snapshot a copy of a small validation set + snapshot of the predictions (predicted probabilities for classifiers) on that validation set.
    - Document and tools to make it easy to manage upgrade of scikit-learn versions:
      - Try to load the old pickle, if it works, use the validation set prediction snapshot to detect that the serialized model still behave the same;
      - If joblib.load / pickle.load not work, use the versioned control training script + historical training set to retrain the model and use the validation set prediction snapshot to assert that it is possible to recover the previous predictive performance: if this is not the case there is probably a bug in scikit-learn that needs to be reported.
20. Everything in Scikit-learn should probably conform to our API contract. We are still in the process of making decisions on some of these related issues.
    - `Pipeline <pipeline.Pipeline>` and `FeatureUnion` modify their input parameters in fit. Fixing this requires making sure we have a good grasp of their use cases to make sure all current functionality is maintained. #8157 #7382
21. (Optional) Improve scikit-learn common tests suite to make sure that (at least for frequently used) models have stable predictions across-versions (to be discussed);
    - Extend documentation to mention how to deploy models in Python-free environments for instance ONNX. and use the above best practices to assess predictive consistency between scikit-learn and ONNX prediction functions on validation set.
    - Document good practices to detect temporal distribution drift for deployed model and good practices for re-training on fresh data without causing catastrophic predictive performance regressions.

1.8.4 Subpackage-specific goals

sklearn.ensemble

- a stacking implementation, #11047

sklearn.cluster

- kmeans variants for non-Euclidean distances, if we can show these have benefits beyond hierarchical clustering.

sklearn.model_selection

- multi-metric scoring is slow #9326

- perhaps we want to be able to get back more than multiple metrics
- the handling of random states in CV splitters is a poor design and contradicts the validation of similar parameters in estimators, #15177
- exploit warm-starting and path algorithms so the benefits of `EstimatorCV` objects can be accessed via `GridSearchCV` and used in Pipelines. #1626
- Cross-validation should be able to be replaced by OOB estimates whenever a cross-validation iterator is used.
- Redundant computations in pipelines should be avoided (related to point above) cf daskml

`sklearn.neighbors`

- Ability to substitute a custom/approximate/precomputed nearest neighbors implementation for ours in all/most contexts that nearest neighbors are used for learning. #10463

`sklearn.pipeline`

- Performance issues with `Pipeline.memory`
- see "Everything in Scikit-learn should conform to our API contract" above

1.9 Scikit-learn governance and decision-making

The purpose of this document is to formalize the governance process used by the scikit-learn project, to clarify how decisions are made and how the various elements of our community interact. This document establishes a decision-making structure that takes into account feedback from all members of the community and strives to find consensus, while avoiding any deadlocks.

This is a meritocratic, consensus-based community project. Anyone with an interest in the project can join the community, contribute to the project design and participate in the decision making process. This document describes how that participation takes place and how to set about earning merit within the project community.

1.9.1 Roles And Responsibilities

Contributors

Contributors are community members who contribute in concrete ways to the project. Anyone can become a contributor, and contributions can take many forms – not only code – as detailed in the *contributors guide*.

Core developers

Core developers are community members who have shown that they are dedicated to the continued development of the project through ongoing engagement with the community. They have shown they can be trusted to maintain scikit-learn with care. Being a core developer allows contributors to more easily carry on with their project related activities by giving them direct access to the project's repository and is represented as being an organization member on the scikit-learn GitHub organization. Core developers are expected to review code contributions, can merge approved pull requests, can cast votes for and against merging a pull-request, and can be involved in deciding major changes to the API.

New core developers can be nominated by any existing core developers. Once they have been nominated, there will be a vote by the current core developers. Voting on new core developers is one of the few activities that takes place on the project's private management list. While it is expected that most votes will be unanimous, a two-thirds majority of the cast votes is enough. The vote needs to be open for at least 1 week.

Core developers that have not contributed to the project (commits or GitHub comments) in the past 12 months will be asked if they want to become emeritus core developers and recant their commit and voting rights until they become active again. The list of core developers, active and emeritus (with dates at which they became active) is public on the scikit-learn website.

Technical Committee

The Technical Committee (TC) members are core developers who have additional responsibilities to ensure the smooth running of the project. TC members are expected to participate in strategic planning, and approve changes to the governance model. The purpose of the TC is to ensure a smooth progress from the big-picture perspective. Indeed changes that impact the full project require a synthetic analysis and a consensus that is both explicit and informed. In cases that the core developer community (which includes the TC members) fails to reach such a consensus in the required time frame, the TC is the entity to resolve the issue. Membership of the TC is by nomination by a core developer. A nomination will result in discussion which cannot take more than a month and then a vote by the core developers which will stay open for a week. TC membership votes are subject to a two-third majority of all cast votes as well as a simple majority approval of all the current TC members. TC members who do not actively engage with the TC duties are expected to resign.

The initial Technical Committee of scikit-learn consists of Alexandre Gramfort, Olivier Grisel, Andreas Müller, Joel Nothman, Hanmin Qin, Gaël Varoquaux, and Roman Yurchak.

1.9.2 Decision Making Process

Decisions about the future of the project are made through discussion with all members of the community. All non-sensitive project management discussion takes place on the project contributors' mailing list and the issue tracker. Occasionally, sensitive discussion occurs on a private list.

Scikit-learn uses a "consensus seeking" process for making decisions. The group tries to find a resolution that has no open objections among core developers. At any point during the discussion, any core-developer can call for a vote, which will conclude one month from the call for the vote. Any vote must be backed by a `SLEP <slep>`. If no option can gather two thirds of the votes cast, the decision is escalated to the TC, which in turn will use consensus seeking with the fallback option of a simple majority vote if no consensus can be found within a month. This is what we hereafter may refer to as "the decision making process".

Decisions (in addition to adding core developers and TC membership as above) are made according to the following rules:

- **Minor Documentation changes**, such as typo fixes, or addition / correction of a sentence, but no change of the scikit-learn.org landing page or the "about" page: Requires +1 by a core developer, no -1 by a core developer (lazy consensus), happens on the issue or pull request page. Core developers are expected to give "reasonable time" to others to give their opinion on the pull request if they're not confident others would agree.
- **Code changes and major documentation changes** require +1 by two core developers, no -1 by a core developer (lazy consensus), happens on the issue of pull-request page.
- **Changes to the API principles and changes to dependencies or supported versions** happen via a *Enhancement proposals (SLEPs)* and follows the decision-making process outlined above.
- **Changes to the governance model** use the same decision process outlined above.

If a veto -1 vote is cast on a lazy consensus, the proposer can appeal to the community and core developers and the change can be approved or rejected using the decision making procedure outlined above.

1.9.3 Enhancement proposals (SLEPs)

For all votes, a proposal must have been made public and discussed before the vote. Such proposal must be a consolidated document, in the form of a 'Scikit-Learn Enhancement Proposal' (SLEP), rather than a long discussion on an issue. A SLEP must be submitted as a pull-request to enhancement proposals using the SLEP template.

CHAPTER

TWO

SCIKIT-LEARN TUTORIALS

2.1 An introduction to machine learning with scikit-learn

Section contents

In this section, we introduce the machine learning vocabulary that we use throughout scikit-learn and give a simple learning example.

2.1.1 Machine learning: the problem setting

In general, a learning problem considers a set of n samples of data and then tries to predict properties of unknown data. If each sample is more than a single number and, for instance, a multi-dimensional entry (aka multivariate data), it is said to have several attributes or **features**.

Learning problems fall into a few categories:

- supervised learning, in which the data comes with additional attributes that we want to predict (*Click here* to go to the scikit-learn supervised learning page).This problem can be either:
  - classification: samples belong to two or more classes and we want to learn from already labeled data how to predict the class of unlabeled data. An example of a classification problem would be handwritten digit recognition, in which the aim is to assign each input vector to one of a finite number of discrete categories. Another way to think of classification is as a discrete (as opposed to continuous) form of supervised learning where one has a limited number of categories and for each of the n samples provided, one is to try to label them with the correct category or class.
  - regression: if the desired output consists of one or more continuous variables, then the task is called *regression*. An example of a regression problem would be the prediction of the length of a salmon as a function of its age and weight.
- unsupervised learning, in which the training data consists of a set of input vectors x without any corresponding target values. The goal in such problems may be to discover groups of similar examples within the data, where it is called clustering, or to determine the distribution of data within the input space, known as density estimation, or to project the data from a high-dimensional space down to two or three dimensions for the purpose of *visualization* (*Click here* to go to the Scikit-Learn unsupervised learning page).

Training set and testing set

Machine learning is about learning some properties of a data set and then testing those properties against another data set. A common practice in machine learning is to evaluate an algorithm by splitting a data set into two. We call one of those sets the **training set**, on which we learn some properties; we call the other set the **testing set**, on which we test the learned properties.

2.1.2 Loading an example dataset

`scikit-learn` comes with a few standard datasets, for instance the iris and digits datasets for classification and the boston house prices dataset for regression.

In the following, we start a Python interpreter from our shell and then load the `iris` and `digits` datasets. Our notational convention is that `$` denotes the shell prompt while `>>>` denotes the Python interpreter prompt:

```
$ python
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> digits = datasets.load_digits()
```

A dataset is a dictionary-like object that holds all the data and some metadata about the data. This data is stored in the `.data` member, which is a `n_samples, n_features` array. In the case of supervised problem, one or more response variables are stored in the `.target` member. More details on the different datasets can be found in the *dedicated section*.

For instance, in the case of the digits dataset, `digits.data` gives access to the features that can be used to classify the digits samples:

```
>>> print(digits.data)
[[ 0.   0.   5. ...   0.   0.   0.]
 [ 0.   0.   0. ...  10.   0.   0.]
 [ 0.   0.   0. ...  16.   9.   0.]
 ...
 [ 0.   0.   1. ...   6.   0.   0.]
 [ 0.   0.   2. ...  12.   0.   0.]
 [ 0.   0.  10. ...  12.   1.   0.]]
```

and `digits.target` gives the ground truth for the digit dataset, that is the number corresponding to each digit image that we are trying to learn:

```
>>> digits.target
array([0, 1, 2, ..., 8, 9, 8])
```

Shape of the data arrays

The data is always a 2D array, shape `(n_samples, n_features)`, although the original data may have had a different shape. In the case of the digits, each original sample is an image of shape `(8, 8)` and can be accessed using:

```
>>> digits.images[0]
array([[  0.,   0.,   5.,  13.,   9.,   1.,   0.,   0.],
       [  0.,   0.,  13.,  15.,  10.,  15.,   5.,   0.],
       [  0.,   3.,  15.,   2.,   0.,  11.,   8.,   0.],
       [  0.,   4.,  12.,   0.,   0.,   8.,   8.,   0.],
       [  0.,   5.,   8.,   0.,   0.,   9.,   8.,   0.],
       [  0.,   4.,  11.,   0.,   1.,  12.,   7.,   0.],
       [  0.,   2.,  14.,   5.,  10.,  12.,   0.,   0.],
       [  0.,   0.,   6.,  13.,  10.,   0.,   0.,   0.]])
```

The *simple example on this dataset* illustrates how starting from the original problem one can shape the data for consumption in scikit-learn.

Loading from external datasets

To load from an external dataset, please refer to *loading external datasets*.

2.1.3 Learning and predicting

In the case of the digits dataset, the task is to predict, given an image, which digit it represents. We are given samples of each of the 10 possible classes (the digits zero through nine) on which we *fit* an estimator to be able to *predict* the classes to which unseen samples belong.

In scikit-learn, an estimator for classification is a Python object that implements the methods `fit(X, y)` and `predict(T)`.

An example of an estimator is the class `sklearn.svm.SVC`, which implements support vector classification. The estimator's constructor takes as arguments the model's parameters.

For now, we will consider the estimator as a black box:

```
>>> from sklearn import svm
>>> clf = svm.SVC(gamma=0.001, C=100.)
```

Choosing the parameters of the model

In this example, we set the value of `gamma` manually. To find good values for these parameters, we can use tools such as *grid search* and *cross validation*.

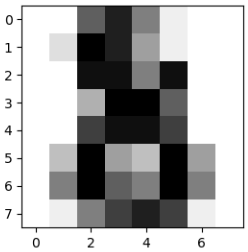
The `clf` (for classifier) estimator instance is first fitted to the model; that is, it must *learn* from the model. This is done by passing our training set to the `fit` method. For the training set, we'll use all the images from our dataset, except for the last image, which we'll reserve for our predicting. We select the training set with the `[:-1]` Python syntax, which produces a new array that contains all but the last item from `digits.data`:

```
>>> clf.fit(digits.data[:-1], digits.target[:-1])
SVC(C=100.0, gamma=0.001)
```

Now you can *predict* new values. In this case, you'll predict using the last image from `digits.data`. By predicting, you'll determine the image from the training set that best matches the last image.

```
>>> clf.predict(digits.data[-1:])
array([8])
```

The corresponding image is:



As you can see, it is a challenging task: after all, the images are of poor resolution. Do you agree with the classifier?

A complete example of this classification problem is available as an example that you can run and study: *Recognizing hand-written digits*.

2.1.4 Model persistence

It is possible to save a model in scikit-learn by using Python's built-in persistence model, pickle:

```
>>> from sklearn import svm
>>> from sklearn import datasets
>>> clf = svm.SVC()
>>> X, y = datasets.load_iris(return_X_y=True)
>>> clf.fit(X, y)
SVC()

>>> import pickle
>>> s = pickle.dumps(clf)
>>> clf2 = pickle.loads(s)
>>> clf2.predict(X[0:1])
array([0])
>>> y[0]
0
```

In the specific case of scikit-learn, it may be more interesting to use joblib's replacement for pickle (`joblib.dump` & `joblib.load`), which is more efficient on big data but it can only pickle to the disk and not to a string:

```
>>> from joblib import dump, load
>>> dump(clf, 'filename.joblib')
```

Later, you can reload the pickled model (possibly in another Python process) with:

```
>>> clf = load('filename.joblib')
```

Note: `joblib.dump` and `joblib.load` functions also accept file-like object instead of filenames. More information on data persistence with Joblib is available here.

Note that pickle has some security and maintainability issues. Please refer to section *Model persistence* for more detailed information about model persistence with scikit-learn.

2.1.5 Conventions

scikit-learn estimators follow certain rules to make their behavior more predictive. These are described in more detail in the *Glossary of Common Terms and API Elements*.

Type casting

Unless otherwise specified, input will be cast to `float64`:

```
>>> import numpy as np
>>> from sklearn import random_projection

>>> rng = np.random.RandomState(0)
>>> X = rng.rand(10, 2000)
>>> X = np.array(X, dtype='float32')
>>> X.dtype
dtype('float32')

>>> transformer = random_projection.GaussianRandomProjection()
>>> X_new = transformer.fit_transform(X)
>>> X_new.dtype
dtype('float64')
```

In this example, `X` is `float32`, which is cast to `float64` by `fit_transform(X)`.

Regression targets are cast to `float64` and classification targets are maintained:

```
>>> from sklearn import datasets
>>> from sklearn.svm import SVC
>>> iris = datasets.load_iris()
>>> clf = SVC()
>>> clf.fit(iris.data, iris.target)
SVC()

>>> list(clf.predict(iris.data[:3]))
[0, 0, 0]

>>> clf.fit(iris.data, iris.target_names[iris.target])
SVC()

>>> list(clf.predict(iris.data[:3]))
['setosa', 'setosa', 'setosa']
```

Here, the first `predict()` returns an integer array, since `iris.target` (an integer array) was used in `fit`. The second `predict()` returns a string array, since `iris.target_names` was for fitting.

Refitting and updating parameters

Hyper-parameters of an estimator can be updated after it has been constructed via the *set_params()* method. Calling `fit()` more than once will overwrite what was learned by any previous `fit()`:

```
>>> import numpy as np
>>> from sklearn.datasets import load_iris
>>> from sklearn.svm import SVC
>>> X, y = load_iris(return_X_y=True)

>>> clf = SVC()
>>> clf.set_params(kernel='linear').fit(X, y)
SVC(kernel='linear')
>>> clf.predict(X[:5])
array([0, 0, 0, 0, 0])
```

(continues on next page)

(continued from previous page)

```
>>> clf.set_params(kernel='rbf').fit(X, y)
SVC()
>>> clf.predict(X[:5])
array([0, 0, 0, 0, 0])
```

Here, the default kernel `rbf` is first changed to `linear` via *SVC.set_params()* after the estimator has been constructed, and changed back to `rbf` to refit the estimator and to make a second prediction.

Multiclass vs. multilabel fitting

When using *multiclass classifiers*, the learning and prediction task that is performed is dependent on the format of the target data fit upon:

```
>>> from sklearn.svm import SVC
>>> from sklearn.multiclass import OneVsRestClassifier
>>> from sklearn.preprocessing import LabelBinarizer

>>> X = [[1, 2], [2, 4], [4, 5], [3, 2], [3, 1]]
>>> y = [0, 0, 1, 1, 2]

>>> classif = OneVsRestClassifier(estimator=SVC(random_state=0))
>>> classif.fit(X, y).predict(X)
array([0, 0, 1, 1, 2])
```

In the above case, the classifier is fit on a 1d array of multiclass labels and the `predict()` method therefore provides corresponding multiclass predictions. It is also possible to fit upon a 2d array of binary label indicators:

```
>>> y = LabelBinarizer().fit_transform(y)
>>> classif.fit(X, y).predict(X)
array([[1, 0, 0],
       [1, 0, 0],
       [0, 1, 0],
       [0, 0, 0],
       [0, 0, 0]])
```

Here, the classifier is `fit()` on a 2d binary label representation of `y`, using the *LabelBinarizer*. In this case `predict()` returns a 2d array representing the corresponding multilabel predictions.

Note that the fourth and fifth instances returned all zeroes, indicating that they matched none of the three labels `fit` upon. With multilabel outputs, it is similarly possible for an instance to be assigned multiple labels:

```
>>> from sklearn.preprocessing import MultiLabelBinarizer
>>> y = [[0, 1], [0, 2], [1, 3], [0, 2, 3], [2, 4]]
>>> y = MultiLabelBinarizer().fit_transform(y)
>>> classif.fit(X, y).predict(X)
array([[1, 1, 0, 0, 0],
       [1, 0, 1, 0, 0],
       [0, 1, 0, 1, 0],
       [1, 0, 1, 0, 0],
       [1, 0, 1, 0, 0]])
```

In this case, the classifier is fit upon instances each assigned multiple labels. The *MultiLabelBinarizer* is used to binarize the 2d array of multilabels to `fit` upon. As a result, `predict()` returns a 2d array with multiple predicted labels for each instance.

2.2 A tutorial on statistical-learning for scientific data processing

Statistical learning

Machine learning is a technique with a growing importance, as the size of the datasets experimental sciences are facing is rapidly growing. Problems it tackles range from building a prediction function linking different observations, to classifying observations, or learning the structure in an unlabeled dataset.

This tutorial will explore *statistical learning*, the use of machine learning techniques with the goal of statistical inference: drawing conclusions on the data at hand.

Scikit-learn is a Python module integrating classic machine learning algorithms in the tightly-knit world of scientific Python packages (NumPy, SciPy, matplotlib).

2.2.1 Statistical learning: the setting and the estimator object in scikit-learn

Datasets

Scikit-learn deals with learning information from one or more datasets that are represented as 2D arrays. They can be understood as a list of multi-dimensional observations. We say that the first axis of these arrays is the **samples** axis, while the second is the **features** axis.

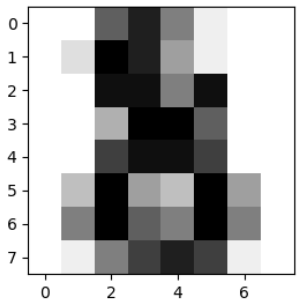
A simple example shipped with scikit-learn: iris dataset

```
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> data = iris.data
>>> data.shape
(150, 4)
```

It is made of 150 observations of irises, each described by 4 features: their sepal and petal length and width, as detailed in `iris.DESCR`.

When the data is not initially in the `(n_samples, n_features)` shape, it needs to be preprocessed in order to be used by scikit-learn.

An example of reshaping data would be the digits dataset



The digits dataset is made of 1797 8x8 images of hand-written digits

```
>>> digits = datasets.load_digits()
>>> digits.images.shape
(1797, 8, 8)
>>> import matplotlib.pyplot as plt
>>> plt.imshow(digits.images[-1], cmap=plt.cm.gray_r)
<matplotlib.image.AxesImage object at ...>
```

To use this dataset with scikit-learn, we transform each 8x8 image into a feature vector of length 64

```
>>> data = digits.images.reshape((digits.images.shape[0], -1))
```

Estimators objects

Fitting data: the main API implemented by scikit-learn is that of the `estimator`. An estimator is any object that learns from data; it may be a classification, regression or clustering algorithm or a *transformer* that extracts/filters useful features from raw data.

All estimator objects expose a `fit` method that takes a dataset (usually a 2-d array):

```
>>> estimator.fit(data)
```

Estimator parameters: All the parameters of an estimator can be set when it is instantiated or by modifying the corresponding attribute:

```
>>> estimator = Estimator(param1=1, param2=2)
>>> estimator.param1
1
```

Estimated parameters: When data is fitted with an estimator, parameters are estimated from the data at hand. All the estimated parameters are attributes of the estimator object ending by an underscore:

```
>>> estimator.estimated_param_
```

2.2.2 Supervised learning: predicting an output variable from high-dimensional observations

The problem solved in supervised learning

Supervised learning consists in learning the link between two datasets: the observed data `X` and an external variable `y` that we are trying to predict, usually called "target" or "labels". Most often, `y` is a 1D array of length `n_samples`.

All supervised estimators in scikit-learn implement a `fit(X, y)` method to fit the model and a `predict(X)` method that, given unlabeled observations `X`, returns the predicted labels `y`.

Vocabulary: classification and regression

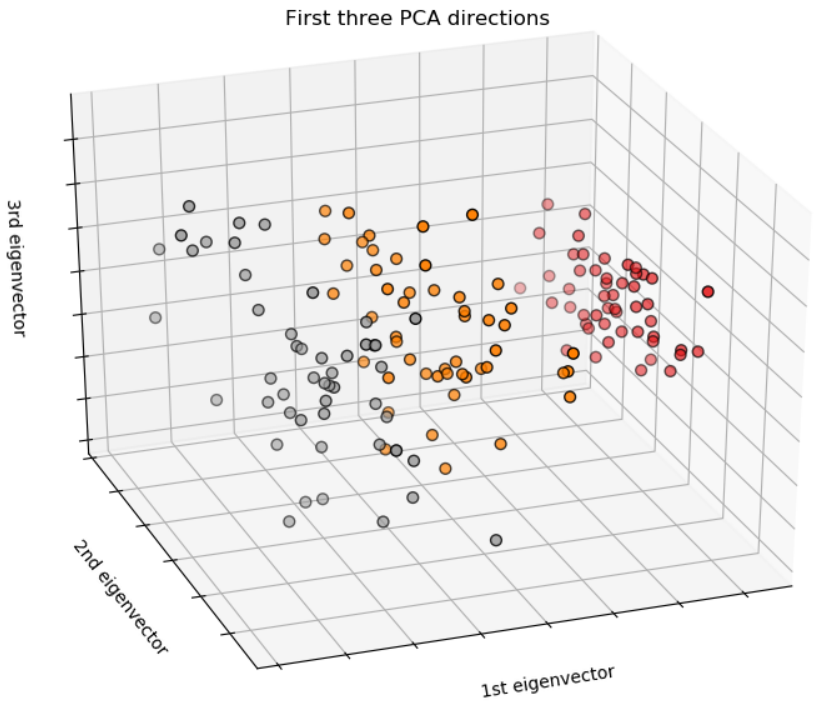
If the prediction task is to classify the observations in a set of finite labels, in other words to "name" the objects observed, the task is said to be a **classification** task. On the other hand, if the goal is to predict a continuous target variable, it is said to be a **regression** task.

When doing classification in scikit-learn, `y` is a vector of integers or strings.

Note: See the *Introduction to machine learning with scikit-learn Tutorial* for a quick run-through on the basic machine learning vocabulary used within scikit-learn.

Nearest neighbor and the curse of dimensionality

Classifying irises:



The iris dataset is a classification task consisting in identifying 3 different types of irises (Setosa, Versicolour, and Virginica) from their petal and sepal length and width:

```
>>> import numpy as np
>>> from sklearn import datasets
>>> iris_X, iris_y = datasets.load_iris(return_X_y=True)
>>> np.unique(iris_y)
array([0, 1, 2])
```

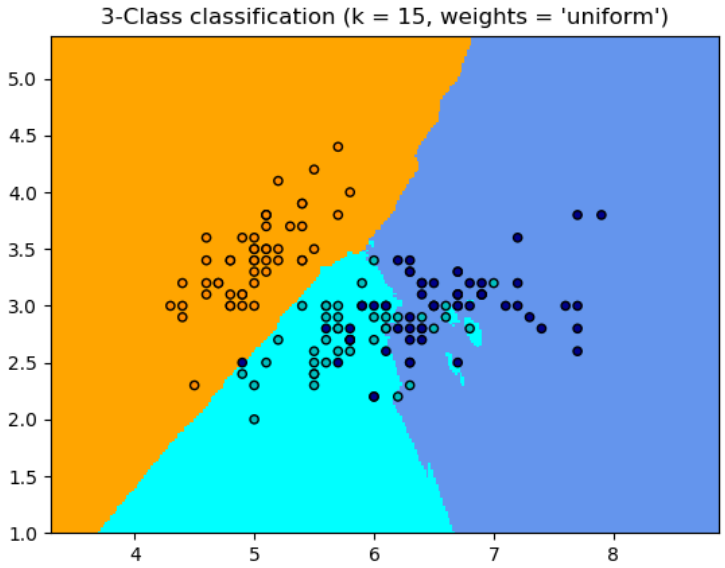
k-Nearest neighbors classifier

The simplest possible classifier is the nearest neighbor: given a new observation `X_test`, find in the training set (i.e. the data used to train the estimator) the observation with the closest feature vector. (Please see the *Nearest Neighbors section* of the online Scikit-learn documentation for more information about this type of classifier.)

Training set and testing set

While experimenting with any learning algorithm, it is important not to test the prediction of an estimator on the data used to fit the estimator as this would not be evaluating the performance of the estimator on **new data**. This is why datasets are often split into *train* and *test* data.

KNN (k nearest neighbors) classification example:



```
>>> # Split iris data in train and test data
>>> # A random permutation, to split the data randomly
>>> np.random.seed(0)
>>> indices = np.random.permutation(len(iris_X))
>>> iris_X_train = iris_X[indices[:-10]]
>>> iris_y_train = iris_y[indices[:-10]]
>>> iris_X_test = iris_X[indices[-10:]]
>>> iris_y_test = iris_y[indices[-10:]]
>>> # Create and fit a nearest-neighbor classifier
>>> from sklearn.neighbors import KNeighborsClassifier
>>> knn = KNeighborsClassifier()
>>> knn.fit(iris_X_train, iris_y_train)
KNeighborsClassifier()
>>> knn.predict(iris_X_test)
array([1, 2, 1, 0, 0, 0, 2, 1, 2, 0])
>>> iris_y_test
array([1, 1, 1, 0, 0, 0, 2, 1, 2, 0])
```

The curse of dimensionality

For an estimator to be effective, you need the distance between neighboring points to be less than some value d, which depends on the problem. In one dimension, this requires on average $n \sim 1/d$ points. In the context of the above k-NN example, if the data is described by just one feature with values ranging from 0 to 1 and with n training observations, then new data will be no further away than $1/n$. Therefore, the nearest neighbor decision rule will be efficient as soon

as $1/n$ is small compared to the scale of between-class feature variations.

If the number of features is p, you now require $n \sim 1/d^p$ points. Let's say that we require 10 points in one dimension: now 10^p points are required in p dimensions to pave the $[0, 1]$ space. As p becomes large, the number of training points required for a good estimator grows exponentially.

For example, if each point is just a single number (8 bytes), then an effective k-NN estimator in a paltry $p \sim 20$ dimensions would require more training data than the current estimated size of the entire internet ($\pm$1000 Exabytes or so).

This is called the curse of dimensionality and is a core problem that machine learning addresses.

Linear model: from regression to sparsity

Diabetes dataset

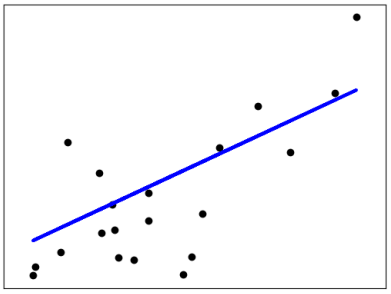
The diabetes dataset consists of 10 physiological variables (age, sex, weight, blood pressure) measure on 442 patients, and an indication of disease progression after one year:

```
>>> diabetes_X, diabetes_y = datasets.load_diabetes(return_X_y=True)
>>> diabetes_X_train = diabetes_X[:-20]
>>> diabetes_X_test  = diabetes_X[-20:]
>>> diabetes_y_train = diabetes_y[:-20]
>>> diabetes_y_test  = diabetes_y[-20:]
```

The task at hand is to predict disease progression from physiological variables.

Linear regression

`LinearRegression`, in its simplest form, fits a linear model to the data set by adjusting a set of parameters in order to make the sum of the squared residuals of the model as small as possible.



Linear models: $y = X\beta + \epsilon$

- X: data
- y: target variable
- β: Coefficients
- ϵ: Observation noise

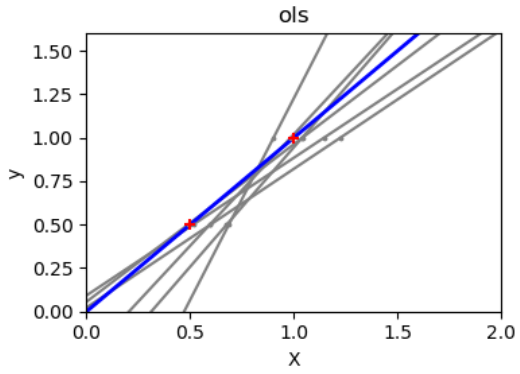
```
>>> from sklearn import linear_model
>>> regr = linear_model.LinearRegression()
>>> regr.fit(diabetes_X_train, diabetes_y_train)
LinearRegression()
>>> print(regr.coef_)
[   0.30349955 -237.63931533  510.53060544  327.73698041 -814.13170937
  492.81458798  102.84845219  184.60648906  743.51961675   76.09517222]

>>> # The mean square error
>>> np.mean((regr.predict(diabetes_X_test) - diabetes_y_test)**2)
2004.56760268...

>>> # Explained variance score: 1 is perfect prediction
>>> # and 0 means that there is no linear relationship
>>> # between X and y.
>>> regr.score(diabetes_X_test, diabetes_y_test)
0.5850753022690...
```

Shrinkage

If there are few data points per dimension, noise in the observations induces high variance:

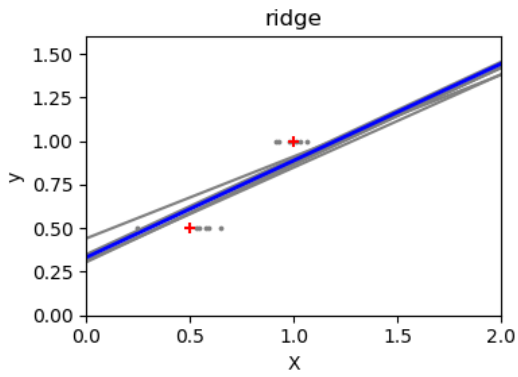


```
>>> X = np.c_[ .5, 1].T
>>> y = [.5, 1]
>>> test = np.c_[ 0, 2].T
>>> regr = linear_model.LinearRegression()

>>> import matplotlib.pyplot as plt
>>> plt.figure()

>>> np.random.seed(0)
>>> for _ in range(6):
...     this_X = .1 * np.random.normal(size=(2, 1)) + X
...     regr.fit(this_X, y)
...     plt.plot(test, regr.predict(test))
...     plt.scatter(this_X, y, s=3)
```

A solution in high-dimensional statistical learning is to *shrink* the regression coefficients to zero: any two randomly chosen set of observations are likely to be uncorrelated. This is called `Ridge` regression:



```
>>> regr = linear_model.Ridge(alpha=.1)

>>> plt.figure()

>>> np.random.seed(0)
>>> for _ in range(6):
...     this_X = .1 * np.random.normal(size=(2, 1)) + X
...     regr.fit(this_X, y)
...     plt.plot(test, regr.predict(test))
...     plt.scatter(this_X, y, s=3)
```

This is an example of **bias/variance tradeoff**: the larger the ridge `alpha` parameter, the higher the bias and the lower the variance.

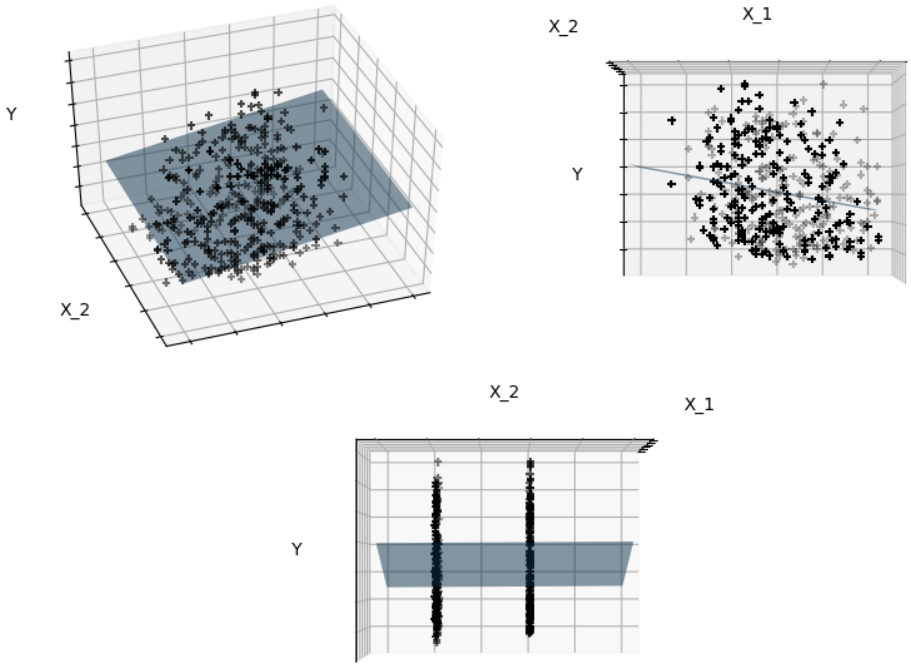
We can choose `alpha` to minimize left out error, this time using the diabetes dataset rather than our synthetic data:

```
>>> alphas = np.logspace(-4, -1, 6)
>>> print([regr.set_params(alpha=alpha)
...             .fit(diabetes_X_train, diabetes_y_train)
...             .score(diabetes_X_test, diabetes_y_test)
...         for alpha in alphas])
[0.5851110683883..., 0.5852073015444..., 0.5854677540698...,
 0.5855512036503..., 0.5830717085554..., 0.57058999437...]
```

Note: Capturing in the fitted parameters noise that prevents the model to generalize to new data is called overfitting. The bias introduced by the ridge regression is called a regularization.

Sparsity

Fitting only features 1 and 2



Note: A representation of the full diabetes dataset would involve 11 dimensions (10 feature dimensions and one of the target variable). It is hard to develop an intuition on such representation, but it may be useful to keep in mind that it would be a fairly *empty* space.

We can see that, although feature 2 has a strong coefficient on the full model, it conveys little information on `y` when considered with feature 1.

To improve the conditioning of the problem (i.e. mitigating the *The curse of dimensionality*), it would be interesting to select only the informative features and set non-informative ones, like feature 2 to 0. Ridge regression will decrease their contribution, but not set them to zero. Another penalization approach, called *Lasso* (least absolute shrinkage and selection operator), can set some coefficients to zero. Such methods are called **sparse method** and sparsity can be seen as an application of Occam's razor: *prefer simpler models*.

```
>>> regr = linear_model.Lasso()
>>> scores = [regr.set_params(alpha=alpha)
...               .fit(diabetes_X_train, diabetes_y_train)
...               .score(diabetes_X_test, diabetes_y_test)
...           for alpha in alphas]
>>> best_alpha = alphas[scores.index(max(scores))]
>>> regr.alpha = best_alpha
>>> regr.fit(diabetes_X_train, diabetes_y_train)
Lasso(alpha=0.025118864315095794)
>>> print(regr.coef_)
[   0.         -212.43764548  517.19478111  313.77959962 -160.8303982    -0.

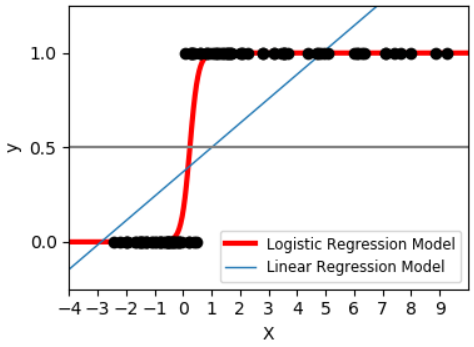
```

Different algorithms for the same problem

Different algorithms can be used to solve the same mathematical problem. For instance the `Lasso` object in scikit-learn solves the lasso regression problem using a coordinate descent method, that is efficient on large datasets. However, scikit-learn also provides the *LassoLars* object using the *LARS* algorithm, which is very efficient for problems in which the weight vector estimated is very sparse (i.e. problems with very few observations).

Classification

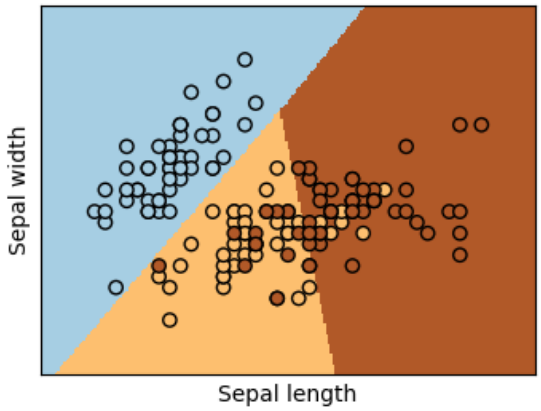


For classification, as in the labeling iris task, linear regression is not the right approach as it will give too much weight to data far from the decision frontier. A linear approach is to fit a sigmoid function or **logistic** function:

$$y = \text{sigmoid}(X\beta - \text{offset}) + \epsilon = \frac{1}{1 + \exp(-X\beta + \text{offset})} + \epsilon$$

```
>>> log = linear_model.LogisticRegression(C=1e5)
>>> log.fit(iris_X_train, iris_y_train)
LogisticRegression(C=100000.0)
```

This is known as *LogisticRegression*.



Multiclass classification

If you have several classes to predict, an option often used is to fit one-versus-all classifiers and then use a voting heuristic for the final decision.

Shrinkage and sparsity with logistic regression

The `C` parameter controls the amount of regularization in the *LogisticRegression* object: a large value for `C` results in less regularization. `penalty="l2"` gives *Shrinkage* (i.e. non-sparse coefficients), while `penalty="l1"` gives *Sparsity*.

Exercise

Try classifying the digits dataset with nearest neighbors and a linear model. Leave out the last 10% and test prediction performance on these observations.

```
from sklearn import datasets, neighbors, linear_model

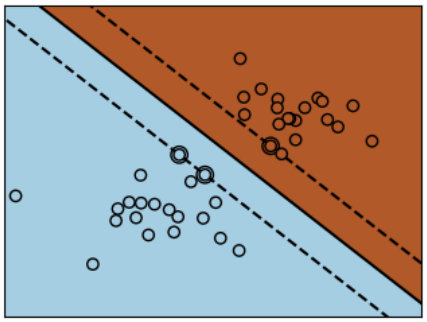
X_digits, y_digits = datasets.load_digits(return_X_y=True)
X_digits = X_digits / X_digits.max()
```

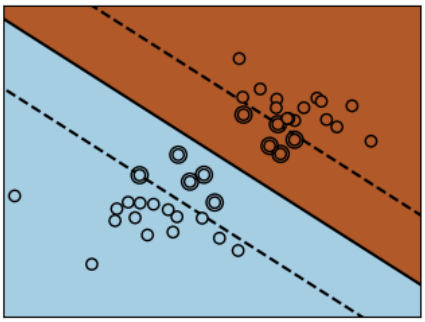
Solution: `../../auto_examples/exercises/plot_digits_classification_exercise.py`

Support vector machines (SVMs)

Linear SVMs

Support Vector Machines belong to the discriminant model family: they try to find a combination of samples to build a plane maximizing the margin between the two classes. Regularization is set by the `C` parameter: a small value for `C` means the margin is calculated using many or all of the observations around the separating line (more regularization); a large value for `C` means the margin is calculated on observations close to the separating line (less regularization).

Unregularized SVM	Regularized SVM (default)
	




Example:

- *Plot different SVM classifiers in the iris dataset*

SVMs can be used in regression –*SVR* (Support Vector Regression)–, or in classification –*SVC* (Support Vector Classification).

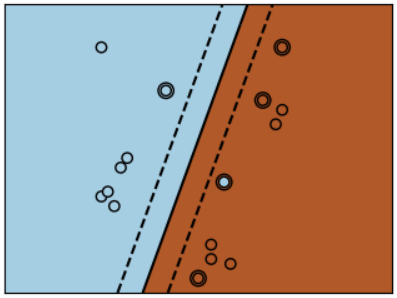
```
>>> from sklearn import svm
>>> svc = svm.SVC(kernel='linear')
>>> svc.fit(iris_X_train, iris_y_train)
SVC(kernel='linear')
```

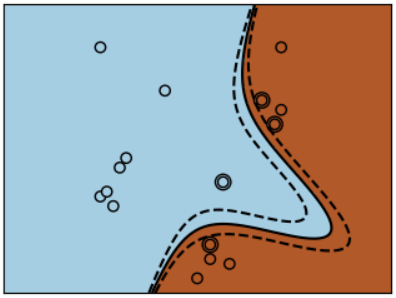
Warning: Normalizing data

For many estimators, including the SVMs, having datasets with unit standard deviation for each feature is important to get good prediction.

Using kernels

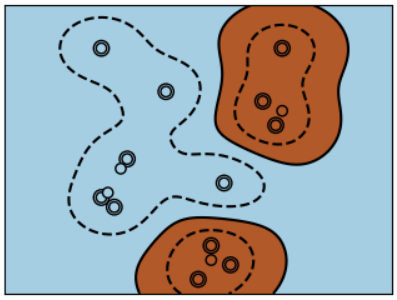
Classes are not always linearly separable in feature space. The solution is to build a decision function that is not linear but may be polynomial instead. This is done using the *kernel trick* that can be seen as creating a decision energy by positioning *kernels* on observations:

Linear kernel	Polynomial kernel
	




`>>> svc = svm.SVC(kernel='linear')`	`>>> svc = svm.SVC(kernel='poly',`
	`...  degree=3)`
	`>>> # degree: polynomial degree`

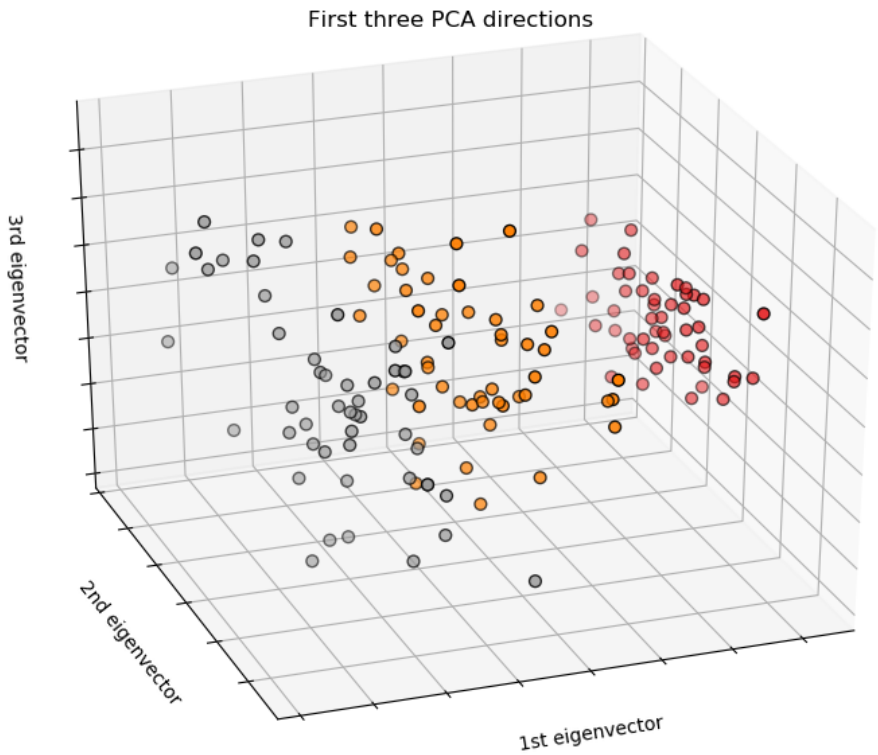
RBF kernel (Radial Basis Function)



```
>>> svc = svm.SVC(kernel='rbf')
>>> # gamma: inverse of size of
>>> # radial kernel
```

Interactive example

See the *SVM GUI* to download `svm_gui.py`; add data points of both classes with right and left button, fit the model and change parameters and data.



Exercise

Try classifying classes 1 and 2 from the iris dataset with SVMs, with the 2 first features. Leave out 10% of each class and test prediction performance on these observations.

Warning: the classes are ordered, do not leave out the last 10%, you would be testing on only one class.

Hint: You can use the `decision_function` method on a grid to get intuitions.

```
iris = datasets.load_iris()
X = iris.data
y = iris.target

X = X[y != 0, :2]
y = y[y != 0]
```

Solution: `../../auto_examples/exercises/plot_iris_exercise.py`

2.2.3 Model selection: choosing estimators and their parameters

Score, and cross-validated scores

As we have seen, every estimator exposes a `score` method that can judge the quality of the fit (or the prediction) on new data. **Bigger is better**.

```
>>> from sklearn import datasets, svm
>>> X_digits, y_digits = datasets.load_digits(return_X_y=True)
>>> svc = svm.SVC(C=1, kernel='linear')
>>> svc.fit(X_digits[:-100], y_digits[:-100]).score(X_digits[-100:], y_digits[-100:])
0.98
```

To get a better measure of prediction accuracy (which we can use as a proxy for goodness of fit of the model), we can successively split the data in *folds* that we use for training and testing:

```
>>> import numpy as np
>>> X_folds = np.array_split(X_digits, 3)
>>> y_folds = np.array_split(y_digits, 3)
>>> scores = list()
>>> for k in range(3):
...     # We use 'list' to copy, in order to 'pop' later on
...     X_train = list(X_folds)
...     X_test = X_train.pop(k)
...     X_train = np.concatenate(X_train)
...     y_train = list(y_folds)
...     y_test = y_train.pop(k)
...     y_train = np.concatenate(y_train)
...     scores.append(svc.fit(X_train, y_train).score(X_test, y_test))
>>> print(scores)
[0.934..., 0.956..., 0.939...]
```

This is called a *KFold* cross-validation.

Cross-validation generators

Scikit-learn has a collection of classes which can be used to generate lists of train/test indices for popular cross-validation strategies.

They expose a `split` method which accepts the input dataset to be split and yields the train/test set indices for each iteration of the chosen cross-validation strategy.

This example shows an example usage of the `split` method.

```
>>> from sklearn.model_selection import KFold, cross_val_score
>>> X = ["a", "a", "a", "b", "b", "c", "c", "c", "c", "c"]
>>> k_fold = KFold(n_splits=5)
>>> for train_indices, test_indices in k_fold.split(X):
...      print('Train: %s | test: %s' % (train_indices, test_indices))
Train: [2 3 4 5 6 7 8 9] | test: [0 1]
Train: [0 1 4 5 6 7 8 9] | test: [2 3]
Train: [0 1 2 3 6 7 8 9] | test: [4 5]
Train: [0 1 2 3 4 5 8 9] | test: [6 7]
Train: [0 1 2 3 4 5 6 7] | test: [8 9]
```

The cross-validation can then be performed easily:

```
>>> [svc.fit(X_digits[train], y_digits[train]).score(X_digits[test], y_digits[test])
...  for train, test in k_fold.split(X_digits)]
[0.963..., 0.922..., 0.963..., 0.963..., 0.930...]
```

The cross-validation score can be directly calculated using the *cross_val_score* helper. Given an estimator, the cross-validation object and the input dataset, the *cross_val_score* splits the data repeatedly into a training and a testing set, trains the estimator using the training set and computes the scores based on the testing set for each iteration of cross-validation.

By default the estimator's `score` method is used to compute the individual scores.

Refer the *metrics module* to learn more on the available scoring methods.

```
>>> cross_val_score(svc, X_digits, y_digits, cv=k_fold, n_jobs=-1)
array([0.96388889, 0.92222222, 0.9637883 , 0.9637883 , 0.93036212])
```

`n_jobs=-1` means that the computation will be dispatched on all the CPUs of the computer.

Alternatively, the `scoring` argument can be provided to specify an alternative scoring method.

```
>>> cross_val_score(svc, X_digits, y_digits, cv=k_fold,
...                 scoring='precision_macro')
array([0.96578289, 0.92708922, 0.96681476, 0.96362897, 0.93192644])
```

Cross-validation generators

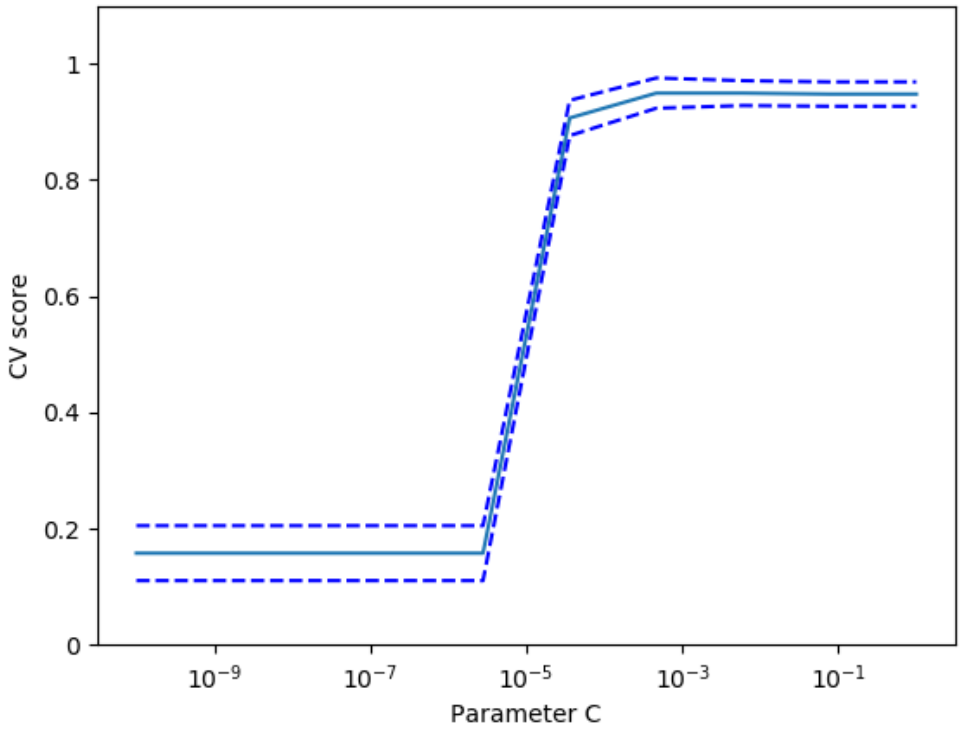
KFold **(n_splits, shuffle, random_state)**	*StratifiedKFold* **(n_splits, shuffle, random_state)**	*GroupKFold* **(n_splits)**
Splits it into K folds, trains on K-1 and then tests on the left-out.	Same as K-Fold but preserves the class distribution within each fold.	Ensures that the same group is not in both testing and training sets.

ShuffleSplit **(n_splits, test_size, train_size, random_state)**	*StratifiedShuffleSplit*	*GroupShuffleSplit*
Generates train/test indices based on random permutation.	Same as shuffle split but preserves the class distribution within each iteration.	Ensures that the same group is not in both testing and training sets.

LeaveOneGroupOut ()	*LeavePGroupsOut* (n_groups)	*LeaveOneOut* ()
Takes a group array to group observations.	Leave P groups out.	Leave one observation out.

LeavePOut (p)	*PredefinedSplit*
Leave P observations out.	Generates train/test indices based on predefined splits.

Exercise



On the digits dataset, plot the cross-validation score of a *SVC* estimator with an linear kernel as a function of parameter `C` (use a logarithmic grid of points, from 1 to 10).

```
import numpy as np
from sklearn.model_selection import cross_val_score
from sklearn import datasets, svm

X, y = datasets.load_digits(return_X_y=True)

svc = svm.SVC(kernel='linear')
C_s = np.logspace(-10, 0, 10)

scores = list()
```

Solution: *Cross-validation on Digits Dataset Exercise*

Grid-search and cross-validated estimators

Grid-search

scikit-learn provides an object that, given data, computes the score during the fit of an estimator on a parameter grid and chooses the parameters to maximize the cross-validation score. This object takes an estimator during the construction and exposes an estimator API:

```
>>> from sklearn.model_selection import GridSearchCV, cross_val_score
>>> Cs = np.logspace(-6, -1, 10)
>>> clf = GridSearchCV(estimator=svc, param_grid=dict(C=Cs),
...                    n_jobs=-1)
>>> clf.fit(X_digits[:1000], y_digits[:1000])
GridSearchCV(cv=None,...
>>> clf.best_score_
0.925...
>>> clf.best_estimator_.C
0.0077...

>>> # Prediction performance on test set is not as good as on train set
>>> clf.score(X_digits[1000:], y_digits[1000:])
0.943...
```

By default, the *GridSearchCV* uses a 3-fold cross-validation. However, if it detects that a classifier is passed, rather than a regressor, it uses a stratified 3-fold. The default will change to a 5-fold cross-validation in version 0.22.

Nested cross-validation

```
>>> cross_val_score(clf, X_digits, y_digits)
array([0.938..., 0.963..., 0.944...])
```

Two cross-validation loops are performed in parallel: one by the *GridSearchCV* estimator to set `gamma` and the other one by `cross_val_score` to measure the prediction performance of the estimator. The resulting scores are unbiased estimates of the prediction score on new data.

Warning: You cannot nest objects with parallel computing (`n_jobs` different than 1).

Cross-validated estimators

Cross-validation to set a parameter can be done more efficiently on an algorithm-by-algorithm basis. This is why, for certain estimators, scikit-learn exposes *Cross-validation: evaluating estimator performance* estimators that set their parameter automatically by cross-validation:

```
>>> from sklearn import linear_model, datasets
>>> lasso = linear_model.LassoCV()
>>> X_diabetes, y_diabetes = datasets.load_diabetes(return_X_y=True)
>>> lasso.fit(X_diabetes, y_diabetes)
LassoCV()
>>> # The estimator chose automatically its lambda:
>>> lasso.alpha_
0.00375...
```

These estimators are called similarly to their counterparts, with 'CV' appended to their name.

Exercise

On the diabetes dataset, find the optimal regularization parameter alpha.

Bonus: How much can you trust the selection of alpha?

```
from sklearn import datasets
from sklearn.linear_model import LassoCV
from sklearn.linear_model import Lasso
from sklearn.model_selection import KFold
from sklearn.model_selection import GridSearchCV

X, y = datasets.load_diabetes(return_X_y=True)
X = X[:150]
```

Solution: *Cross-validation on diabetes Dataset Exercise*

2.2.4 Unsupervised learning: seeking representations of the data

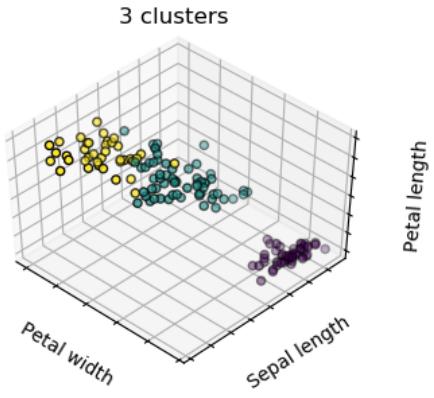
Clustering: grouping observations together

The problem solved in clustering

Given the iris dataset, if we knew that there were 3 types of iris, but did not have access to a taxonomist to label them: we could try a **clustering task**: split the observations into well-separated group called *clusters*.

K-means clustering

Note that there exist a lot of different clustering criteria and associated algorithms. The simplest clustering algorithm is *K-means*.



```
>>> from sklearn import cluster, datasets
>>> X_iris, y_iris = datasets.load_iris(return_X_y=True)

>>> k_means = cluster.KMeans(n_clusters=3)
>>> k_means.fit(X_iris)
KMeans(n_clusters=3)
```

(continues on next page)

(continued from previous page)

```
>>> print(k_means.labels_[::10])
[1 1 1 1 1 0 0 0 0 0 2 2 2 2 2]
>>> print(y_iris[::10])
[0 0 0 0 0 1 1 1 1 1 2 2 2 2 2]
```

Warning: There is absolutely no guarantee of recovering a ground truth. First, choosing the right number of clusters is hard. Second, the algorithm is sensitive to initialization, and can fall into local minima, although scikit-learn employs several tricks to mitigate this issue.

		Bad initialization	**8 clusters**	**Ground truth**

Don't over-interpret clustering results

Application example: vector quantization

Clustering in general and KMeans, in particular, can be seen as a way of choosing a small number of exemplars to compress the information. The problem is sometimes known as vector quantization. For instance, this can be used to posterize an image:

```
>>> import scipy as sp
>>> try:
...     face = sp.face(gray=True)
... except AttributeError:
...     from scipy import misc
...     face = misc.face(gray=True)
>>> X = face.reshape((-1, 1)) # We need an (n_sample, n_feature) array
>>> k_means = cluster.KMeans(n_clusters=5, n_init=1)
>>> k_means.fit(X)
KMeans(n_clusters=5, n_init=1)
>>> values = k_means.cluster_centers_.squeeze()
>>> labels = k_means.labels_
>>> face_compressed = np.choose(labels, values)
>>> face_compressed.shape = face.shape
```

			Raw image	K-means quantization	Equal bins	Image histogram

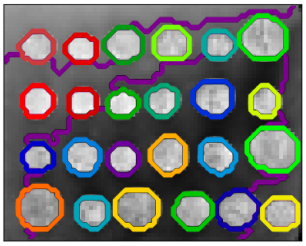
Hierarchical agglomerative clustering: Ward

A *Hierarchical clustering* method is a type of cluster analysis that aims to build a hierarchy of clusters. In general, the various approaches of this technique are either:

- **Agglomerative** - bottom-up approaches: each observation starts in its own cluster, and clusters are iteratively merged in such a way to minimize a *linkage* criterion. This approach is particularly interesting when the clusters of interest are made of only a few observations. When the number of clusters is large, it is much more computationally efficient than k-means.
- **Divisive** - top-down approaches: all observations start in one cluster, which is iteratively split as one moves down the hierarchy. For estimating large numbers of clusters, this approach is both slow (due to all observations starting as one cluster, which it splits recursively) and statistically ill-posed.

Connectivity-constrained clustering

With agglomerative clustering, it is possible to specify which samples can be clustered together by giving a connectivity graph. Graphs in scikit-learn are represented by their adjacency matrix. Often, a sparse matrix is used. This can be useful, for instance, to retrieve connected regions (sometimes also referred to as connected components) when clustering an image:



```
from scipy.ndimage.filters import gaussian_filter

import matplotlib.pyplot as plt

import skimage
from skimage.data import coins
from skimage.transform import rescale

from sklearn.feature_extraction.image import grid_to_graph
from sklearn.cluster import AgglomerativeClustering

# these were introduced in skimage-0.14
if LooseVersion(skimage.__version__) >= '0.14':
    rescale_params = {'anti_aliasing': False, 'multichannel': False}
else:
    rescale_params = {}

# ###############################################################################
# Generate data
orig_coins = coins()
```

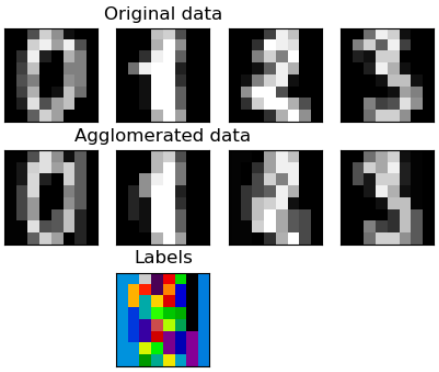
(continues on next page)

(continued from previous page)

```
# Resize it to 20% of the original size to speed up the processing
# Applying a Gaussian filter for smoothing prior to down-scaling
# reduces aliasing artifacts.
smoothened_coins = gaussian_filter(orig_coins, sigma=2)
```

Feature agglomeration

We have seen that sparsity could be used to mitigate the curse of dimensionality, *i.e* an insufficient amount of observations compared to the number of features. Another approach is to merge together similar features: **feature agglomeration**. This approach can be implemented by clustering in the feature direction, in other words clustering the transposed data.



```
>>> digits = datasets.load_digits()
>>> images = digits.images
>>> X = np.reshape(images, (len(images), -1))
>>> connectivity = grid_to_graph(*images[0].shape)

>>> agglo = cluster.FeatureAgglomeration(connectivity=connectivity,
...                                      n_clusters=32)
>>> agglo.fit(X)
FeatureAgglomeration(connectivity=..., n_clusters=32)
>>> X_reduced = agglo.transform(X)

>>> X_approx = agglo.inverse_transform(X_reduced)
>>> images_approx = np.reshape(X_approx, images.shape)
```

`transform` and `inverse_transform` methods

Some estimators expose a `transform` method, for instance to reduce the dimensionality of the dataset.

Decompositions: from a signal to components and loadings

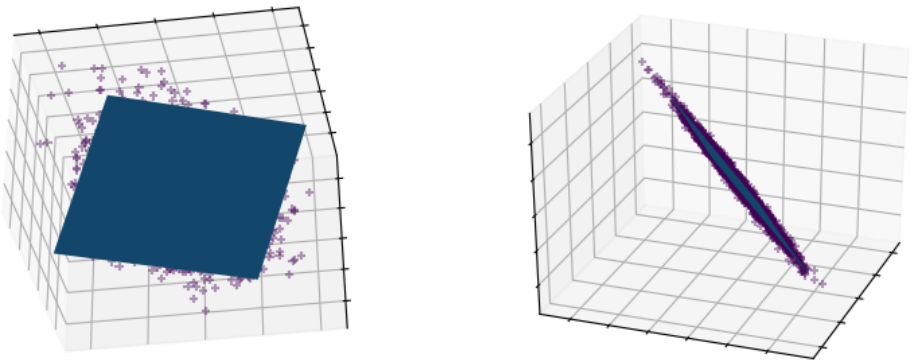
Components and loadings

If X is our multivariate data, then the problem that we are trying to solve is to rewrite it on a different observational basis: we want to learn loadings L and a set of components C such that $X = L\ C$. Different criteria exist to choose

the components

Principal component analysis: PCA

Principal component analysis (PCA) selects the successive components that explain the maximum variance in the signal.



The point cloud spanned by the observations above is very flat in one direction: one of the three univariate features can almost be exactly computed using the other two. PCA finds the directions in which the data is not *flat*

When used to *transform* data, PCA can reduce the dimensionality of the data by projecting on a principal subspace.

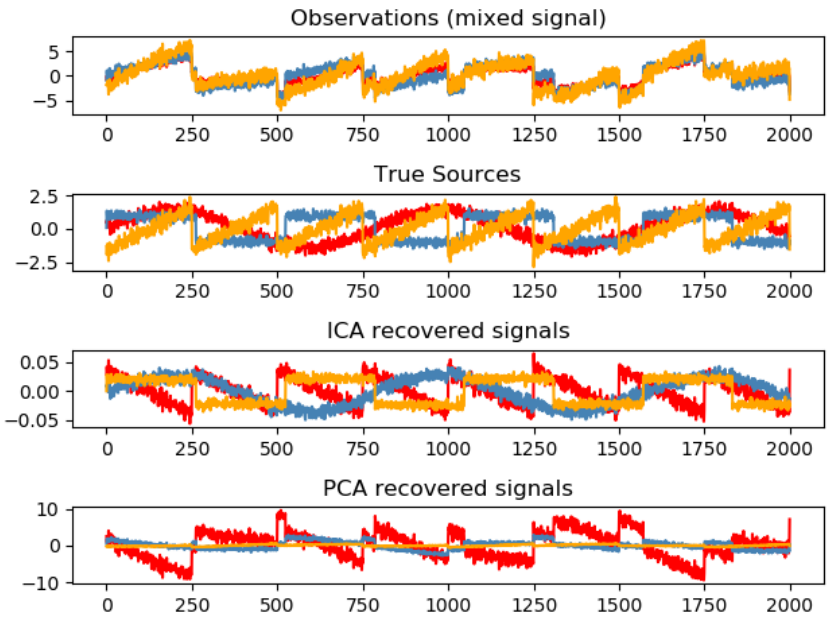
```
>>> # Create a signal with only 2 useful dimensions
>>> x1 = np.random.normal(size=100)
>>> x2 = np.random.normal(size=100)
>>> x3 = x1 + x2
>>> X = np.c_[x1, x2, x3]

>>> from sklearn import decomposition
>>> pca = decomposition.PCA()
>>> pca.fit(X)
PCA()
>>> print(pca.explained_variance_)
[  2.18565811e+00   1.19346747e+00   8.43026679e-32]

>>> # As we can see, only the 2 first components are useful
>>> pca.n_components = 2
>>> X_reduced = pca.fit_transform(X)
>>> X_reduced.shape
(100, 2)
```

Independent Component Analysis: ICA

Independent component analysis (ICA) selects components so that the distribution of their loadings carries a maximum amount of independent information. It is able to recover **non-Gaussian** independent signals:



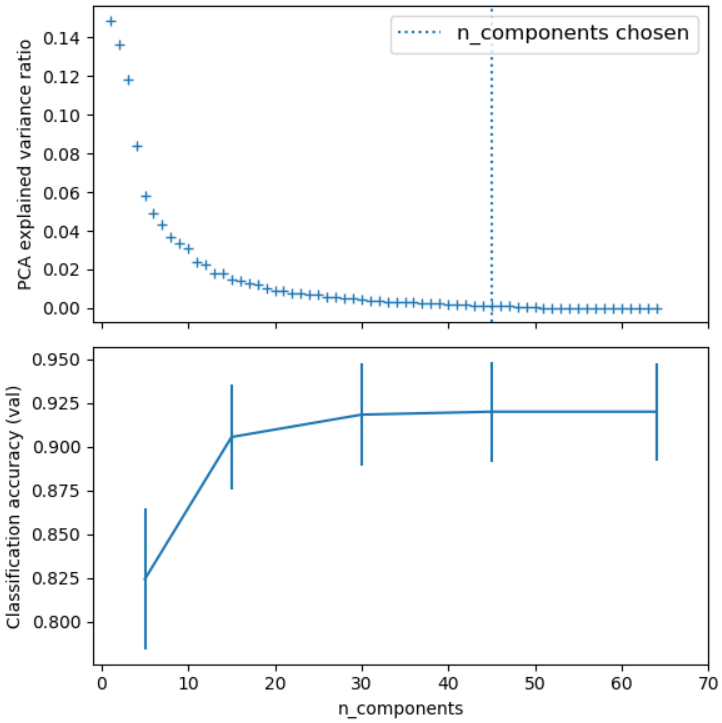
```
>>> # Generate sample data
>>> import numpy as np
>>> from scipy import signal
>>> time = np.linspace(0, 10, 2000)
>>> s1 = np.sin(2 * time)  # Signal 1 : sinusoidal signal
>>> s2 = np.sign(np.sin(3 * time))  # Signal 2 : square signal
>>> s3 = signal.sawtooth(2 * np.pi * time)  # Signal 3: saw tooth signal
>>> S = np.c_[s1, s2, s3]
>>> S += 0.2 * np.random.normal(size=S.shape)  # Add noise
>>> S /= S.std(axis=0)  # Standardize data
>>> # Mix data
>>> A = np.array([[1, 1, 1], [0.5, 2, 1], [1.5, 1, 2]])  # Mixing matrix
>>> X = np.dot(S, A.T)  # Generate observations

>>> # Compute ICA
>>> ica = decomposition.FastICA()
>>> S_ = ica.fit_transform(X)  # Get the estimated sources
>>> A_ = ica.mixing_.T
>>> np.allclose(X,  np.dot(S_, A_) + ica.mean_)
True
```

2.2.5 Putting it all together

Pipelining

We have seen that some estimators can transform data and that some estimators can predict variables. We can also create combined estimators:



```
import numpy as np
import matplotlib.pyplot as plt
import pandas as pd

from sklearn import datasets
from sklearn.decomposition import PCA
from sklearn.linear_model import LogisticRegression
from sklearn.pipeline import Pipeline
from sklearn.model_selection import GridSearchCV

# Define a pipeline to search for the best combination of PCA truncation
# and classifier regularization.
pca = PCA()
# set the tolerance to a large value to make the example faster
logistic = LogisticRegression(max_iter=10000, tol=0.1)
pipe = Pipeline(steps=[('pca', pca), ('logistic', logistic)])

X_digits, y_digits = datasets.load_digits(return_X_y=True)

# Parameters of pipelines can be set using '__' separated parameter names:
param_grid = {
    'pca__n_components': [5, 15, 30, 45, 64],
    'logistic__C': np.logspace(-4, 4, 4),
}
search = GridSearchCV(pipe, param_grid, n_jobs=-1)
search.fit(X_digits, y_digits)
print("Best parameter (CV score=%0.3f):" % search.best_score_)
print(search.best_params_)

# Plot the PCA spectrum
```

(continues on next page)

(continued from previous page)

```
pca.fit(X_digits)

fig, (ax0, ax1) = plt.subplots(nrows=2, sharex=True, figsize=(6, 6))
ax0.plot(np.arange(1, pca.n_components_ + 1),
         pca.explained_variance_ratio_, '+', linewidth=2)
ax0.set_ylabel('PCA explained variance ratio')

ax0.axvline(search.best_estimator_.named_steps['pca'].n_components,
            linestyle=':', label='n_components chosen')
ax0.legend(prop=dict(size=12))
```

Face recognition with eigenfaces

The dataset used in this example is a preprocessed excerpt of the "Labeled Faces in the Wild", also known as LFW:

http://vis-www.cs.umass.edu/lfw/lfw-funneled.tgz (233MB)

```

– _'Another excellent free online course that takes a more general approach to Artificial Intelligence': https://www.udacity.com/course/intro-to-artificial-intelligence–cs271

2.3 Working With Text Data

The goal of this guide is to explore some of the main `scikit-learn` tools on a single practical task: analyzing a collection of text documents (newsgroups posts) on twenty different topics.

In this section we will see how to:

- load the file contents and the categories
- extract feature vectors suitable for machine learning
- train a linear model to perform categorization
- use a grid search strategy to find a good configuration of both the feature extraction components and the classifier

2.3.1 Tutorial setup

To get started with this tutorial, you must first install *scikit-learn* and all of its required dependencies.

Please refer to the *installation instructions* page for more information and for system-specific instructions.

The source of this tutorial can be found within your scikit-learn folder:

```
scikit-learn/doc/tutorial/text_analytics/
```

The source can also be found on Github.

The tutorial folder should contain the following sub-folders:

- `*.rst files` - the source of the tutorial document written with sphinx
- `data` - folder to put the datasets used during the tutorial
- `skeletons` - sample incomplete scripts for the exercises
- `solutions` - solutions of the exercises

You can already copy the skeletons into a new folder somewhere on your hard-drive named `sklearn_tut_workspace` where you will edit your own files for the exercises while keeping the original skeletons intact:

```
% cp -r skeletons work_directory/sklearn_tut_workspace
```

Machine learning algorithms need data. Go to each `$TUTORIAL_HOME/data` sub-folder and run the `fetch_data.py` script from there (after having read them first).

For instance:

```
% cd $TUTORIAL_HOME/data/languages
% less fetch_data.py
% python fetch_data.py
```

2.3.2 Loading the 20 newsgroups dataset

The dataset is called "Twenty Newsgroups". Here is the official description, quoted from the website:

> The 20 Newsgroups data set is a collection of approximately 20,000 newsgroup documents, partitioned (nearly) evenly across 20 different newsgroups. To the best of our knowledge, it was originally collected by Ken Lang, probably for his paper "Newsweeder: Learning to filter netnews," though he does not explicitly mention this collection. The 20 newsgroups collection has become a popular data set for experiments in text applications of machine learning techniques, such as text classification and text clustering.

In the following we will use the built-in dataset loader for 20 newsgroups from scikit-learn. Alternatively, it is possible to download the dataset manually from the website and use the *`sklearn.datasets.load_files`* function by pointing it to the `20news-bydate-train` sub-folder of the uncompressed archive folder.

In order to get faster execution times for this first example we will work on a partial dataset with only 4 categories out of the 20 available in the dataset:

```
>>> categories = ['alt.atheism', 'soc.religion.christian',
...               'comp.graphics', 'sci.med']
```

We can now load the list of files matching those categories as follows:

```
>>> from sklearn.datasets import fetch_20newsgroups
>>> twenty_train = fetch_20newsgroups(subset='train',
...     categories=categories, shuffle=True, random_state=42)
```

The returned dataset is a `scikit-learn` "bunch": a simple holder object with fields that can be both accessed as python `dict` keys or `object` attributes for convenience, for instance the `target_names` holds the list of the requested category names:

```
>>> twenty_train.target_names
['alt.atheism', 'comp.graphics', 'sci.med', 'soc.religion.christian']
```

The files themselves are loaded in memory in the `data` attribute. For reference the filenames are also available:

```
>>> len(twenty_train.data)
2257
>>> len(twenty_train.filenames)
2257
```

Let's print the first lines of the first loaded file:

```
>>> print("\n".join(twenty_train.data[0].split("\n")[:3]))
From: sd345@city.ac.uk (Michael Collier)
Subject: Converting images to HP LaserJet III?
```

(continues on next page)

(continued from previous page)

```
Nntp-Posting-Host: hampton

>>> print(twenty_train.target_names[twenty_train.target[0]])
comp.graphics
```

Supervised learning algorithms will require a category label for each document in the training set. In this case the category is the name of the newsgroup which also happens to be the name of the folder holding the individual documents.

For speed and space efficiency reasons `scikit-learn` loads the target attribute as an array of integers that corresponds to the index of the category name in the `target_names` list. The category integer id of each sample is stored in the `target` attribute:

```
>>> twenty_train.target[:10]
array([1, 1, 3, 3, 3, 3, 3, 2, 2, 2])
```

It is possible to get back the category names as follows:

```
>>> for t in twenty_train.target[:10]:
...     print(twenty_train.target_names[t])
...
comp.graphics
comp.graphics
soc.religion.christian
soc.religion.christian
soc.religion.christian
soc.religion.christian
soc.religion.christian
sci.med
sci.med
sci.med
```

You might have noticed that the samples were shuffled randomly when we called `fetch_20newsgroups(..., shuffle=True, random_state=42)`: this is useful if you wish to select only a subset of samples to quickly train a model and get a first idea of the results before re-training on the complete dataset later.

2.3.3 Extracting features from text files

In order to perform machine learning on text documents, we first need to turn the text content into numerical feature vectors.

Bags of words

The most intuitive way to do so is to use a bags of words representation:

1. Assign a fixed integer id to each word occurring in any document of the training set (for instance by building a dictionary from words to integer indices).
2. For each document `#i`, count the number of occurrences of each word `w` and store it in `X[i, j]` as the value of feature `#j` where `j` is the index of word `w` in the dictionary.

The bags of words representation implies that `n_features` is the number of distinct words in the corpus: this number is typically larger than 100,000.

If `n_samples == 10000`, storing `X` as a NumPy array of type float32 would require 10000 x 100000 x 4 bytes = **4GB in RAM** which is barely manageable on today's computers.

Fortunately, **most values in X will be zeros** since for a given document less than a few thousand distinct words will be used. For this reason we say that bags of words are typically **high-dimensional sparse datasets**. We can save a lot of memory by only storing the non-zero parts of the feature vectors in memory.

`scipy.sparse` matrices are data structures that do exactly this, and `scikit-learn` has built-in support for these structures.

Tokenizing text with `scikit-learn`

Text preprocessing, tokenizing and filtering of stopwords are all included in *`CountVectorizer`*, which builds a dictionary of features and transforms documents to feature vectors:

```
>>> from sklearn.feature_extraction.text import CountVectorizer
>>> count_vect = CountVectorizer()
>>> X_train_counts = count_vect.fit_transform(twenty_train.data)
>>> X_train_counts.shape
(2257, 35788)
```

`CountVectorizer` supports counts of N-grams of words or consecutive characters. Once fitted, the vectorizer has built a dictionary of feature indices:

```
>>> count_vect.vocabulary_.get(u'algorithm')
4690
```

The index value of a word in the vocabulary is linked to its frequency in the whole training corpus.

From occurrences to frequencies

Occurrence count is a good start but there is an issue: longer documents will have higher average count values than shorter documents, even though they might talk about the same topics.

To avoid these potential discrepancies it suffices to divide the number of occurrences of each word in a document by the total number of words in the document: these new features are called `tf` for Term Frequencies.

Another refinement on top of tf is to downscale weights for words that occur in many documents in the corpus and are therefore less informative than those that occur only in a smaller portion of the corpus.

This downscaling is called tf–idf for "Term Frequency times Inverse Document Frequency".

Both **tf** and **tf–idf** can be computed as follows using *`TfidfTransformer`*:

```
>>> from sklearn.feature_extraction.text import TfidfTransformer
>>> tf_transformer = TfidfTransformer(use_idf=False).fit(X_train_counts)
>>> X_train_tf = tf_transformer.transform(X_train_counts)
>>> X_train_tf.shape
(2257, 35788)
```

In the above example-code, we firstly use the `fit(..)` method to fit our estimator to the data and secondly the `transform(..)` method to transform our count-matrix to a tf-idf representation. These two steps can be combined to achieve the same end result faster by skipping redundant processing. This is done through using the `fit_transform(..)` method as shown below, and as mentioned in the note in the previous section:

```
>>> tfidf_transformer = TfidfTransformer()
>>> X_train_tfidf = tfidf_transformer.fit_transform(X_train_counts)
>>> X_train_tfidf.shape
(2257, 35788)
```

2.3.4 Training a classifier

Now that we have our features, we can train a classifier to try to predict the category of a post. Let's start with a *naïve Bayes* classifier, which provides a nice baseline for this task. `scikit-learn` includes several variants of this classifier; the one most suitable for word counts is the multinomial variant:

```
>>> from sklearn.naive_bayes import MultinomialNB
>>> clf = MultinomialNB().fit(X_train_tfidf, twenty_train.target)
```

To try to predict the outcome on a new document we need to extract the features using almost the same feature extracting chain as before. The difference is that we call `transform` instead of `fit_transform` on the transformers, since they have already been fit to the training set:

```
>>> docs_new = ['God is love', 'OpenGL on the GPU is fast']
>>> X_new_counts = count_vect.transform(docs_new)
>>> X_new_tfidf = tfidf_transformer.transform(X_new_counts)

>>> predicted = clf.predict(X_new_tfidf)

>>> for doc, category in zip(docs_new, predicted):
...     print('%r => %s' % (doc, twenty_train.target_names[category]))
...
'God is love' => soc.religion.christian
'OpenGL on the GPU is fast' => comp.graphics
```

2.3.5 Building a pipeline

In order to make the vectorizer => transformer => classifier easier to work with, `scikit-learn` provides a *`Pipeline`* class that behaves like a compound classifier:

```
>>> from sklearn.pipeline import Pipeline
>>> text_clf = Pipeline([
...     ('vect', CountVectorizer()),
...     ('tfidf', TfidfTransformer()),
...     ('clf', MultinomialNB()),
... ])
```

The names `vect`, `tfidf` and `clf` (classifier) are arbitrary. We will use them to perform grid search for suitable hyperparameters below. We can now train the model with a single command:

```
>>> text_clf.fit(twenty_train.data, twenty_train.target)
Pipeline(...)
```

2.3.6 Evaluation of the performance on the test set

Evaluating the predictive accuracy of the model is equally easy:

```
>>> import numpy as np
>>> twenty_test = fetch_20newsgroups(subset='test',
...     categories=categories, shuffle=True, random_state=42)
>>> docs_test = twenty_test.data
>>> predicted = text_clf.predict(docs_test)
>>> np.mean(predicted == twenty_test.target)
0.8348...
```

We achieved 83.5% accuracy. Let's see if we can do better with a linear *support vector machine (SVM)*, which is widely regarded as one of the best text classification algorithms (although it's also a bit slower than naïve Bayes). We can change the learner by simply plugging a different classifier object into our pipeline:

```
>>> from sklearn.linear_model import SGDClassifier
>>> text_clf = Pipeline([
...     ('vect', CountVectorizer()),
...     ('tfidf', TfidfTransformer()),
...     ('clf', SGDClassifier(loss='hinge', penalty='l2',
...                           alpha=1e-3, random_state=42,
...                           max_iter=5, tol=None)),
... ])

>>> text_clf.fit(twenty_train.data, twenty_train.target)
Pipeline(...)
>>> predicted = text_clf.predict(docs_test)
>>> np.mean(predicted == twenty_test.target)
0.9101...
```

We achieved 91.3% accuracy using the SVM. `scikit-learn` provides further utilities for more detailed performance analysis of the results:

```
>>> from sklearn import metrics
>>> print(metrics.classification_report(twenty_test.target, predicted,
...     target_names=twenty_test.target_names))
                        precision    recall  f1-score   support

           alt.atheism       0.95      0.80      0.87       319
         comp.graphics       0.87      0.98      0.92       389
               sci.med       0.94      0.89      0.91       396
soc.religion.christian       0.90      0.95      0.93       398

              accuracy                           0.91      1502
             macro avg       0.91      0.91      0.91      1502
          weighted avg       0.91      0.91      0.91      1502

>>> metrics.confusion_matrix(twenty_test.target, predicted)
array([[256,  11,  16,  36],
       [  4, 380,   3,   2],
       [  5,  35, 353,   3],
       [  5,  11,   4, 378]])
```

As expected the confusion matrix shows that posts from the newsgroups on atheism and Christianity are more often confused for one another than with computer graphics.

2.3.7 Parameter tuning using grid search

We've already encountered some parameters such as `use_idf` in the `TfidfTransformer`. Classifiers tend to have many parameters as well; e.g., `MultinomialNB` includes a smoothing parameter `alpha` and `SGDClassifier` has a penalty parameter `alpha` and configurable loss and penalty terms in the objective function (see the module documentation, or use the Python `help` function to get a description of these).

Instead of tweaking the parameters of the various components of the chain, it is possible to run an exhaustive search of the best parameters on a grid of possible values. We try out all classifiers on either words or bigrams, with or without idf, and with a penalty parameter of either 0.01 or 0.001 for the linear SVM:

```
>>> from sklearn.model_selection import GridSearchCV
>>> parameters = {
...     'vect__ngram_range': [(1, 1), (1, 2)],
...     'tfidf__use_idf': (True, False),
...     'clf__alpha': (1e-2, 1e-3),
... }
```

Obviously, such an exhaustive search can be expensive. If we have multiple CPU cores at our disposal, we can tell the grid searcher to try these eight parameter combinations in parallel with the `n_jobs` parameter. If we give this parameter a value of `-1`, grid search will detect how many cores are installed and use them all:

```
>>> gs_clf = GridSearchCV(text_clf, parameters, cv=5, n_jobs=-1)
```

The grid search instance behaves like a normal `scikit-learn` model. Let's perform the search on a smaller subset of the training data to speed up the computation:

```
>>> gs_clf = gs_clf.fit(twenty_train.data[:400], twenty_train.target[:400])
```

The result of calling `fit` on a `GridSearchCV` object is a classifier that we can use to `predict`:

```
>>> twenty_train.target_names[gs_clf.predict(['God is love'])[0]]
'soc.religion.christian'
```

The object's `best_score_` and `best_params_` attributes store the best mean score and the parameters setting corresponding to that score:

```
>>> gs_clf.best_score_
0.9...
>>> for param_name in sorted(parameters.keys()):
...     print("%s: %r" % (param_name, gs_clf.best_params_[param_name]))
...
clf__alpha: 0.001
tfidf__use_idf: True
vect__ngram_range: (1, 1)
```

A more detailed summary of the search is available at `gs_clf.cv_results_`.

The `cv_results_` parameter can be easily imported into pandas as a `DataFrame` for further inspection.

Exercises

To do the exercises, copy the content of the 'skeletons' folder as a new folder named 'workspace':

```
% cp -r skeletons workspace
```

You can then edit the content of the workspace without fear of losing the original exercise instructions.

Then fire an ipython shell and run the work-in-progress script with:

```
[1] %run workspace/exercise_XX_script.py arg1 arg2 arg3
```

If an exception is triggered, use `%debug` to fire-up a post mortem ipdb session.

Refine the implementation and iterate until the exercise is solved.

For each exercise, the skeleton file provides all the necessary import statements, boilerplate code to load the data and sample code to evaluate the predictive accuracy of the model.

2.3.8 Exercise 1: Language identification

- Write a text classification pipeline using a custom preprocessor and `CharNGramAnalyzer` using data from Wikipedia articles as training set.
- Evaluate the performance on some held out test set.

ipython command line:

```
%run workspace/exercise_01_language_train_model.py data/languages/paragraphs/
```

2.3.9 Exercise 2: Sentiment Analysis on movie reviews

- Write a text classification pipeline to classify movie reviews as either positive or negative.
- Find a good set of parameters using grid search.
- Evaluate the performance on a held out test set.

ipython command line:

```
%run workspace/exercise_02_sentiment.py data/movie_reviews/txt_sentoken/
```

2.3.10 Exercise 3: CLI text classification utility

Using the results of the previous exercises and the `cPickle` module of the standard library, write a command line utility that detects the language of some text provided on `stdin` and estimate the polarity (positive or negative) if the text is written in English.

Bonus point if the utility is able to give a confidence level for its predictions.

2.3.11 Where to from here

Here are a few suggestions to help further your scikit-learn intuition upon the completion of this tutorial:

- Try playing around with the `analyzer` and `token normalisation` under *`CountVectorizer`*.
- If you don't have labels, try using *Clustering* on your problem.
- If you have multiple labels per document, e.g categories, have a look at the *Multiclass and multilabel section*.
- Try using *Truncated SVD* for latent semantic analysis.
- Have a look at using *Out-of-core Classification* to learn from data that would not fit into the computer main memory.
- Have a look at the *Hashing Vectorizer* as a memory efficient alternative to *`CountVectorizer`*.

2.4 Choosing the right estimator

Often the hardest part of solving a machine learning problem can be finding the right estimator for the job.

Different estimators are better suited for different types of data and different problems.

The flowchart below is designed to give users a bit of a rough guide on how to approach problems with regard to which estimators to try on your data.

Click on any estimator in the chart below to see its documentation.

2.5 External Resources, Videos and Talks

For written tutorials, see the *Tutorial section* of the documentation.

2.5.1 New to Scientific Python?

For those that are still new to the scientific Python ecosystem, we highly recommend the Python Scientific Lecture Notes. This will help you find your footing a bit and will definitely improve your scikit-learn experience. A basic understanding of NumPy arrays is recommended to make the most of scikit-learn.

2.5.2 External Tutorials

There are several online tutorials available which are geared toward specific subject areas:

- Machine Learning for NeuroImaging in Python
- Machine Learning for Astronomical Data Analysis

2.5.3 Videos

- An introduction to scikit-learn Part I and Part II at Scipy 2013 by Gael Varoquaux, Jake Vanderplas and Olivier Grisel. Notebooks on github.
- Introduction to scikit-learn by Gael Varoquaux at ICML 2010

  A three minute video from a very early stage of scikit-learn, explaining the basic idea and approach we are following.
- Introduction to statistical learning with scikit-learn by Gael Varoquaux at SciPy 2011

  An extensive tutorial, consisting of four sessions of one hour. The tutorial covers the basics of machine learning, many algorithms and how to apply them using scikit-learn. The material corresponding is now in the scikit-learn documentation section *A tutorial on statistical-learning for scientific data processing*.
- Statistical Learning for Text Classification with scikit-learn and NLTK (and slides) by Olivier Grisel at PyCon 2011

  Thirty minute introduction to text classification. Explains how to use NLTK and scikit-learn to solve real-world text classification tasks and compares against cloud-based solutions.
- Introduction to Interactive Predictive Analytics in Python with scikit-learn by Olivier Grisel at PyCon 2012

  3-hours long introduction to prediction tasks using scikit-learn.
- scikit-learn - Machine Learning in Python by Jake Vanderplas at the 2012 PyData workshop at Google

  Interactive demonstration of some scikit-learn features. 75 minutes.
- scikit-learn tutorial by Jake Vanderplas at PyData NYC 2012

  Presentation using the online tutorial, 45 minutes.

Note: Doctest Mode

The code-examples in the above tutorials are written in a *python-console* format. If you wish to easily execute these examples in **IPython**, use:

```
%doctest_mode
```

in the IPython-console. You can then simply copy and paste the examples directly into IPython without having to worry about removing the **>>>** manually.

CHAPTER

THREE

GETTING STARTED

The purpose of this guide is to illustrate some of the main features that `scikit-learn` provides. It assumes a very basic working knowledge of machine learning practices (model fitting, predicting, cross-validation, etc.). Please refer to our *installation instructions* for installing `scikit-learn`.

`Scikit-learn` is an open source machine learning library that supports supervised and unsupervised learning. It also provides various tools for model fitting, data preprocessing, model selection and evaluation, and many other utilities.

3.1 Fitting and predicting: estimator basics

`Scikit-learn` provides dozens of built-in machine learning algorithms and models, called *estimators*. Each estimator can be fitted to some data using its *fit* method.

Here is a simple example where we fit a *`RandomForestClassifier`* to some very basic data:

```
>>> from sklearn.ensemble import RandomForestClassifier
>>> clf = RandomForestClassifier(random_state=0)
>>> X = [[ 1,  2,  3],  # 2 samples, 3 features
...      [11, 12, 13]]
>>> y = [0, 1]  # classes of each sample
>>> clf.fit(X, y)
RandomForestClassifier(random_state=0)
```

The *fit* method generally accepts 2 inputs:

- The samples matrix (or design matrix) *X*. The size of `X` is typically `(n_samples, n_features)`, which means that samples are represented as rows and features are represented as columns.
- The target values *y* which are real numbers for regression tasks, or integers for classification (or any other discrete set of values). For unsupervized learning tasks, `y` does not need to be specified. `y` is usually 1d array where the `i` th entry corresponds to the target of the `i` th sample (row) of `X`.

Both `X` and `y` are usually expected to be numpy arrays or equivalent *array-like* data types, though some estimators work with other formats such as sparse matrices.

Once the estimator is fitted, it can be used for predicting target values of new data. You don't need to re-train the estimator:

```
>>> clf.predict(X)  # predict classes of the training data
array([0, 1])
>>> clf.predict([[4, 5, 6], [14, 15, 16]])  # predict classes of new data
array([0, 1])
```

3.2 Transformers and pre-processors

Machine learning workflows are often composed of different parts. A typical pipeline consists of a pre-processing step that transforms or imputes the data, and a final predictor that predicts target values.

In `scikit-learn`, pre-processors and transformers follow the same API as the estimator objects (they actually all inherit from the same `BaseEstimator` class). The transformer objects don't have a *predict* method but rather a *transform* method that outputs a newly transformed sample matrix `X`:

```
>>> from sklearn.preprocessing import StandardScaler
>>> X = [[0, 15],
...      [1, -10]]
>>> StandardScaler().fit(X).transform(X)
array([[-1.,  1.],
       [ 1., -1.]])
```

Sometimes, you want to apply different transformations to different features: the *ColumnTransformer* is designed for these use-cases.

3.3 Pipelines: chaining pre-processors and estimators

Transformers and estimators (predictors) can be combined together into a single unifying object: a `Pipeline`. The pipeline offers the same API as a regular estimator: it can be fitted and used for prediction with `fit` and `predict`. As we will see later, using a pipeline will also prevent you from data leakage, i.e. disclosing some testing data in your training data.

In the following example, we *load the Iris dataset*, split it into train and test sets, and compute the accuracy score of a pipeline on the test data:

```
>>> from sklearn.preprocessing import StandardScaler
>>> from sklearn.linear_model import LogisticRegression
>>> from sklearn.pipeline import make_pipeline
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.metrics import accuracy_score
...
>>> # create a pipeline object
>>> pipe = make_pipeline(
...     StandardScaler(),
...     LogisticRegression(random_state=0)
... )
...
>>> # load the iris dataset and split it into train and test sets
>>> X, y = load_iris(return_X_y=True)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
...
>>> # fit the whole pipeline
>>> pipe.fit(X_train, y_train)
Pipeline(steps=[('standardscaler', StandardScaler()),
                ('logisticregression', LogisticRegression(random_state=0))])
>>> # we can now use it like any other estimator
>>> accuracy_score(pipe.predict(X_test), y_test)
0.97...
```

3.4 Model evaluation

Fitting a model to some data does not entail that it will predict well on unseen data. This needs to be directly evaluated. We have just seen the *train_test_split* helper that splits a dataset into train and test sets, but scikit-learn provides many other tools for model evaluation, in particular for *cross-validation*.

We here briefly show how to perform a 5-fold cross-validation procedure, using the *cross_validate* helper. Note that it is also possible to manually iterate over the folds, use different data splitting strategies, and use custom scoring functions. Please refer to our *User Guide* for more details:

```
>>> from sklearn.datasets import make_regression
>>> from sklearn.linear_model import LinearRegression
>>> from sklearn.model_selection import cross_validate
...
>>> X, y = make_regression(n_samples=1000, random_state=0)
>>> lr = LinearRegression()
...
>>> result = cross_validate(lr, X, y)  # defaults to 5-fold CV
>>> result['test_score']  # r_squared score is high because dataset is easy
array([1., 1., 1., 1., 1.])
```

3.5 Automatic parameter searches

All estimators have parameters (often called hyper-parameters in the literature) that can be tuned. The generalization power of an estimator often critically depends on a few parameters. For example a *RandomForestRegressor* has a n_estimators parameter that determines the number of trees in the forest, and a max_depth parameter that determines the maximum depth of each tree. Quite often, it is not clear what the exact values of these parameters should be since they depend on the data at hand.

Scikit-learn provides tools to automatically find the best parameter combinations (via cross-validation). In the following example, we randomly search over the parameter space of a random forest with a *RandomizedSearchCV* object. When the search is over, the *RandomizedSearchCV* behaves as a *RandomForestRegressor* that has been fitted with the best set of parameters. Read more in the *User Guide*:

```
>>> from sklearn.datasets import fetch_california_housing
>>> from sklearn.ensemble import RandomForestRegressor
>>> from sklearn.model_selection import RandomizedSearchCV
>>> from sklearn.model_selection import train_test_split
>>> from scipy.stats import randint
...
>>> X, y = fetch_california_housing(return_X_y=True)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
...
>>> # define the parameter space that will be searched over
>>> param_distributions = {'n_estimators': randint(1, 5),
...                        'max_depth': randint(5, 10)}
...
>>> # now create a searchCV object and fit it to the data
>>> search = RandomizedSearchCV(estimator=RandomForestRegressor(random_state=0),
...                             n_iter=5,
...                             param_distributions=param_distributions,
...                             random_state=0)
>>> search.fit(X_train, y_train)
RandomizedSearchCV(estimator=RandomForestRegressor(random_state=0), n_iter=5,
```

(continues on next page)

(continued from previous page)

```
                    param_distributions={'max_depth': ...,
                                         'n_estimators': ...},
                    random_state=0)
>>> search.best_params_
{'max_depth': 9, 'n_estimators': 4}

>>> # the search object now acts like a normal random forest estimator
>>> # with max_depth=9 and n_estimators=4
>>> search.score(X_test, y_test)
0.73...
```

Note: In practice, you almost always want to *search over a pipeline*, instead of a single estimator. One of the main reasons is that if you apply a pre-processing step to the whole dataset without using a pipeline, and then perform any kind of cross-validation, you would be breaking the fundamental assumption of independence between training and testing data. Indeed, since you pre-processed the data using the whole dataset, some information about the test sets are available to the train sets. This will lead to over-estimating the generalization power of the estimator (you can read more in this kaggle post).

Using a pipeline for cross-validation and searching will largely keep you from this common pitfall.

3.6 Next steps

We have briefly covered estimator fitting and predicting, pre-processing steps, pipelines, cross-validation tools and automatic hyper-parameter searches. This guide should give you an overview of some of the main features of the library, but there is much more to `scikit-learn`!

Please refer to our *User Guide* for details on all the tools that we provide. You can also find an exhaustive list of the public API in the *API Reference*.

You can also look at our numerous *examples* that illustrate the use of `scikit-learn` in many different contexts.

The *tutorials* also contain additional learning resources.

CHAPTER

FOUR

USER GUIDE

4.1 Supervised learning

4.1.1 Linear Models

The following are a set of methods intended for regression in which the target value is expected to be a linear combination of the features. In mathematical notation, if $\hat{y}$ is the predicted value.

$$\hat{y}(w, x) = w_0 + w_1 x_1 + ... + w_p x_p$$

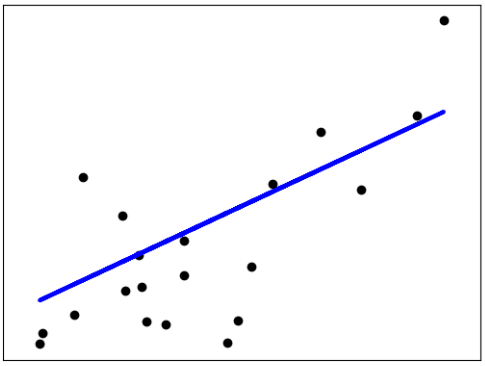
Across the module, we designate the vector $w = (w_1, ..., w_p)$ as `coef_` and w_0 as `intercept_`.

To perform classification with generalized linear models, see *Logistic regression*.

Ordinary Least Squares

`LinearRegression` fits a linear model with coefficients $w = (w_1, ..., w_p)$ to minimize the residual sum of squares between the observed targets in the dataset, and the targets predicted by the linear approximation. Mathematically it solves a problem of the form:

$$\min_w ||Xw - y||_2^2$$



`LinearRegression` will take in its `fit` method arrays X, y and will store the coefficients w of the linear model in its `coef_` member:

```
>>> from sklearn import linear_model
>>> reg = linear_model.LinearRegression()
>>> reg.fit([[0, 0], [1, 1], [2, 2]], [0, 1, 2])
LinearRegression()
>>> reg.coef_
array([0.5, 0.5])
```

The coefficient estimates for Ordinary Least Squares rely on the independence of the features. When features are correlated and the columns of the design matrix X have an approximate linear dependence, the design matrix becomes close to singular and as a result, the least-squares estimate becomes highly sensitive to random errors in the observed target, producing a large variance. This situation of *multicollinearity* can arise, for example, when data are collected without an experimental design.

Examples:

- *Linear Regression Example*

Ordinary Least Squares Complexity

The least squares solution is computed using the singular value decomposition of X. If X is a matrix of shape `(n_samples, n_features)` this method has a cost of $O(n_{\text{samples}} n_{\text{features}}^2)$, assuming that $n_{\text{samples}} \geq n_{\text{features}}$.

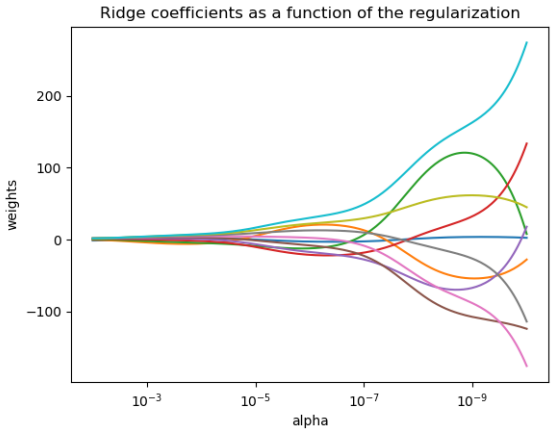
Ridge regression and classification

Regression

`Ridge` regression addresses some of the problems of *Ordinary Least Squares* by imposing a penalty on the size of the coefficients. The ridge coefficients minimize a penalized residual sum of squares:

$$\min_w ||Xw - y||_2^2 + \alpha ||w||_2^2$$

The complexity parameter $\alpha \geq 0$ controls the amount of shrinkage: the larger the value of α, the greater the amount of shrinkage and thus the coefficients become more robust to collinearity.



As with other linear models, `Ridge` will take in its `fit` method arrays X, y and will store the coefficients w of the linear model in its `coef_` member:

```
>>> from sklearn import linear_model
>>> reg = linear_model.Ridge(alpha=.5)
>>> reg.fit([[0, 0], [0, 0], [1, 1]], [0, .1, 1])
Ridge(alpha=0.5)
>>> reg.coef_
array([0.34545455, 0.34545455])
>>> reg.intercept_
0.13636...
```

Classification

The *Ridge* regressor has a classifier variant: *RidgeClassifier*. This classifier first converts binary targets to `{-1, 1}` and then treats the problem as a regression task, optimizing the same objective as above. The predicted class corresponds to the sign of the regressor's prediction. For multiclass classification, the problem is treated as multi-output regression, and the predicted class corresponds to the output with the highest value.

It might seem questionable to use a (penalized) Least Squares loss to fit a classification model instead of the more traditional logistic or hinge losses. However in practice all those models can lead to similar cross-validation scores in terms of accuracy or precision/recall, while the penalized least squares loss used by the *RidgeClassifier* allows for a very different choice of the numerical solvers with distinct computational performance profiles.

The *RidgeClassifier* can be significantly faster than e.g. *LogisticRegression* with a high number of classes, because it is able to compute the projection matrix $(X^T X)^{-1} X^T$ only once.

This classifier is sometimes referred to as a Least Squares Support Vector Machines with a linear kernel.

Examples:

- *Plot Ridge coefficients as a function of the regularization*
- *Classification of text documents using sparse features*

Ridge Complexity

This method has the same order of complexity as *Ordinary Least Squares*.

Setting the regularization parameter: generalized Cross-Validation

RidgeCV implements ridge regression with built-in cross-validation of the alpha parameter. The object works in the same way as GridSearchCV except that it defaults to Generalized Cross-Validation (GCV), an efficient form of leave-one-out cross-validation:

```
>>> import numpy as np
>>> from sklearn import linear_model
>>> reg = linear_model.RidgeCV(alphas=np.logspace(-6, 6, 13))
>>> reg.fit([[0, 0], [0, 0], [1, 1]], [0, .1, 1])
RidgeCV(alphas=array([1.e-06, 1.e-05, 1.e-04, 1.e-03, 1.e-02, 1.e-01, 1.e+00, 1.e+01,
      1.e+02, 1.e+03, 1.e+04, 1.e+05, 1.e+06]))
>>> reg.alpha_
0.01
```

Specifying the value of the *cv* attribute will trigger the use of cross-validation with `GridSearchCV`, for example `cv=10` for 10-fold cross-validation, rather than Generalized Cross-Validation.

Lasso

The `Lasso` is a linear model that estimates sparse coefficients. It is useful in some contexts due to its tendency to prefer solutions with fewer non-zero coefficients, effectively reducing the number of features upon which the given solution is dependent. For this reason Lasso and its variants are fundamental to the field of compressed sensing. Under certain conditions, it can recover the exact set of non-zero coefficients (see *Compressive sensing: tomography reconstruction with L1 prior (Lasso)*).

Mathematically, it consists of a linear model with an added regularization term. The objective function to minimize is:

$$\min_w \frac{1}{2n_{\text{samples}}}||Xw - y||_2^2 + \alpha||w||_1$$

The lasso estimate thus solves the minimization of the least-squares penalty with $\alpha||w||_1$ added, where α is a constant and $||w||_1$ is the ℓ_1-norm of the coefficient vector.

The implementation in the class `Lasso` uses coordinate descent as the algorithm to fit the coefficients. See *Least Angle Regression* for another implementation:

```
>>> from sklearn import linear_model
>>> reg = linear_model.Lasso(alpha=0.1)
>>> reg.fit([[0, 0], [1, 1]], [0, 1])
Lasso(alpha=0.1)
>>> reg.predict([[1, 1]])
array([0.8])
```

The function `lasso_path` is useful for lower-level tasks, as it computes the coefficients along the full path of possible values.

Examples:

- *Lasso and Elastic Net for Sparse Signals*
- *Compressive sensing: tomography reconstruction with L1 prior (Lasso)*

Note: Feature selection with Lasso

As the Lasso regression yields sparse models, it can thus be used to perform feature selection, as detailed in *L1-based feature selection*.

The following two references explain the iterations used in the coordinate descent solver of scikit-learn, as well as the duality gap computation used for convergence control.

References

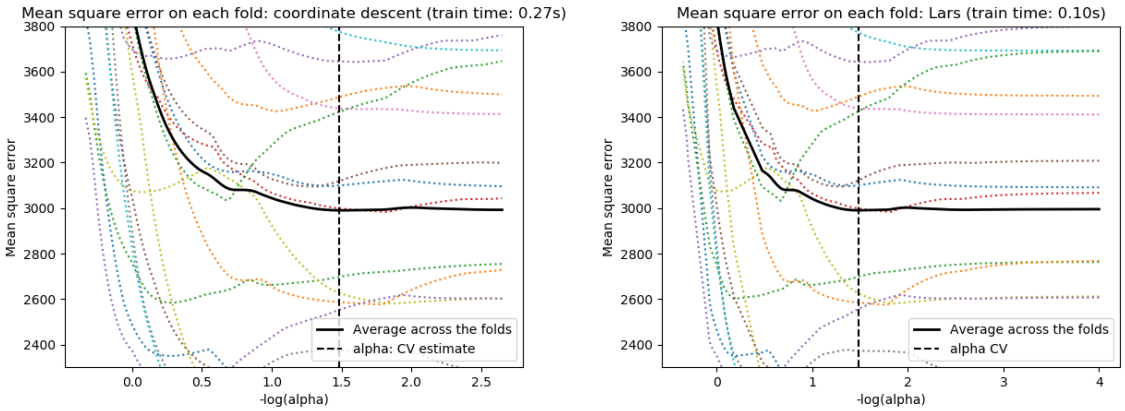
Setting regularization parameter

The `alpha` parameter controls the degree of sparsity of the estimated coefficients.

Using cross-validation

scikit-learn exposes objects that set the Lasso `alpha` parameter by cross-validation: `LassoCV` and `LassoLarsCV`. `LassoLarsCV` is based on the *Least Angle Regression* algorithm explained below.

For high-dimensional datasets with many collinear features, `LassoCV` is most often preferable. However, `LassoLarsCV` has the advantage of exploring more relevant values of `alpha` parameter, and if the number of samples is very small compared to the number of features, it is often faster than `LassoCV`.

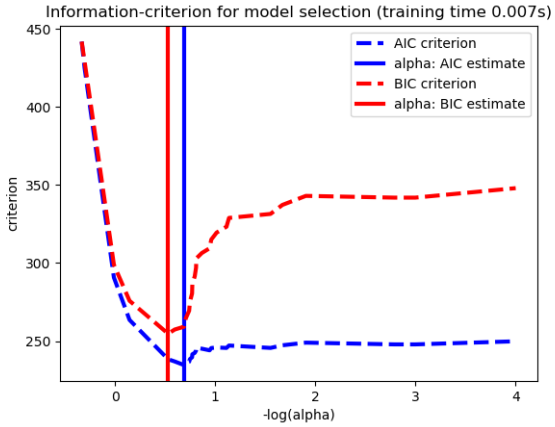


Information-criteria based model selection

Alternatively, the estimator `LassoLarsIC` proposes to use the Akaike information criterion (AIC) and the Bayes Information criterion (BIC). It is a computationally cheaper alternative to find the optimal value of alpha as the regularization path is computed only once instead of k+1 times when using k-fold cross-validation. However, such criteria needs a proper estimation of the degrees of freedom of the solution, are derived for large samples (asymptotic results) and assume the model is correct, i.e. that the data are actually generated by this model. They also tend to break when the problem is badly conditioned (more features than samples).

Examples:

- *Lasso model selection: Cross-Validation / AIC / BIC*



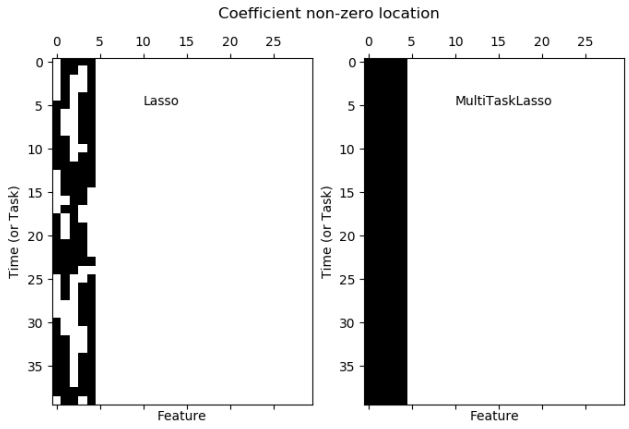
Comparison with the regularization parameter of SVM

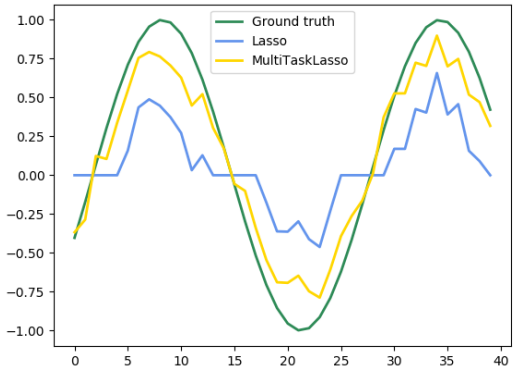
The equivalence between `alpha` and the regularization parameter of SVM, `C` is given by `alpha = 1 / C` or `alpha = 1 / (n_samples * C)`, depending on the estimator and the exact objective function optimized by the model.

Multi-task Lasso

The *`MultiTaskLasso`* is a linear model that estimates sparse coefficients for multiple regression problems jointly: `y` is a 2D array, of shape `(n_samples, n_tasks)`. The constraint is that the selected features are the same for all the regression problems, also called tasks.

The following figure compares the location of the non-zero entries in the coefficient matrix W obtained with a simple Lasso or a MultiTaskLasso. The Lasso estimates yield scattered non-zeros while the non-zeros of the MultiTaskLasso are full columns.





Fitting a time-series model, imposing that any active feature be active at all times.

Examples:

- *Joint feature selection with multi-task Lasso*

Mathematically, it consists of a linear model trained with a mixed ℓ_1 ℓ_2-norm for regularization. The objective function to minimize is:

$$\min_w \frac{1}{2n_{\text{samples}}}||XW - Y||^2_{\text{Fro}} + \alpha||W||_{21}$$

where Fro indicates the Frobenius norm

$$||A||_{\text{Fro}} = \sqrt{\sum_{ij} a_{ij}^2}$$

and ℓ_1 ℓ_2 reads

$$||A||_{21} = \sum_i \sqrt{\sum_j a_{ij}^2}.$$

The implementation in the class `MultiTaskLasso` uses coordinate descent as the algorithm to fit the coefficients.

Elastic-Net

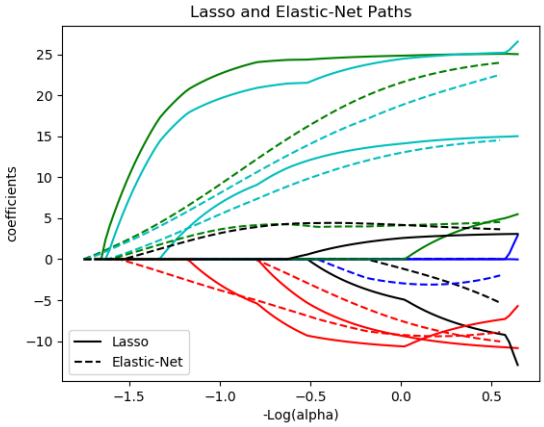
`ElasticNet` is a linear regression model trained with both ℓ_1 and ℓ_2-norm regularization of the coefficients. This combination allows for learning a sparse model where few of the weights are non-zero like `Lasso`, while still maintaining the regularization properties of `Ridge`. We control the convex combination of ℓ_1 and ℓ_2 using the `l1_ratio` parameter.

Elastic-net is useful when there are multiple features which are correlated with one another. Lasso is likely to pick one of these at random, while elastic-net is likely to pick both.

A practical advantage of trading-off between Lasso and Ridge is that it allows Elastic-Net to inherit some of Ridge's stability under rotation.

The objective function to minimize is in this case

$$\min_w \frac{1}{2n_{\text{samples}}}||Xw - y||_2^2 + \alpha\rho||w||_1 + \frac{\alpha(1-\rho)}{2}||w||_2^2$$



The class `ElasticNetCV` can be used to set the parameters `alpha` (α) and `l1_ratio` (ρ) by cross-validation.

Examples:

- *Lasso and Elastic Net for Sparse Signals*
- *Lasso and Elastic Net*

The following two references explain the iterations used in the coordinate descent solver of scikit-learn, as well as the duality gap computation used for convergence control.

References

- "Regularization Path For Generalized linear Models by Coordinate Descent", Friedman, Hastie & Tibshirani, J Stat Softw, 2010 (Paper).
- "An Interior-Point Method for Large-Scale L1-Regularized Least Squares," S. J. Kim, K. Koh, M. Lustig, S. Boyd and D. Gorinevsky, in IEEE Journal of Selected Topics in Signal Processing, 2007 (Paper)

Multi-task Elastic-Net

The `MultiTaskElasticNet` is an elastic-net model that estimates sparse coefficients for multiple regression problems jointly: `Y` is a 2D array of shape `(n_samples, n_tasks)`. The constraint is that the selected features are the same for all the regression problems, also called tasks.

Mathematically, it consists of a linear model trained with a mixed ℓ_1 ℓ_2-norm and ℓ_2-norm for regularization. The objective function to minimize is:

$$\min_W \frac{1}{2n_{\text{samples}}}||XW - Y||^2_{\text{Fro}} + \alpha\rho||W||_{21} + \frac{\alpha(1-\rho)}{2}||W||^2_{\text{Fro}}$$

The implementation in the class `MultiTaskElasticNet` uses coordinate descent as the algorithm to fit the coefficients.

The class `MultiTaskElasticNetCV` can be used to set the parameters `alpha` (α) and `l1_ratio` (ρ) by cross-validation.

Least Angle Regression

Least-angle regression (LARS) is a regression algorithm for high-dimensional data, developed by Bradley Efron, Trevor Hastie, Iain Johnstone and Robert Tibshirani. LARS is similar to forward stepwise regression. At each step, it finds the feature most correlated with the target. When there are multiple features having equal correlation, instead of continuing along the same feature, it proceeds in a direction equiangular between the features.

The advantages of LARS are:

- It is numerically efficient in contexts where the number of features is significantly greater than the number of samples.
- It is computationally just as fast as forward selection and has the same order of complexity as ordinary least squares.
- It produces a full piecewise linear solution path, which is useful in cross-validation or similar attempts to tune the model.
- If two features are almost equally correlated with the target, then their coefficients should increase at approximately the same rate. The algorithm thus behaves as intuition would expect, and also is more stable.
- It is easily modified to produce solutions for other estimators, like the Lasso.

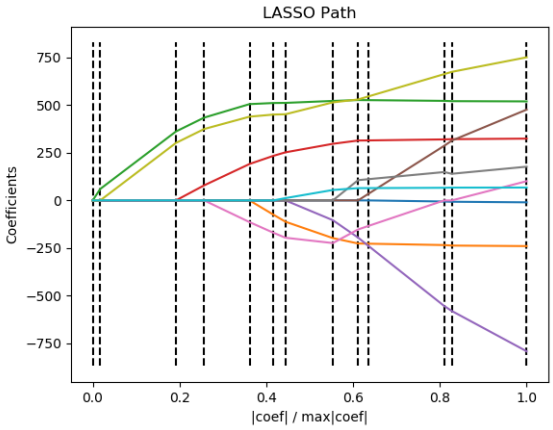
The disadvantages of the LARS method include:

- Because LARS is based upon an iterative refitting of the residuals, it would appear to be especially sensitive to the effects of noise. This problem is discussed in detail by Weisberg in the discussion section of the Efron et al. (2004) Annals of Statistics article.

The LARS model can be used using estimator *Lars*, or its low-level implementation *lars_path* or *lars_path_gram*.

LARS Lasso

LassoLars is a lasso model implemented using the LARS algorithm, and unlike the implementation based on coordinate descent, this yields the exact solution, which is piecewise linear as a function of the norm of its coefficients.



```
>>> from sklearn import linear_model
>>> reg = linear_model.LassoLars(alpha=.1)
>>> reg.fit([[0, 0], [1, 1]], [0, 1])
LassoLars(alpha=0.1)
```

(continues on next page)

(continued from previous page)

```
>>> reg.coef_
array([0.717157..., 0.        ])
```

Examples:

- *Lasso path using LARS*

The Lars algorithm provides the full path of the coefficients along the regularization parameter almost for free, thus a common operation is to retrieve the path with one of the functions `lars_path` or `lars_path_gram`.

Mathematical formulation

The algorithm is similar to forward stepwise regression, but instead of including features at each step, the estimated coefficients are increased in a direction equiangular to each one's correlations with the residual.

Instead of giving a vector result, the LARS solution consists of a curve denoting the solution for each value of the ℓ_1 norm of the parameter vector. The full coefficients path is stored in the array `coef_path_`, which has size (n_features, max_features+1). The first column is always zero.

References:

- Original Algorithm is detailed in the paper Least Angle Regression by Hastie et al.

Orthogonal Matching Pursuit (OMP)

`OrthogonalMatchingPursuit` and `orthogonal_mp` implements the OMP algorithm for approximating the fit of a linear model with constraints imposed on the number of non-zero coefficients (ie. the ℓ_0 pseudo-norm).

Being a forward feature selection method like *Least Angle Regression*, orthogonal matching pursuit can approximate the optimum solution vector with a fixed number of non-zero elements:

$$\arg\min_{\gamma} ||y - X\gamma||_2^2 \text{ subject to } ||\gamma||_0 \leq n_{\text{nonzero\_coefs}}$$

Alternatively, orthogonal matching pursuit can target a specific error instead of a specific number of non-zero coefficients. This can be expressed as:

$$\arg\min_{\gamma} ||\gamma||_0 \text{ subject to } ||y - X\gamma||_2^2 \leq \text{tol}$$

OMP is based on a greedy algorithm that includes at each step the atom most highly correlated with the current residual. It is similar to the simpler matching pursuit (MP) method, but better in that at each iteration, the residual is recomputed using an orthogonal projection on the space of the previously chosen dictionary elements.

Examples:

- *Orthogonal Matching Pursuit*

References:

- https://www.cs.technion.ac.il/~ronrubin/Publications/KSVD-OMP-v2.pdf

Bayesian Regression

Bayesian regression techniques can be used to include regularization parameters in the estimation procedure: the regularization parameter is not set in a hard sense but tuned to the data at hand.

This can be done by introducing uninformative priors over the hyper parameters of the model. The ℓ_2 regularization used in *Ridge regression and classification* is equivalent to finding a maximum a posteriori estimation under a Gaussian prior over the coefficients w with precision λ^{-1}. Instead of setting `lambda` manually, it is possible to treat it as a random variable to be estimated from the data.

To obtain a fully probabilistic model, the output y is assumed to be Gaussian distributed around Xw:

$$p(y|X, w, \alpha) = \mathcal{N}(y|Xw, \alpha)$$

where α is again treated as a random variable that is to be estimated from the data.

The advantages of Bayesian Regression are:

- It adapts to the data at hand.
- It can be used to include regularization parameters in the estimation procedure.

The disadvantages of Bayesian regression include:

- Inference of the model can be time consuming.

References

- A good introduction to Bayesian methods is given in C. Bishop: Pattern Recognition and Machine learning
- Original Algorithm is detailed in the book `Bayesian learning for neural networks` by Radford M. Neal

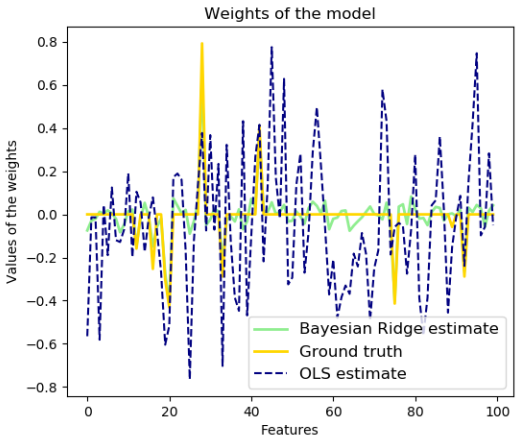
Bayesian Ridge Regression

`BayesianRidge` estimates a probabilistic model of the regression problem as described above. The prior for the coefficient w is given by a spherical Gaussian:

$$p(w|\lambda) = \mathcal{N}(w|0, \lambda^{-1}\mathbf{I}_p)$$

The priors over α and λ are chosen to be gamma distributions, the conjugate prior for the precision of the Gaussian. The resulting model is called *Bayesian Ridge Regression*, and is similar to the classical `Ridge`.

The parameters w, α and λ are estimated jointly during the fit of the model, the regularization parameters α and λ being estimated by maximizing the *log marginal likelihood*. The scikit-learn implementation is based on the algorithm described in Appendix A of (Tipping, 2001) where the update of the parameters α and λ is done as suggested in (MacKay, 1992). The initial value of the maximization procedure can be set with the hyperparameters `alpha_init` and `lambda_init`.



There are four more hyperparameters, α_1, α_2, λ_1 and λ_2 of the gamma prior distributions over α and λ. These are usually chosen to be *non-informative*. By default $\alpha_1 = \alpha_2 = \lambda_1 = \lambda_2 = 10^{-6}$.

Bayesian Ridge Regression is used for regression:

```
>>> from sklearn import linear_model
>>> X = [[0., 0.], [1., 1.], [2., 2.], [3., 3.]]
>>> Y = [0., 1., 2., 3.]
>>> reg = linear_model.BayesianRidge()
>>> reg.fit(X, Y)
BayesianRidge()
```

After being fitted, the model can then be used to predict new values:

```
>>> reg.predict([[1, 0.]])
array([0.50000013])
```

The coefficients w of the model can be accessed:

```
>>> reg.coef_
array([0.49999993, 0.49999993])
```

Due to the Bayesian framework, the weights found are slightly different to the ones found by *Ordinary Least Squares*. However, Bayesian Ridge Regression is more robust to ill-posed problems.

Examples:

- *Bayesian Ridge Regression*
- *Curve Fitting with Bayesian Ridge Regression*

References:

- Section 3.3 in Christopher M. Bishop: Pattern Recognition and Machine Learning, 2006
- David J. C. MacKay, Bayesian Interpolation, 1992.
- Michael E. Tipping, Sparse Bayesian Learning and the Relevance Vector Machine, 2001.

Automatic Relevance Determination - ARD

`ARDRegression` is very similar to *Bayesian Ridge Regression*, but can lead to sparser coefficients w[1][2]. `ARDRegression` poses a different prior over w, by dropping the assumption of the Gaussian being spherical.

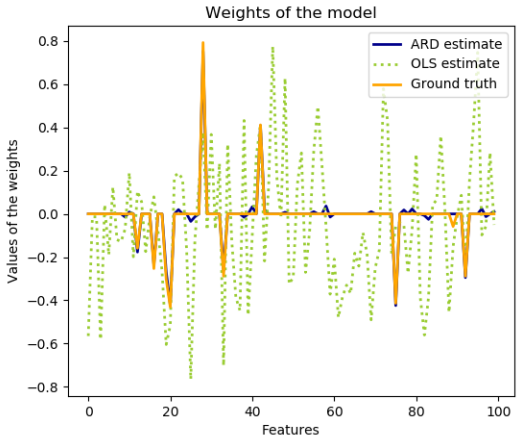
Instead, the distribution over w is assumed to be an axis-parallel, elliptical Gaussian distribution.

This means each coefficient w_i is drawn from a Gaussian distribution, centered on zero and with a precision λ_i:

$$p(w|\lambda) = \mathcal{N}(w|0, A^{-1})$$

with $\text{diag}(A) = \lambda = \{\lambda_1, ..., \lambda_p\}$.

In contrast to *Bayesian Ridge Regression*, each coordinate of w_i has its own standard deviation λ_i. The prior over all λ_i is chosen to be the same gamma distribution given by hyperparameters λ_1 and λ_2.



ARD is also known in the literature as *Sparse Bayesian Learning* and *Relevance Vector Machine*[3][4].

Examples:

- *Automatic Relevance Determination Regression (ARD)*

References:

Logistic regression

Logistic regression, despite its name, is a linear model for classification rather than regression. Logistic regression is also known in the literature as logit regression, maximum-entropy classification (MaxEnt) or the log-linear classifier. In this model, the probabilities describing the possible outcomes of a single trial are modeled using a logistic function.

Logistic regression is implemented in `LogisticRegression`. This implementation can fit binary, One-vs-Rest, or multinomial logistic regression with optional ℓ_1, ℓ_2 or Elastic-Net regularization.

[1] Christopher M. Bishop: Pattern Recognition and Machine Learning, Chapter 7.2.1
[2] David Wipf and Srikantan Nagarajan: A new view of automatic relevance determination
[3] Michael E. Tipping: Sparse Bayesian Learning and the Relevance Vector Machine
[4] Tristan Fletcher: Relevance Vector Machines explained

Note: Regularization is applied by default, which is common in machine learning but not in statistics. Another advantage of regularization is that it improves numerical stability. No regularization amounts to setting C to a very high value.

As an optimization problem, binary class ℓ_2 penalized logistic regression minimizes the following cost function:

$$\min_{w,c} \frac{1}{2} w^T w + C \sum_{i=1}^{n} \log(\exp(-y_i(X_i^T w + c)) + 1).$$

Similarly, ℓ_1 regularized logistic regression solves the following optimization problem:

$$\min_{w,c} \|w\|_1 + C \sum_{i=1}^{n} \log(\exp(-y_i(X_i^T w + c)) + 1).$$

Elastic-Net regularization is a combination of ℓ_1 and ℓ_2, and minimizes the following cost function:

$$\min_{w,c} \frac{1-\rho}{2} w^T w + \rho \|w\|_1 + C \sum_{i=1}^{n} \log(\exp(-y_i(X_i^T w + c)) + 1),$$

where ρ controls the strength of ℓ_1 regularization vs. ℓ_2 regularization (it corresponds to the `l1_ratio` parameter).

Note that, in this notation, it's assumed that the target y_i takes values in the set $-1, 1$ at trial i. We can also see that Elastic-Net is equivalent to ℓ_1 when $\rho = 1$ and equivalent to ℓ_2 when $\rho = 0$.

The solvers implemented in the class *LogisticRegression* are "liblinear", "newton-cg", "lbfgs", "sag" and "saga":

The solver "liblinear" uses a coordinate descent (CD) algorithm, and relies on the excellent C++ LIBLINEAR library, which is shipped with scikit-learn. However, the CD algorithm implemented in liblinear cannot learn a true multinomial (multiclass) model; instead, the optimization problem is decomposed in a "one-vs-rest" fashion so separate binary classifiers are trained for all classes. This happens under the hood, so *LogisticRegression* instances using this solver behave as multiclass classifiers. For ℓ_1 regularization *sklearn.svm.l1_min_c* allows to calculate the lower bound for C in order to get a non "null" (all feature weights to zero) model.

The "lbfgs", "sag" and "newton-cg" solvers only support ℓ_2 regularization or no regularization, and are found to converge faster for some high-dimensional data. Setting `multi_class` to "multinomial" with these solvers learns a true multinomial logistic regression model[5], which means that its probability estimates should be better calibrated than the default "one-vs-rest" setting.

The "sag" solver uses Stochastic Average Gradient descent[6]. It is faster than other solvers for large datasets, when both the number of samples and the number of features are large.

The "saga" solver[7] is a variant of "sag" that also supports the non-smooth `penalty="l1"`. This is therefore the solver of choice for sparse multinomial logistic regression. It is also the only solver that supports `penalty="elasticnet"`.

The "lbfgs" is an optimization algorithm that approximates the Broyden–Fletcher–Goldfarb–Shanno algorithm[8], which belongs to quasi-Newton methods. The "lbfgs" solver is recommended for use for small data-sets but for larger datasets its performance suffers.[9]

The following table summarizes the penalties supported by each solver:

[5] Christopher M. Bishop: Pattern Recognition and Machine Learning, Chapter 4.3.4

[6] Mark Schmidt, Nicolas Le Roux, and Francis Bach: Minimizing Finite Sums with the Stochastic Average Gradient.

[7] Aaron Defazio, Francis Bach, Simon Lacoste-Julien: SAGA: A Fast Incremental Gradient Method With Support for Non-Strongly Convex Composite Objectives.

[8] https://en.wikipedia.org/wiki/Broyden%E2%80%93Fletcher%E2%80%93Goldfarb%E2%80%93Shanno_algorithm

[9] "Performance Evaluation of Lbfgs vs other solvers"

	Solvers				
Penalties	**'liblinear'**	**'lbfgs'**	**'newton-cg'**	**'sag'**	**'saga'**
Multinomial + L2 penalty	no	yes	yes	yes	yes
OVR + L2 penalty	yes	yes	yes	yes	yes
Multinomial + L1 penalty	no	no	no	no	yes
OVR + L1 penalty	yes	no	no	no	yes
Elastic-Net	no	no	no	no	yes
No penalty ('none')	no	yes	yes	yes	yes
Behaviors					
Penalize the intercept (bad)	yes	no	no	no	no
Faster for large datasets	no	no	no	yes	yes
Robust to unscaled datasets	yes	yes	yes	no	no

The "lbfgs" solver is used by default for its robustness. For large datasets the "saga" solver is usually faster. For large dataset, you may also consider using `SGDClassifier` with 'log' loss, which might be even faster but requires more tuning.

Examples:

- *L1 Penalty and Sparsity in Logistic Regression*
- *Regularization path of L1- Logistic Regression*
- *Plot multinomial and One-vs-Rest Logistic Regression*
- *Multiclass sparse logistic regression on 20newgroups*
- *MNIST classification using multinomial logistic + L1*

Differences from liblinear:

There might be a difference in the scores obtained between `LogisticRegression` with `solver=liblinear` or `LinearSVC` and the external liblinear library directly, when `fit_intercept=False` and the fit `coef_` (or) the data to be predicted are zeroes. This is because for the sample(s) with `decision_function` zero, `LogisticRegression` and `LinearSVC` predict the negative class, while liblinear predicts the positive class. Note that a model with `fit_intercept=False` and having many samples with `decision_function` zero, is likely to be a underfit, bad model and you are advised to set `fit_intercept=True` and increase the intercept_scaling.

Note: Feature selection with sparse logistic regression

A logistic regression with ℓ_1 penalty yields sparse models, and can thus be used to perform feature selection, as detailed in *L1-based feature selection*.

Note: P-value estimation

It is possible to obtain the p-values and confidence intervals for coefficients in cases of regression without penalization. The `statsmodels package <https://pypi.org/project/statsmodels/>` natively supports this. Within sklearn, one could use bootstrapping instead as well.

LogisticRegressionCV implements Logistic Regression with built-in cross-validation support, to find the optimal `C` and `l1_ratio` parameters according to the `scoring` attribute. The "newton-cg", "sag", "saga" and "lbfgs" solvers are found to be faster for high-dimensional dense data, due to warm-starting (see *Glossary*).

Stochastic Gradient Descent - SGD

Stochastic gradient descent is a simple yet very efficient approach to fit linear models. It is particularly useful when the number of samples (and the number of features) is very large. The `partial_fit` method allows online/out-of-core learning.

The classes *SGDClassifier* and *SGDRegressor* provide functionality to fit linear models for classification and regression using different (convex) loss functions and different penalties. E.g., with `loss="log"`, *SGDClassifier* fits a logistic regression model, while with `loss="hinge"` it fits a linear support vector machine (SVM).

References

- *Stochastic Gradient Descent*

Perceptron

The *Perceptron* is another simple classification algorithm suitable for large scale learning. By default:

- It does not require a learning rate.
- It is not regularized (penalized).
- It updates its model only on mistakes.

The last characteristic implies that the Perceptron is slightly faster to train than SGD with the hinge loss and that the resulting models are sparser.

Passive Aggressive Algorithms

The passive-aggressive algorithms are a family of algorithms for large-scale learning. They are similar to the Perceptron in that they do not require a learning rate. However, contrary to the Perceptron, they include a regularization parameter `C`.

For classification, *PassiveAggressiveClassifier* can be used with `loss='hinge'` (PA-I) or `loss='squared_hinge'` (PA-II). For regression, *PassiveAggressiveRegressor* can be used with `loss='epsilon_insensitive'` (PA-I) or `loss='squared_epsilon_insensitive'` (PA-II).

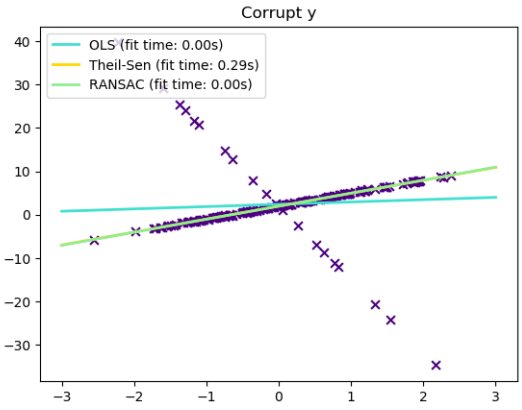
Robustness regression: outliers and modeling errors

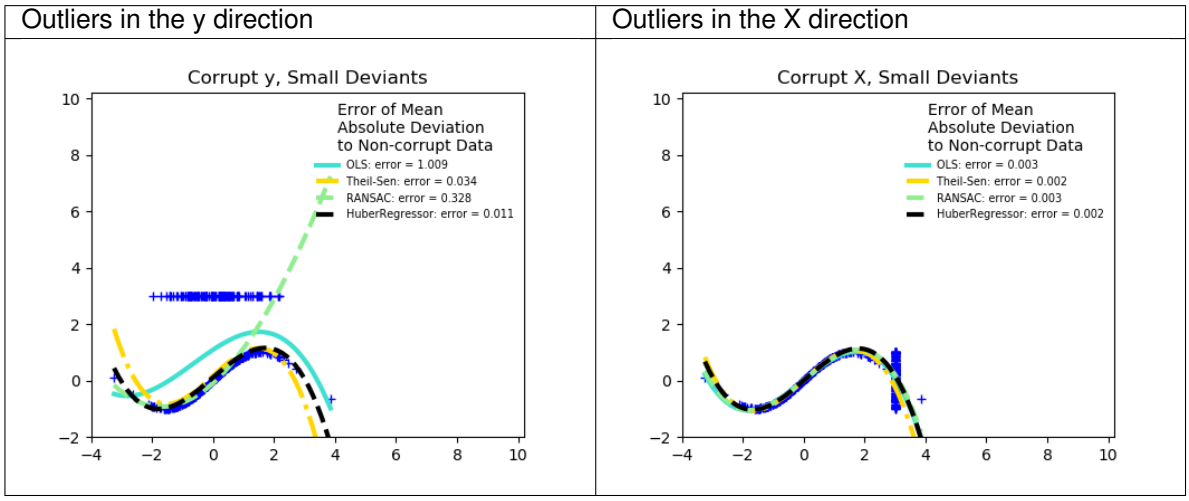
Robust regression aims to fit a regression model in the presence of corrupt data: either outliers, or error in the model.



Different scenario and useful concepts

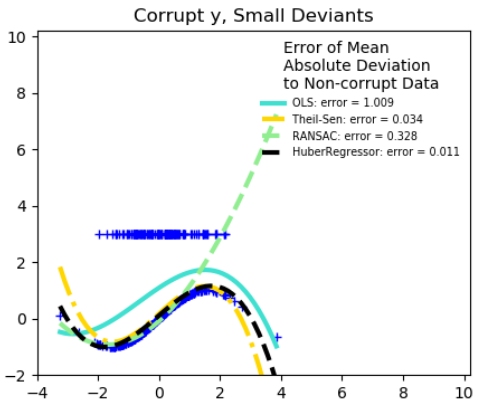
There are different things to keep in mind when dealing with data corrupted by outliers:

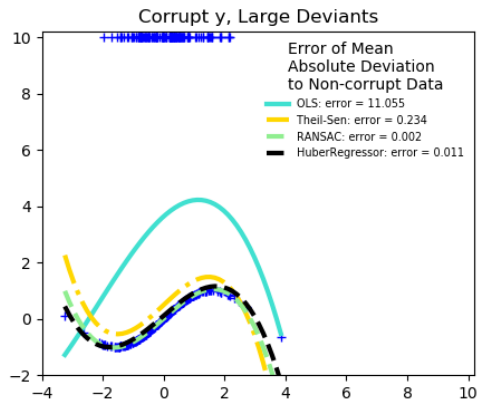
- **Outliers in X or in y**?



- **Fraction of outliers versus amplitude of error**

  The number of outlying points matters, but also how much they are outliers.

Small outliers	Large outliers
	




An important notion of robust fitting is that of breakdown point: the fraction of data that can be outlying for the fit to start missing the inlying data.

Note that in general, robust fitting in high-dimensional setting (large `n_features`) is very hard. The robust models here will probably not work in these settings.

Trade-offs: which estimator?

Scikit-learn provides 3 robust regression estimators: *RANSAC*, *Theil Sen* and *HuberRegressor*.

- *HuberRegressor* should be faster than *RANSAC* and *Theil Sen* unless the number of samples are very large, i.e `n_samples` >> `n_features`. This is because *RANSAC* and *Theil Sen* fit on smaller subsets of the data. However, both *Theil Sen* and *RANSAC* are unlikely to be as robust as *HuberRegressor* for the default parameters.
- *RANSAC* is faster than *Theil Sen* and scales much better with the number of samples.
- *RANSAC* will deal better with large outliers in the y direction (most common situation).
- *Theil Sen* will cope better with medium-size outliers in the X direction, but this property will disappear in high-dimensional settings.

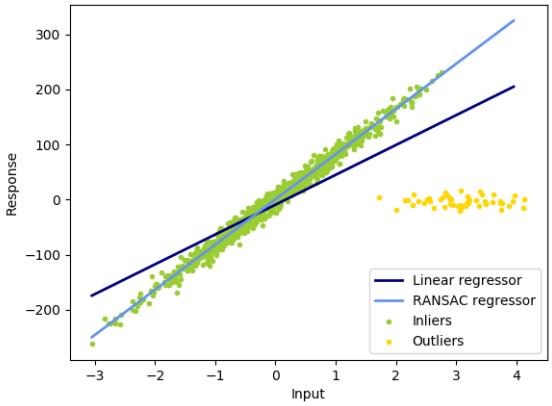
When in doubt, use *RANSAC*.

RANSAC: RANdom SAmple Consensus

RANSAC (RANdom SAmple Consensus) fits a model from random subsets of inliers from the complete data set.

RANSAC is a non-deterministic algorithm producing only a reasonable result with a certain probability, which is dependent on the number of iterations (see `max_trials` parameter). It is typically used for linear and non-linear regression problems and is especially popular in the field of photogrammetric computer vision.

The algorithm splits the complete input sample data into a set of inliers, which may be subject to noise, and outliers, which are e.g. caused by erroneous measurements or invalid hypotheses about the data. The resulting model is then estimated only from the determined inliers.



Details of the algorithm

Each iteration performs the following steps:

1. Select `min_samples` random samples from the original data and check whether the set of data is valid (see `is_data_valid`).
2. Fit a model to the random subset (`base_estimator.fit`) and check whether the estimated model is valid (see `is_model_valid`).
3. Classify all data as inliers or outliers by calculating the residuals to the estimated model (`base_estimator.predict(X) - y`) - all data samples with absolute residuals smaller than the `residual_threshold` are considered as inliers.
4. Save fitted model as best model if number of inlier samples is maximal. In case the current estimated model has the same number of inliers, it is only considered as the best model if it has better score.

These steps are performed either a maximum number of times (`max_trials`) or until one of the special stop criteria are met (see `stop_n_inliers` and `stop_score`). The final model is estimated using all inlier samples (consensus set) of the previously determined best model.

The `is_data_valid` and `is_model_valid` functions allow to identify and reject degenerate combinations of random sub-samples. If the estimated model is not needed for identifying degenerate cases, `is_data_valid` should be used as it is called prior to fitting the model and thus leading to better computational performance.

Theil-Sen estimator: generalized-median-based estimator

The `TheilSenRegressor` estimator uses a generalization of the median in multiple dimensions. It is thus robust to multivariate outliers. Note however that the robustness of the estimator decreases quickly with the dimensionality of the problem. It loses its robustness properties and becomes no better than an ordinary least squares in high dimension.

Examples:

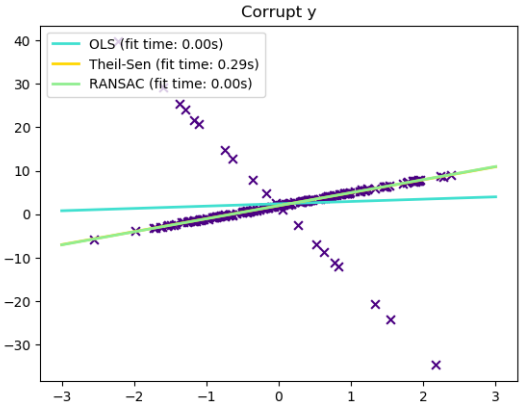
- *Theil-Sen Regression*
- *Robust linear estimator fitting*

References:

- https://en.wikipedia.org/wiki/Theil%E2%80%93Sen_estimator

Theoretical considerations

`TheilSenRegressor` is comparable to the *Ordinary Least Squares (OLS)* in terms of asymptotic efficiency and as an unbiased estimator. In contrast to OLS, Theil-Sen is a non-parametric method which means it makes no assumption about the underlying distribution of the data. Since Theil-Sen is a median-based estimator, it is more robust against corrupted data aka outliers. In univariate setting, Theil-Sen has a breakdown point of about 29.3% in case of a simple linear regression which means that it can tolerate arbitrary corrupted data of up to 29.3%.



The implementation of `TheilSenRegressor` in scikit-learn follows a generalization to a multivariate linear regression model[10] using the spatial median which is a generalization of the median to multiple dimensions[11].

In terms of time and space complexity, Theil-Sen scales according to

$$\binom{n_{\text{samples}}}{n_{\text{subsamples}}}$$

[10] Xin Dang, Hanxiang Peng, Xueqin Wang and Heping Zhang: Theil-Sen Estimators in a Multiple Linear Regression Model.

[11] T. Kärkkäinen and S. Äyrämö: On Computation of Spatial Median for Robust Data Mining.

which makes it infeasible to be applied exhaustively to problems with a large number of samples and features. Therefore, the magnitude of a subpopulation can be chosen to limit the time and space complexity by considering only a random subset of all possible combinations.

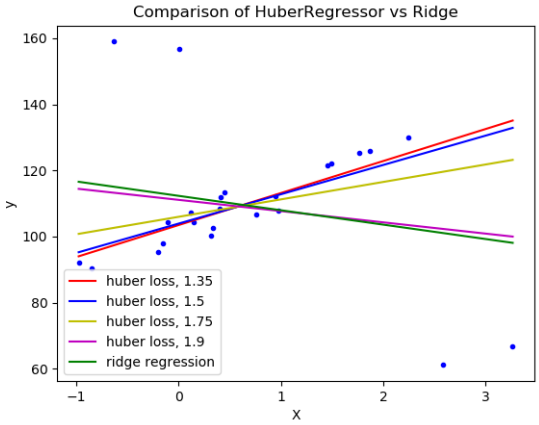
Examples:

- *Theil-Sen Regression*

References:

Huber Regression

The `HuberRegressor` is different to `Ridge` because it applies a linear loss to samples that are classified as outliers. A sample is classified as an inlier if the absolute error of that sample is lesser than a certain threshold. It differs from `TheilSenRegressor` and `RANSACRegressor` because it does not ignore the effect of the outliers but gives a lesser weight to them.



The loss function that `HuberRegressor` minimizes is given by

$$\min_{w,\sigma} \sum_{i=1}^{n} \left(\sigma + H_\epsilon \left(\frac{X_i w - y_i}{\sigma} \right) \sigma \right) + \alpha ||w||_2{}^2$$

where

$$H_\epsilon(z) = \begin{cases} z^2, & \text{if } |z| < \epsilon, \\ 2\epsilon|z| - \epsilon^2, & \text{otherwise} \end{cases}$$

It is advised to set the parameter `epsilon` to 1.35 to achieve 95% statistical efficiency.

Notes

The `HuberRegressor` differs from using `SGDRegressor` with loss set to `huber` in the following ways.

- `HuberRegressor` is scaling invariant. Once `epsilon` is set, scaling `X` and `y` down or up by different values would produce the same robustness to outliers as before. as compared to `SGDRegressor` where `epsilon` has to be set again when `X` and `y` are scaled.
- `HuberRegressor` should be more efficient to use on data with small number of samples while `SGDRegressor` needs a number of passes on the training data to produce the same robustness.

Examples:

- *HuberRegressor vs Ridge on dataset with strong outliers*

References:

- Peter J. Huber, Elvezio M. Ronchetti: Robust Statistics, Concomitant scale estimates, pg 172

Note that this estimator is different from the R implementation of Robust Regression (http://www.ats.ucla.edu/stat/r/dae/rreg.htm) because the R implementation does a weighted least squares implementation with weights given to each sample on the basis of how much the residual is greater than a certain threshold.

Polynomial regression: extending linear models with basis functions

One common pattern within machine learning is to use linear models trained on nonlinear functions of the data. This approach maintains the generally fast performance of linear methods, while allowing them to fit a much wider range of data.

For example, a simple linear regression can be extended by constructing **polynomial features** from the coefficients. In the standard linear regression case, you might have a model that looks like this for two-dimensional data:

$$\hat{y}(w, x) = w_0 + w_1 x_1 + w_2 x_2$$

If we want to fit a paraboloid to the data instead of a plane, we can combine the features in second-order polynomials, so that the model looks like this:

$$\hat{y}(w, x) = w_0 + w_1 x_1 + w_2 x_2 + w_3 x_1 x_2 + w_4 x_1^2 + w_5 x_2^2$$

The (sometimes surprising) observation is that this is *still a linear model*: to see this, imagine creating a new set of features

$$z = [x_1, x_2, x_1 x_2, x_1^2, x_2^2]$$

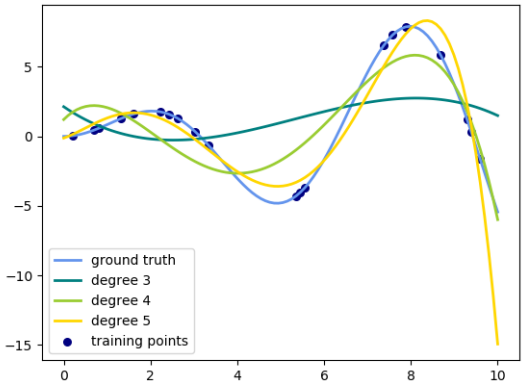
With this re-labeling of the data, our problem can be written

$$\hat{y}(w, z) = w_0 + w_1 z_1 + w_2 z_2 + w_3 z_3 + w_4 z_4 + w_5 z_5$$

We see that the resulting *polynomial regression* is in the same class of linear models we considered above (i.e. the model is linear in w) and can be solved by the same techniques. By considering linear fits within a higher-dimensional space built with these basis functions, the model has the flexibility to fit a much broader range of data.

Here is an example of applying this idea to one-dimensional data, using polynomial features of varying degrees:

This figure is created using the `PolynomialFeatures` transformer, which transforms an input data matrix into a new data matrix of a given degree. It can be used as follows:



```
>>> from sklearn.preprocessing import PolynomialFeatures
>>> import numpy as np
>>> X = np.arange(6).reshape(3, 2)
>>> X
array([[0, 1],
       [2, 3],
       [4, 5]])
>>> poly = PolynomialFeatures(degree=2)
>>> poly.fit_transform(X)
array([[ 1.,  0.,  1.,  0.,  0.,  1.],
       [ 1.,  2.,  3.,  4.,  6.,  9.],
       [ 1.,  4.,  5., 16., 20., 25.]])
```

The features of X have been transformed from $[x_1, x_2]$ to $[1, x_1, x_2, x_1^2, x_1x_2, x_2^2]$, and can now be used within any linear model.

This sort of preprocessing can be streamlined with the *Pipeline* tools. A single object representing a simple polynomial regression can be created and used as follows:

```
>>> from sklearn.preprocessing import PolynomialFeatures
>>> from sklearn.linear_model import LinearRegression
>>> from sklearn.pipeline import Pipeline
>>> import numpy as np
>>> model = Pipeline([('poly', PolynomialFeatures(degree=3)),
...                   ('linear', LinearRegression(fit_intercept=False))])
>>> # fit to an order-3 polynomial data
>>> x = np.arange(5)
>>> y = 3 - 2 * x + x ** 2 - x ** 3
>>> model = model.fit(x[:, np.newaxis], y)
>>> model.named_steps['linear'].coef_
array([ 3., -2.,  1., -1.])
```

The linear model trained on polynomial features is able to exactly recover the input polynomial coefficients.

In some cases it's not necessary to include higher powers of any single feature, but only the so-called *interaction features* that multiply together at most d distinct features. These can be gotten from `PolynomialFeatures` with the setting `interaction_only=True`.

For example, when dealing with boolean features, $x_i^n = x_i$ for all n and is therefore useless; but $x_i x_j$ represents the conjunction of two booleans. This way, we can solve the XOR problem with a linear classifier:

```
>>> from sklearn.linear_model import Perceptron
>>> from sklearn.preprocessing import PolynomialFeatures
>>> import numpy as np
>>> X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]])
>>> y = X[:, 0] ^ X[:, 1]
>>> y
array([0, 1, 1, 0])
>>> X = PolynomialFeatures(interaction_only=True).fit_transform(X).astype(int)
>>> X
array([[1, 0, 0, 0],
       [1, 0, 1, 0],
       [1, 1, 0, 0],
       [1, 1, 1, 1]])
>>> clf = Perceptron(fit_intercept=False, max_iter=10, tol=None,
...                  shuffle=False).fit(X, y)
```

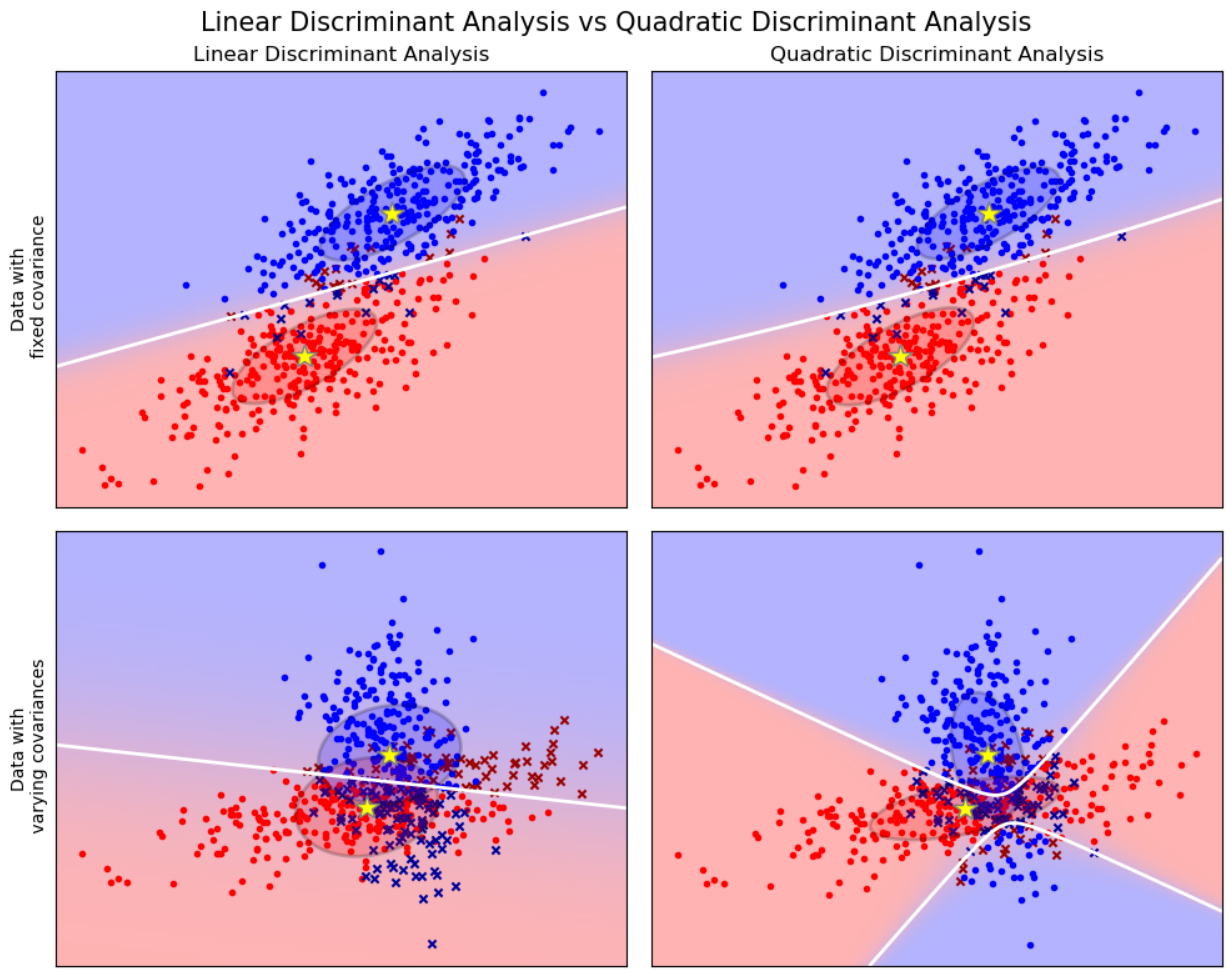
And the classifier "predictions" are perfect:

```
>>> clf.predict(X)
array([0, 1, 1, 0])
>>> clf.score(X, y)
1.0
```

4.1.2 Linear and Quadratic Discriminant Analysis

Linear Discriminant Analysis (*discriminant_analysis.LinearDiscriminantAnalysis*) and Quadratic Discriminant Analysis (*discriminant_analysis.QuadraticDiscriminantAnalysis*) are two classic classifiers, with, as their names suggest, a linear and a quadratic decision surface, respectively.

These classifiers are attractive because they have closed-form solutions that can be easily computed, are inherently multiclass, have proven to work well in practice, and have no hyperparameters to tune.



The plot shows decision boundaries for Linear Discriminant Analysis and Quadratic Discriminant Analysis. The bottom row demonstrates that Linear Discriminant Analysis can only learn linear boundaries, while Quadratic Discriminant Analysis can learn quadratic boundaries and is therefore more flexible.

Examples:

Linear and Quadratic Discriminant Analysis with covariance ellipsoid: Comparison of LDA and QDA on synthetic data.

Dimensionality reduction using Linear Discriminant Analysis

`discriminant_analysis.LinearDiscriminantAnalysis` can be used to perform supervised dimensionality reduction, by projecting the input data to a linear subspace consisting of the directions which maximize the separation between classes (in a precise sense discussed in the mathematics section below). The dimension of the output is necessarily less than the number of classes, so this is, in general, a rather strong dimensionality reduction, and only makes sense in a multiclass setting.

This is implemented in `discriminant_analysis.LinearDiscriminantAnalysis.transform`. The desired dimensionality can be set using the `n_components` constructor parameter. This parameter has no influence on `discriminant_analysis.LinearDiscriminantAnalysis.fit` or `discriminant_analysis.`

LinearDiscriminantAnalysis.predict.

Examples:

Comparison of LDA and PCA 2D projection of Iris dataset: Comparison of LDA and PCA for dimensionality reduction of the Iris dataset

Mathematical formulation of the LDA and QDA classifiers

Both LDA and QDA can be derived from simple probabilistic models which model the class conditional distribution of the data $P(X|y=k)$ for each class k. Predictions can then be obtained by using Bayes' rule:

$$P(y=k|X) = \frac{P(X|y=k)P(y=k)}{P(X)} = \frac{P(X|y=k)P(y=k)}{\sum_l P(X|y=l)\cdot P(y=l)}$$

and we select the class k which maximizes this conditional probability.

More specifically, for linear and quadratic discriminant analysis, $P(X|y)$ is modeled as a multivariate Gaussian distribution with density:

$$P(X|y=k) = \frac{1}{(2\pi)^{d/2}|\Sigma_k|^{1/2}} \exp\left(-\frac{1}{2}(X-\mu_k)^t\Sigma_k^{-1}(X-\mu_k)\right)$$

where d is the number of features.

To use this model as a classifier, we just need to estimate from the training data the class priors $P(y=k)$ (by the proportion of instances of class k), the class means μ_k (by the empirical sample class means) and the covariance matrices (either by the empirical sample class covariance matrices, or by a regularized estimator: see the section on shrinkage below).

In the case of LDA, the Gaussians for each class are assumed to share the same covariance matrix: $\Sigma_k = \Sigma$ for all k. This leads to linear decision surfaces, which can be seen by comparing the log-probability ratios $\log[P(y=k|X)/P(y=l|X)]$:

$$\log\left(\frac{P(y=k|X)}{P(y=l|X)}\right) = \log\left(\frac{P(X|y=k)P(y=k)}{P(X|y=l)P(y=l)}\right) = 0 \Leftrightarrow$$
$$(\mu_k-\mu_l)^t\Sigma^{-1}X = \frac{1}{2}(\mu_k^t\Sigma^{-1}\mu_k - \mu_l^t\Sigma^{-1}\mu_l) - \log\frac{P(y=k)}{P(y=l)}$$

In the case of QDA, there are no assumptions on the covariance matrices Σ_k of the Gaussians, leading to quadratic decision surfaces. See[3] for more details.

Note: Relation with Gaussian Naive Bayes

If in the QDA model one assumes that the covariance matrices are diagonal, then the inputs are assumed to be conditionally independent in each class, and the resulting classifier is equivalent to the Gaussian Naive Bayes classifier *naive_bayes.GaussianNB*.

Mathematical formulation of LDA dimensionality reduction

To understand the use of LDA in dimensionality reduction, it is useful to start with a geometric reformulation of the LDA classification rule explained above. We write K for the total number of target classes. Since in LDA we assume

[3] "The Elements of Statistical Learning", Hastie T., Tibshirani R., Friedman J., Section 4.3, p.106-119, 2008.

that all classes have the same estimated covariance Σ, we can rescale the data so that this covariance is the identity:

$$X^* = D^{-1/2}U^t X \text{ with } \Sigma = UDU^t$$

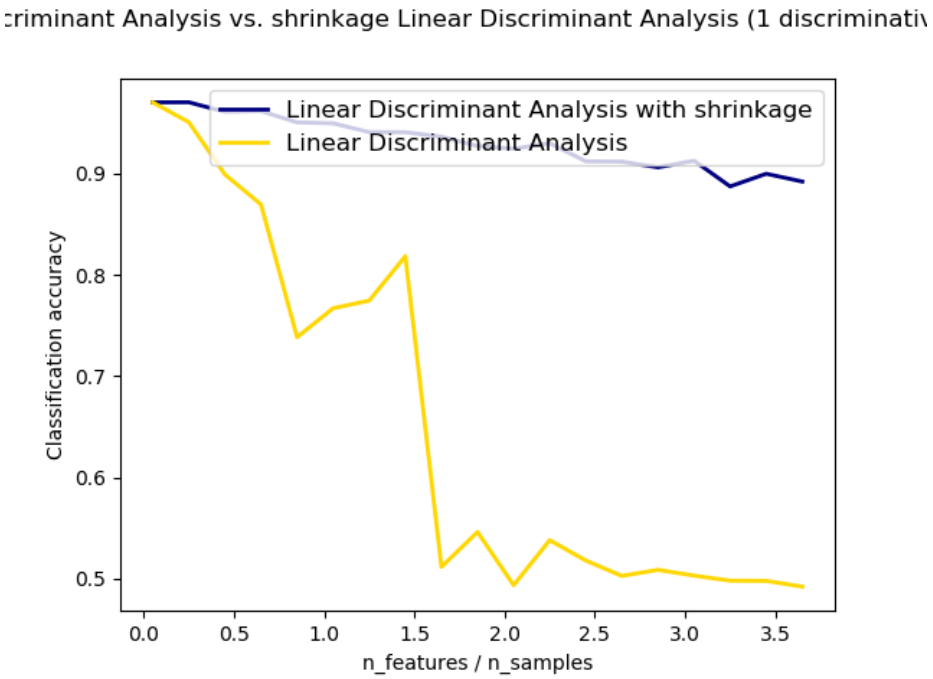
Then one can show that to classify a data point after scaling is equivalent to finding the estimated class mean μ_k^* which is closest to the data point in the Euclidean distance. But this can be done just as well after projecting on the $K-1$ affine subspace H_K generated by all the μ_k^* for all classes. This shows that, implicit in the LDA classifier, there is a dimensionality reduction by linear projection onto a $K-1$ dimensional space.

We can reduce the dimension even more, to a chosen L, by projecting onto the linear subspace H_L which maximizes the variance of the μ_k^* after projection (in effect, we are doing a form of PCA for the transformed class means μ_k^*). This L corresponds to the `n_components` parameter used in the *discriminant_analysis.LinearDiscriminantAnalysis.transform* method. See[3] for more details.

Shrinkage

Shrinkage is a tool to improve estimation of covariance matrices in situations where the number of training samples is small compared to the number of features. In this scenario, the empirical sample covariance is a poor estimator. Shrinkage LDA can be used by setting the `shrinkage` parameter of the *discriminant_analysis.LinearDiscriminantAnalysis* class to 'auto'. This automatically determines the optimal shrinkage parameter in an analytic way following the lemma introduced by Ledoit and Wolf[4]. Note that currently shrinkage only works when setting the `solver` parameter to 'lsqr' or 'eigen'.

The `shrinkage` parameter can also be manually set between 0 and 1. In particular, a value of 0 corresponds to no shrinkage (which means the empirical covariance matrix will be used) and a value of 1 corresponds to complete shrinkage (which means that the diagonal matrix of variances will be used as an estimate for the covariance matrix). Setting this parameter to a value between these two extrema will estimate a shrunk version of the covariance matrix.



[4] Ledoit O, Wolf M. Honey, I Shrunk the Sample Covariance Matrix. The Journal of Portfolio Management 30(4), 110-119, 2004.

Estimation algorithms

The default solver is 'svd'. It can perform both classification and transform, and it does not rely on the calculation of the covariance matrix. This can be an advantage in situations where the number of features is large. However, the 'svd' solver cannot be used with shrinkage.

The 'lsqr' solver is an efficient algorithm that only works for classification. It supports shrinkage.

The 'eigen' solver is based on the optimization of the between class scatter to within class scatter ratio. It can be used for both classification and transform, and it supports shrinkage. However, the 'eigen' solver needs to compute the covariance matrix, so it might not be suitable for situations with a high number of features.

Examples:

Normal and Shrinkage Linear Discriminant Analysis for classification: Comparison of LDA classifiers with and without shrinkage.

References:

4.1.3 Kernel ridge regression

Kernel ridge regression (KRR) [M2012] combines *Ridge regression and classification* (linear least squares with l2-norm regularization) with the kernel trick. It thus learns a linear function in the space induced by the respective kernel and the data. For non-linear kernels, this corresponds to a non-linear function in the original space.

The form of the model learned by `KernelRidge` is identical to support vector regression (`SVR`). However, different loss functions are used: KRR uses squared error loss while support vector regression uses ϵ-insensitive loss, both combined with l2 regularization. In contrast to `SVR`, fitting `KernelRidge` can be done in closed-form and is typically faster for medium-sized datasets. On the other hand, the learned model is non-sparse and thus slower than SVR, which learns a sparse model for $\epsilon > 0$, at prediction-time.

The following figure compares `KernelRidge` and `SVR` on an artificial dataset, which consists of a sinusoidal target function and strong noise added to every fifth datapoint. The learned model of `KernelRidge` and `SVR` is plotted, where both complexity/regularization and bandwidth of the RBF kernel have been optimized using grid-search. The learned functions are very similar; however, fitting `KernelRidge` is approx. seven times faster than fitting `SVR` (both with grid-search). However, prediction of 100000 target values is more than three times faster with SVR since it has learned a sparse model using only approx. 1/3 of the 100 training datapoints as support vectors.

The next figure compares the time for fitting and prediction of `KernelRidge` and `SVR` for different sizes of the training set. Fitting `KernelRidge` is faster than `SVR` for medium-sized training sets (less than 1000 samples); however, for larger training sets `SVR` scales better. With regard to prediction time, `SVR` is faster than `KernelRidge` for all sizes of the training set because of the learned sparse solution. Note that the degree of sparsity and thus the prediction time depends on the parameters ϵ and C of the `SVR`; $\epsilon = 0$ would correspond to a dense model.

4.1.4 Support Vector Machines

Support vector machines (SVMs) are a set of supervised learning methods used for *classification*, *regression* and *outliers detection*.

The advantages of support vector machines are:

- Effective in high dimensional spaces.
- Still effective in cases where number of dimensions is greater than the number of samples.
- Uses a subset of training points in the decision function (called support vectors), so it is also memory efficient.
- Versatile: different *Kernel functions* can be specified for the decision function. Common kernels are provided, but it is also possible to specify custom kernels.

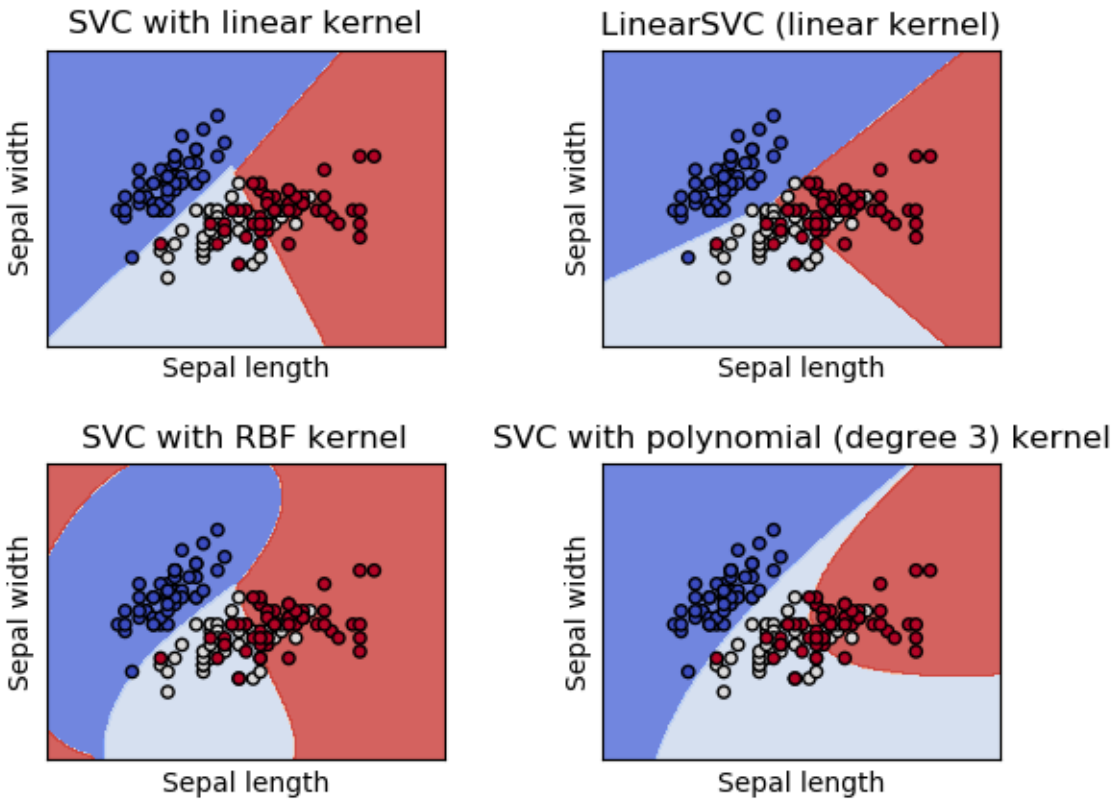
The disadvantages of support vector machines include:

- If the number of features is much greater than the number of samples, avoid over-fitting in choosing *Kernel functions* and regularization term is crucial.
- SVMs do not directly provide probability estimates, these are calculated using an expensive five-fold cross-validation (see *Scores and probabilities*, below).

The support vector machines in scikit-learn support both dense (`numpy.ndarray` and convertible to that by `numpy.asarray`) and sparse (any `scipy.sparse`) sample vectors as input. However, to use an SVM to make predictions for sparse data, it must have been fit on such data. For optimal performance, use C-ordered `numpy.ndarray` (dense) or `scipy.sparse.csr_matrix` (sparse) with `dtype=float64`.

Classification

SVC, *NuSVC* and *LinearSVC* are classes capable of performing multi-class classification on a dataset.



SVC and *NuSVC* are similar methods, but accept slightly different sets of parameters and have different mathematical formulations (see section *Mathematical formulation*). On the other hand, *LinearSVC* is another implementation of Support Vector Classification for the case of a linear kernel. Note that *LinearSVC* does not accept keyword `kernel`, as this is assumed to be linear. It also lacks some of the members of *SVC* and *NuSVC*, like `support_`.

As other classifiers, *SVC*, *NuSVC* and *LinearSVC* take as input two arrays: an array X of size `[n_samples, n_features]` holding the training samples, and an array y of class labels (strings or integers), size `[n_samples]`:

```
>>> from sklearn import svm
>>> X = [[0, 0], [1, 1]]
>>> y = [0, 1]
>>> clf = svm.SVC()
>>> clf.fit(X, y)
SVC()
```

After being fitted, the model can then be used to predict new values:

```
>>> clf.predict([[2., 2.]])
array([1])
```

SVMs decision function depends on some subset of the training data, called the support vectors. Some properties of these support vectors can be found in members `support_vectors_`, `support_` and `n_support`:

```
>>> # get support vectors
>>> clf.support_vectors_
array([[0., 0.],
       [1., 1.]])
>>> # get indices of support vectors
>>> clf.support_
array([0, 1]...)
>>> # get number of support vectors for each class
>>> clf.n_support_
array([1, 1]...)
```

Multi-class classification

SVC and *NuSVC* implement the "one-against-one" approach (Knerr et al., 1990) for multi- class classification. If `n_class` is the number of classes, then `n_class * (n_class - 1) / 2` classifiers are constructed and each one trains data from two classes. To provide a consistent interface with other classifiers, the `decision_function_shape` option allows to monotically transform the results of the "one-against-one" classifiers to a decision function of shape `(n_samples, n_classes)`.

```
>>> X = [[0], [1], [2], [3]]
>>> Y = [0, 1, 2, 3]
>>> clf = svm.SVC(decision_function_shape='ovo')
>>> clf.fit(X, Y)
SVC(decision_function_shape='ovo')
>>> dec = clf.decision_function([[1]])
>>> dec.shape[1] # 4 classes: 4*3/2 = 6
6
>>> clf.decision_function_shape = "ovr"
>>> dec = clf.decision_function([[1]])
>>> dec.shape[1] # 4 classes
4
```

On the other hand, *LinearSVC* implements "one-vs-the-rest" multi-class strategy, thus training n_class models. If there are only two classes, only one model is trained:

```
>>> lin_clf = svm.LinearSVC()
>>> lin_clf.fit(X, Y)
LinearSVC()
>>> dec = lin_clf.decision_function([[1]])
>>> dec.shape[1]
4
```

See *Mathematical formulation* for a complete description of the decision function.

Note that the *LinearSVC* also implements an alternative multi-class strategy, the so-called multi-class SVM formulated by Crammer and Singer, by using the option `multi_class='crammer_singer'`. This method is consistent, which is not true for one-vs-rest classification. In practice, one-vs-rest classification is usually preferred, since the results are mostly similar, but the runtime is significantly less.

For "one-vs-rest" *LinearSVC* the attributes `coef_` and `intercept_` have the shape `[n_class, n_features]` and `[n_class]` respectively. Each row of the coefficients corresponds to one of the `n_class` many "one-vs-rest" classifiers and similar for the intercepts, in the order of the "one" class.

In the case of "one-vs-one" *SVC*, the layout of the attributes is a little more involved. In the case of having a linear kernel, the attributes `coef_` and `intercept_` have the shape `[n_class * (n_class - 1) / 2, n_features]` and `[n_class * (n_class - 1) / 2]` respectively. This is similar to the layout for *LinearSVC* described above, with each row now corresponding to a binary classifier. The order for classes 0 to n is "0 vs 1", "0 vs 2" , ... "0 vs n", "1 vs 2", "1 vs 3", "1 vs n", . . . "n-1 vs n".

The shape of `dual_coef_` is `[n_class-1, n_SV]` with a somewhat hard to grasp layout. The columns correspond to the support vectors involved in any of the `n_class * (n_class - 1) / 2` "one-vs-one" classifiers. Each of the support vectors is used in `n_class - 1` classifiers. The `n_class - 1` entries in each row correspond to the dual coefficients for these classifiers.

This might be made more clear by an example:

Consider a three class problem with class 0 having three support vectors v_0^0, v_0^1, v_0^2 and class 1 and 2 having two support vectors v_1^0, v_1^1 and v_2^0, v_2^1 respectively. For each support vector v_i^j, there are two dual coefficients. Let's call the coefficient of support vector v_i^j in the classifier between classes i and k $\alpha_{i,k}^j$. Then `dual_coef_` looks like this:

$\alpha_{0,1}^0$	$\alpha_{0,2}^0$	Coefficients for SVs of class 0
$\alpha_{0,1}^1$	$\alpha_{0,2}^1$	
$\alpha_{0,1}^2$	$\alpha_{0,2}^2$	
$\alpha_{1,0}^0$	$\alpha_{1,2}^0$	Coefficients for SVs of class 1
$\alpha_{1,0}^1$	$\alpha_{1,2}^1$	
$\alpha_{2,0}^0$	$\alpha_{2,1}^0$	Coefficients for SVs of class 2
$\alpha_{2,0}^1$	$\alpha_{2,1}^1$	

Scores and probabilities

The `decision_function` method of *SVC* and *NuSVC* gives per-class scores for each sample (or a single score per sample in the binary case). When the constructor option `probability` is set to `True`, class membership probability estimates (from the methods `predict_proba` and `predict_log_proba`) are enabled. In the binary case, the probabilities are calibrated using Platt scaling: logistic regression on the SVM's scores, fit by an additional cross-validation on the training data. In the multiclass case, this is extended as per Wu et al. (2004).

Needless to say, the cross-validation involved in Platt scaling is an expensive operation for large datasets. In addition, the probability estimates may be inconsistent with the scores, in the sense that the "argmax" of the scores may not be the argmax of the probabilities. (E.g., in binary classification, a sample may be labeled by `predict` as belonging

to a class that has probability <½ according to `predict_proba`.) Platt's method is also known to have theoretical issues. If confidence scores are required, but these do not have to be probabilities, then it is advisable to set `probability=False` and use `decision_function` instead of `predict_proba`.

Please note that when `decision_function_shape='ovr'` and `n_classes > 2`, unlike `decision_function`, the `predict` method does not try to break ties by default. You can set `break_ties=True` for the output of `predict` to be the same as `np.argmax(clf.decision_function(...), axis=1)`, otherwise the first class among the tied classes will always be returned; but have in mind that it comes with a computational cost.

Unbalanced problems

In problems where it is desired to give more importance to certain classes or certain individual samples keywords `class_weight` and `sample_weight` can be used.

SVC (but not *NuSVC*) implement a keyword `class_weight` in the `fit` method. It's a dictionary of the form `{class_label : value}`, where value is a floating point number > 0 that sets the parameter `C` of class `class_label` to `C * value`.

SVC, *NuSVC*, *SVR*, *NuSVR*, *LinearSVC*, *LinearSVR* and *OneClassSVM* implement also weights for individual samples in method `fit` through keyword `sample_weight`. Similar to `class_weight`, these set the parameter `C` for the i-th example to `C * sample_weight[i]`.

Examples:

- *Plot different SVM classifiers in the iris dataset*,
- *SVM: Maximum margin separating hyperplane*,
- *SVM: Separating hyperplane for unbalanced classes*
- *SVM-Anova: SVM with univariate feature selection*,
- *Non-linear SVM*
- *SVM: Weighted samples*,

Regression

The method of Support Vector Classification can be extended to solve regression problems. This method is called Support Vector Regression.

The model produced by support vector classification (as described above) depends only on a subset of the training data, because the cost function for building the model does not care about training points that lie beyond the margin. Analogously, the model produced by Support Vector Regression depends only on a subset of the training data, because the cost function for building the model ignores any training data close to the model prediction.

There are three different implementations of Support Vector Regression: *SVR*, *NuSVR* and *LinearSVR*. *LinearSVR* provides a faster implementation than *SVR* but only considers linear kernels, while *NuSVR* implements a slightly different formulation than *SVR* and *LinearSVR*. See *Implementation details* for further details.

As with classification classes, the fit method will take as argument vectors X, y, only that in this case y is expected to have floating point values instead of integer values:

```
>>> from sklearn import svm
>>> X = [[0, 0], [2, 2]]
>>> y = [0.5, 2.5]
>>> clf = svm.SVR()
>>> clf.fit(X, y)
SVR()
>>> clf.predict([[1, 1]])
array([1.5])
```

Examples:

- *Support Vector Regression (SVR) using linear and non-linear kernels*

Density estimation, novelty detection

The class *OneClassSVM* implements a One-Class SVM which is used in outlier detection.

See *Novelty and Outlier Detection* for the description and usage of OneClassSVM.

Complexity

Support Vector Machines are powerful tools, but their compute and storage requirements increase rapidly with the number of training vectors. The core of an SVM is a quadratic programming problem (QP), separating support vectors from the rest of the training data. The QP solver used by this libsvm-based implementation scales between $O(n_{features} \times n_{samples}^2)$ and $O(n_{features} \times n_{samples}^3)$ depending on how efficiently the libsvm cache is used in practice (dataset dependent). If the data is very sparse $n_{features}$ should be replaced by the average number of non-zero features in a sample vector.

Also note that for the linear case, the algorithm used in *LinearSVC* by the liblinear implementation is much more efficient than its libsvm-based *SVC* counterpart and can scale almost linearly to millions of samples and/or features.

Tips on Practical Use

- **Avoiding data copy**: For *SVC*, *SVR*, *NuSVC* and *NuSVR*, if the data passed to certain methods is not C-ordered contiguous, and double precision, it will be copied before calling the underlying C implementation. You can check whether a given numpy array is C-contiguous by inspecting its `flags` attribute.

  For *LinearSVC* (and *LogisticRegression*) any input passed as a numpy array will be copied and converted to the liblinear internal sparse data representation (double precision floats and int32 indices of non-zero components). If you want to fit a large-scale linear classifier without copying a dense numpy C-contiguous double precision array as input we suggest to use the *SGDClassifier* class instead. The objective function can be configured to be almost the same as the *LinearSVC* model.

- **Kernel cache size**: For *SVC*, *SVR*, *NuSVC* and *NuSVR*, the size of the kernel cache has a strong impact on run times for larger problems. If you have enough RAM available, it is recommended to set `cache_size` to a higher value than the default of 200(MB), such as 500(MB) or 1000(MB).

- **Setting C**: `C` is `1` by default and it's a reasonable default choice. If you have a lot of noisy observations you should decrease it. It corresponds to regularize more the estimation.

  LinearSVC and *LinearSVR* are less sensitive to `C` when it becomes large, and prediction results stop improving after a certain threshold. Meanwhile, larger `C` values will take more time to train, sometimes up to 10 times longer, as shown by Fan et al. (2008)

- Support Vector Machine algorithms are not scale invariant, so **it is highly recommended to scale your data**. For example, scale each attribute on the input vector X to [0,1] or [-1,+1], or standardize it to have mean 0 and variance 1. Note that the *same* scaling must be applied to the test vector to obtain meaningful results. See section *Preprocessing data* for more details on scaling and normalization.

- Parameter `nu` in *NuSVC*/*OneClassSVM*/*NuSVR* approximates the fraction of training errors and support vectors.

- In *SVC*, if data for classification are unbalanced (e.g. many positive and few negative), set `class_weight='balanced'` and/or try different penalty parameters `C`.

- **Randomness of the underlying implementations**: The underlying implementations of *SVC* and *NuSVC* use a random number generator only to shuffle the data for probability estimation (when `probability` is set to `True`). This randomness can be controlled with the `random_state` parameter. If `probability` is set to `False` these estimators are not random and `random_state` has no effect on the results. The underlying *OneClassSVM* implementation is similar to the ones of *SVC* and *NuSVC*. As no probability estimation is provided for *OneClassSVM*, it is not random.

  The underlying *LinearSVC* implementation uses a random number generator to select features when fitting the model with a dual coordinate descent (i.e when `dual` is set to `True`). It is thus not uncommon, to have slightly different results for the same input data. If that happens, try with a smaller tol parameter. This randomness can also be controlled with the `random_state` parameter. When `dual` is set to `False` the underlying implementation of *LinearSVC* is not random and `random_state` has no effect on the results.

- Using L1 penalization as provided by `LinearSVC(loss='l2', penalty='l1', dual=False)` yields a sparse solution, i.e. only a subset of feature weights is different from zero and contribute to the decision function. Increasing `C` yields a more complex model (more feature are selected). The `C` value that yields a "null" model (all weights equal to zero) can be calculated using *l1_min_c*.

- Fan, Rong-En, et al., "LIBLINEAR: A library for large linear classification.", Journal of machine learning research 9.Aug (2008): 1871-1874.

Kernel functions

The *kernel function* can be any of the following:

- linear: $\langle x, x' \rangle$.
- polynomial: $(\gamma \langle x, x' \rangle + r)^d$. d is specified by keyword `degree`, r by `coef0`.
- rbf: $\exp(-\gamma \|x - x'\|^2)$. γ is specified by keyword `gamma`, must be greater than 0.
- sigmoid ($\tanh(\gamma \langle x, x' \rangle + r)$), where r is specified by `coef0`.

Different kernels are specified by keyword kernel at initialization:

```
>>> linear_svc = svm.SVC(kernel='linear')
>>> linear_svc.kernel
```

(continues on next page)

(continued from previous page)

```
'linear'
>>> rbf_svc = svm.SVC(kernel='rbf')
>>> rbf_svc.kernel
'rbf'
```

Custom Kernels

You can define your own kernels by either giving the kernel as a python function or by precomputing the Gram matrix.

Classifiers with custom kernels behave the same way as any other classifiers, except that:

- Field `support_vectors_` is now empty, only indices of support vectors are stored in `support_`
- A reference (and not a copy) of the first argument in the `fit()` method is stored for future reference. If that array changes between the use of `fit()` and `predict()` you will have unexpected results.

Using Python functions as kernels

You can also use your own defined kernels by passing a function to the keyword `kernel` in the constructor.

Your kernel must take as arguments two matrices of shape `(n_samples_1, n_features)`, `(n_samples_2, n_features)` and return a kernel matrix of shape `(n_samples_1, n_samples_2)`.

The following code defines a linear kernel and creates a classifier instance that will use that kernel:

```
>>> import numpy as np
>>> from sklearn import svm
>>> def my_kernel(X, Y):
...     return np.dot(X, Y.T)
...
>>> clf = svm.SVC(kernel=my_kernel)
```

Examples:

- *SVM with custom kernel*.

Using the Gram matrix

Set `kernel='precomputed'` and pass the Gram matrix instead of X in the fit method. At the moment, the kernel values between *all* training vectors and the test vectors must be provided.

```
>>> import numpy as np
>>> from sklearn import svm
>>> X = np.array([[0, 0], [1, 1]])
>>> y = [0, 1]
>>> clf = svm.SVC(kernel='precomputed')
>>> # linear kernel computation
>>> gram = np.dot(X, X.T)
>>> clf.fit(gram, y)
SVC(kernel='precomputed')
>>> # predict on training examples
```

(continues on next page)

(continued from previous page)

```
>>> clf.predict(gram)
array([0, 1])
```

Parameters of the RBF Kernel

When training an SVM with the *Radial Basis Function* (RBF) kernel, two parameters must be considered: `C` and `gamma`. The parameter `C`, common to all SVM kernels, trades off misclassification of training examples against simplicity of the decision surface. A low `C` makes the decision surface smooth, while a high `C` aims at classifying all training examples correctly. `gamma` defines how much influence a single training example has. The larger `gamma` is, the closer other examples must be to be affected.

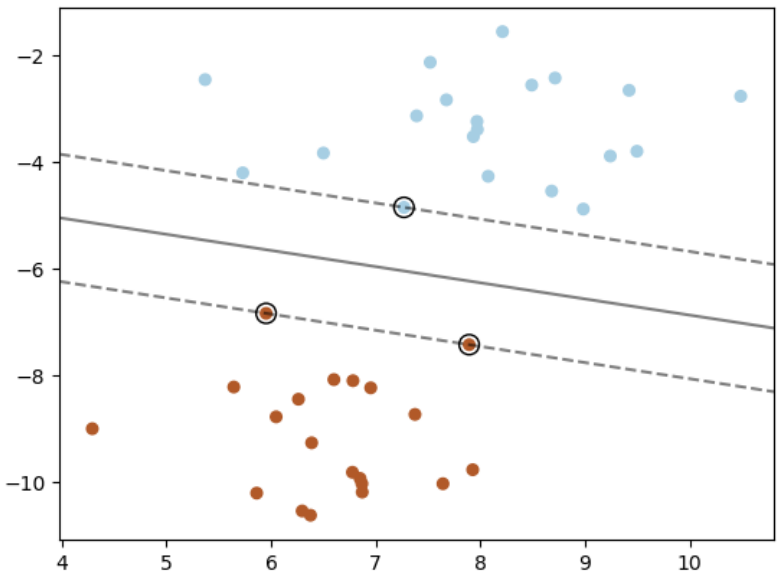
Proper choice of `C` and `gamma` is critical to the SVM's performance. One is advised to use *sklearn.model_selection.GridSearchCV* with `C` and `gamma` spaced exponentially far apart to choose good values.

Examples:

- *RBF SVM parameters*

Mathematical formulation

A support vector machine constructs a hyper-plane or set of hyper-planes in a high or infinite dimensional space, which can be used for classification, regression or other tasks. Intuitively, a good separation is achieved by the hyper-plane that has the largest distance to the nearest training data points of any class (so-called functional margin), since in general the larger the margin the lower the generalization error of the classifier.



SVC

Given training vectors $x_i \in \mathbb{R}^p$, i=1,..., n, in two classes, and a vector $y \in \{1, -1\}^n$, SVC solves the following primal problem:

$$\min_{w,b,\zeta} \frac{1}{2} w^T w + C \sum_{i=1}^{n} \zeta_i$$
$$\text{subject to } y_i(w^T \phi(x_i) + b) \geq 1 - \zeta_i,$$
$$\zeta_i \geq 0, i = 1, ..., n$$

Its dual is

$$\min_{\alpha} \frac{1}{2} \alpha^T Q \alpha - e^T \alpha$$
$$\text{subject to } y^T \alpha = 0$$
$$0 \leq \alpha_i \leq C, i = 1, ..., n$$

where e is the vector of all ones, $C > 0$ is the upper bound, Q is an n by n positive semidefinite matrix, $Q_{ij} \equiv y_i y_j K(x_i, x_j)$, where $K(x_i, x_j) = \phi(x_i)^T \phi(x_j)$ is the kernel. Here training vectors are implicitly mapped into a higher (maybe infinite) dimensional space by the function ϕ.

The decision function is:

$$\text{sgn}(\sum_{i=1}^{n} y_i \alpha_i K(x_i, x) + \rho)$$

Note: While SVM models derived from libsvm and liblinear use `C` as regularization parameter, most other estimators use `alpha`. The exact equivalence between the amount of regularization of two models depends on the exact objective function optimized by the model. For example, when the estimator used is `sklearn.linear_model.Ridge` regression, the relation between them is given as $C = \frac{1}{alpha}$.

This parameters can be accessed through the members `dual_coef_` which holds the product $y_i \alpha_i$, `support_vectors_` which holds the support vectors, and `intercept_` which holds the independent term ρ :

- "Support-vector networks", C. Cortes, V. Vapnik - Machine Learning, 20, 273-297 (1995).

NuSVC

We introduce a new parameter ν which controls the number of support vectors and training errors. The parameter $\nu \in (0, 1]$ is an upper bound on the fraction of training errors and a lower bound of the fraction of support vectors.

It can be shown that the ν-SVC formulation is a reparameterization of the C-SVC and therefore mathematically equivalent.

SVR

Given training vectors $x_i \in \mathbb{R}^p$, i=1,..., n, and a vector $y \in \mathbb{R}^n$ ε-SVR solves the following primal problem:

$$\min_{w,b,\zeta,\zeta^*} \frac{1}{2} w^T w + C \sum_{i=1}^{n} (\zeta_i + \zeta_i^*)$$

$$\text{subject to } y_i - w^T \phi(x_i) - b \leq \varepsilon + \zeta_i,$$
$$w^T \phi(x_i) + b - y_i \leq \varepsilon + \zeta_i^*,$$
$$\zeta_i, \zeta_i^* \geq 0, i = 1, ..., n$$

Its dual is

$$\min_{\alpha,\alpha^*} \frac{1}{2} (\alpha - \alpha^*)^T Q (\alpha - \alpha^*) + \varepsilon e^T (\alpha + \alpha^*) - y^T (\alpha - \alpha^*)$$

$$\text{subject to } e^T (\alpha - \alpha^*) = 0$$
$$0 \leq \alpha_i, \alpha_i^* \leq C, i = 1, ..., n$$

where e is the vector of all ones, $C > 0$ is the upper bound, Q is an n by n positive semidefinite matrix, $Q_{ij} \equiv K(x_i, x_j) = \phi(x_i)^T \phi(x_j)$ is the kernel. Here training vectors are implicitly mapped into a higher (maybe infinite) dimensional space by the function ϕ.

The decision function is:

$$\sum_{i=1}^{n} (\alpha_i - \alpha_i^*) K(x_i, x) + \rho$$

These parameters can be accessed through the members `dual_coef_` which holds the difference $\alpha_i - \alpha_i^*$, `support_vectors_` which holds the support vectors, and `intercept_` which holds the independent term ρ

4.1.5 Stochastic Gradient Descent

Stochastic Gradient Descent (SGD) is a simple yet very efficient approach to discriminative learning of linear classifiers under convex loss functions such as (linear) Support Vector Machines and Logistic Regression. Even though

SGD has been around in the machine learning community for a long time, it has received a considerable amount of attention just recently in the context of large-scale learning.

SGD has been successfully applied to large-scale and sparse machine learning problems often encountered in text classification and natural language processing. Given that the data is sparse, the classifiers in this module easily scale to problems with more than 10^5 training examples and more than 10^5 features.

The advantages of Stochastic Gradient Descent are:

- Efficiency.
- Ease of implementation (lots of opportunities for code tuning).

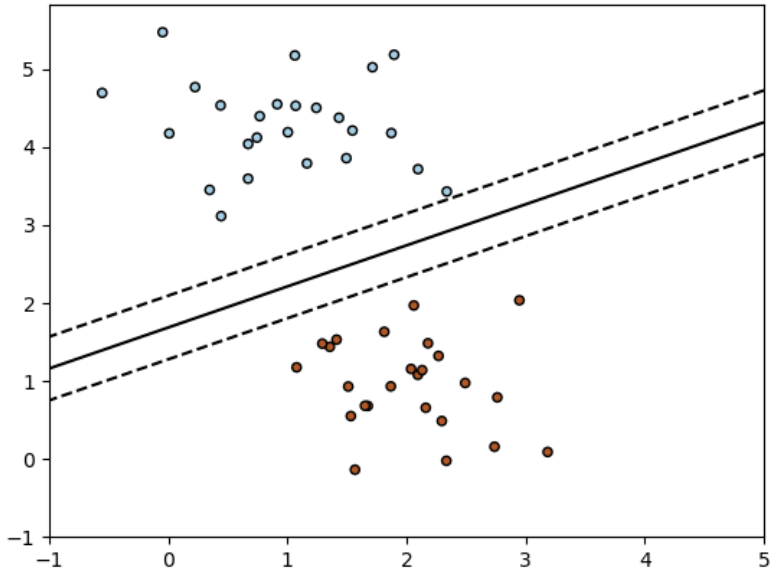
The disadvantages of Stochastic Gradient Descent include:

- SGD requires a number of hyperparameters such as the regularization parameter and the number of iterations.
- SGD is sensitive to feature scaling.

Classification

Warning: Make sure you permute (shuffle) your training data before fitting the model or use `shuffle=True` to shuffle after each iteration.

The class *`SGDClassifier`* implements a plain stochastic gradient descent learning routine which supports different loss functions and penalties for classification.



As other classifiers, SGD has to be fitted with two arrays: an array X of size [n_samples, n_features] holding the training samples, and an array Y of size [n_samples] holding the target values (class labels) for the training samples:

```
>>> from sklearn.linear_model import SGDClassifier
>>> X = [[0., 0.], [1., 1.]]
```

(continues on next page)

(continued from previous page)

```
>>> y = [0, 1]
>>> clf = SGDClassifier(loss="hinge", penalty="l2", max_iter=5)
>>> clf.fit(X, y)
SGDClassifier(max_iter=5)
```

After being fitted, the model can then be used to predict new values:

```
>>> clf.predict([[2., 2.]])
array([1])
```

SGD fits a linear model to the training data. The member `coef_` holds the model parameters:

```
>>> clf.coef_
array([[9.9..., 9.9...]])
```

Member `intercept_` holds the intercept (aka offset or bias):

```
>>> clf.intercept_
array([-9.9...])
```

Whether or not the model should use an intercept, i.e. a biased hyperplane, is controlled by the parameter `fit_intercept`.

To get the signed distance to the hyperplane use *`SGDClassifier.decision_function`*:

```
>>> clf.decision_function([[2., 2.]])
array([29.6...])
```

The concrete loss function can be set via the `loss` parameter. *`SGDClassifier`* supports the following loss functions:

- `loss="hinge"`: (soft-margin) linear Support Vector Machine,
- `loss="modified_huber"`: smoothed hinge loss,
- `loss="log"`: logistic regression,
- and all regression losses below.

The first two loss functions are lazy, they only update the model parameters if an example violates the margin constraint, which makes training very efficient and may result in sparser models, even when L2 penalty is used.

Using `loss="log"` or `loss="modified_huber"` enables the `predict_proba` method, which gives a vector of probability estimates $P(y|x)$ per sample x:

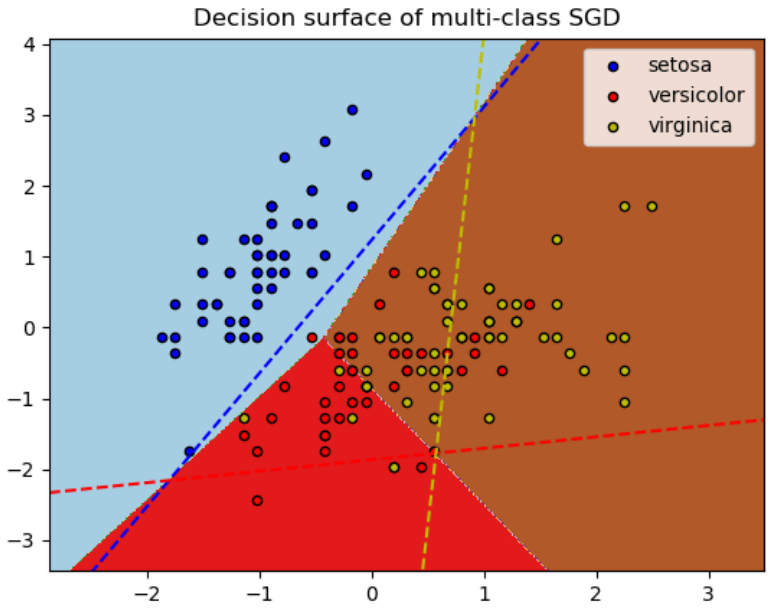
```
>>> clf = SGDClassifier(loss="log", max_iter=5).fit(X, y)
>>> clf.predict_proba([[1., 1.]])
array([[0.00..., 0.99...]])
```

The concrete penalty can be set via the `penalty` parameter. SGD supports the following penalties:

- `penalty="l2"`: L2 norm penalty on `coef_`.
- `penalty="l1"`: L1 norm penalty on `coef_`.
- `penalty="elasticnet"`: Convex combination of L2 and L1; `(1 - l1_ratio) * L2 + l1_ratio * L1`.

The default setting is `penalty="l2"`. The L1 penalty leads to sparse solutions, driving most coefficients to zero. The Elastic Net solves some deficiencies of the L1 penalty in the presence of highly correlated attributes. The parameter `l1_ratio` controls the convex combination of L1 and L2 penalty.

SGDClassifier supports multi-class classification by combining multiple binary classifiers in a "one versus all" (OVA) scheme. For each of the K classes, a binary classifier is learned that discriminates between that and all other $K-1$ classes. At testing time, we compute the confidence score (i.e. the signed distances to the hyperplane) for each classifier and choose the class with the highest confidence. The Figure below illustrates the OVA approach on the iris dataset. The dashed lines represent the three OVA classifiers; the background colors show the decision surface induced by the three classifiers.



In the case of multi-class classification `coef_` is a two-dimensional array of `shape=[n_classes, n_features]` and `intercept_` is a one-dimensional array of `shape=[n_classes]`. The i-th row of `coef_` holds the weight vector of the OVA classifier for the i-th class; classes are indexed in ascending order (see attribute `classes_`). Note that, in principle, since they allow to create a probability model, `loss="log"` and `loss="modified_huber"` are more suitable for one-vs-all classification.

SGDClassifier supports both weighted classes and weighted instances via the fit parameters `class_weight` and `sample_weight`. See the examples below and the docstring of *SGDClassifier.fit* for further information.

Examples:

- *SGD: Maximum margin separating hyperplane*,
- *Plot multi-class SGD on the iris dataset*
- *SGD: Weighted samples*
- *Comparing various online solvers*
- *SVM: Separating hyperplane for unbalanced classes* (See the `Note`)

SGDClassifier supports averaged SGD (ASGD). Averaging can be enabled by setting `` `average=True` ``. ASGD works by averaging the coefficients of the plain SGD over each iteration over a sample. When using ASGD the learning rate can be larger and even constant leading on some datasets to a speed up in training time.

For classification with a logistic loss, another variant of SGD with an averaging strategy is available with Stochastic Average Gradient (SAG) algorithm, available as a solver in *LogisticRegression*.

Regression

The class *SGDRegressor* implements a plain stochastic gradient descent learning routine which supports different loss functions and penalties to fit linear regression models. *SGDRegressor* is well suited for regression problems with a large number of training samples (> 10.000), for other problems we recommend *Ridge*, *Lasso*, or *ElasticNet*.

The concrete loss function can be set via the `loss` parameter. *SGDRegressor* supports the following loss functions:

- `loss="squared_loss"`: Ordinary least squares,
- `loss="huber"`: Huber loss for robust regression,
- `loss="epsilon_insensitive"`: linear Support Vector Regression.

The Huber and epsilon-insensitive loss functions can be used for robust regression. The width of the insensitive region has to be specified via the parameter `epsilon`. This parameter depends on the scale of the target variables.

SGDRegressor supports averaged SGD as *SGDClassifier*. Averaging can be enabled by setting `` `average=True` ``.

For regression with a squared loss and a l2 penalty, another variant of SGD with an averaging strategy is available with Stochastic Average Gradient (SAG) algorithm, available as a solver in *Ridge*.

Stochastic Gradient Descent for sparse data

Note: The sparse implementation produces slightly different results than the dense implementation due to a shrunk learning rate for the intercept.

There is built-in support for sparse data given in any matrix in a format supported by scipy.sparse. For maximum efficiency, however, use the CSR matrix format as defined in scipy.sparse.csr_matrix.

Examples:

- *Classification of text documents using sparse features*

Complexity

The major advantage of SGD is its efficiency, which is basically linear in the number of training examples. If X is a matrix of size (n, p) training has a cost of $O(kn\bar{p})$, where k is the number of iterations (epochs) and $\bar{p}$ is the average number of non-zero attributes per sample.

Recent theoretical results, however, show that the runtime to get some desired optimization accuracy does not increase as the training set size increases.

Stopping criterion

The classes *SGDClassifier* and *SGDRegressor* provide two criteria to stop the algorithm when a given level of convergence is reached:

- With `early_stopping=True`, the input data is split into a training set and a validation set. The model is then fitted on the training set, and the stopping criterion is based on the prediction score computed on the validation set. The size of the validation set can be changed with the parameter `validation_fraction`.
- With `early_stopping=False`, the model is fitted on the entire input data and the stopping criterion is based on the objective function computed on the input data.

In both cases, the criterion is evaluated once by epoch, and the algorithm stops when the criterion does not improve `n_iter_no_change` times in a row. The improvement is evaluated with a tolerance `tol`, and the algorithm stops in any case after a maximum number of iteration `max_iter`.

Tips on Practical Use

- Stochastic Gradient Descent is sensitive to feature scaling, so it is highly recommended to scale your data. For example, scale each attribute on the input vector X to [0,1] or [-1,+1], or standardize it to have mean 0 and variance 1. Note that the *same* scaling must be applied to the test vector to obtain meaningful results. This can be easily done using `StandardScaler`:

```
from sklearn.preprocessing import StandardScaler
scaler = StandardScaler()
scaler.fit(X_train)  # Don't cheat - fit only on training data
X_train = scaler.transform(X_train)
X_test = scaler.transform(X_test)  # apply same transformation to test data
```

  If your attributes have an intrinsic scale (e.g. word frequencies or indicator features) scaling is not needed.

- Finding a reasonable regularization term α is best done using `GridSearchCV`, usually in the range `10.0**-np.arange(1,7)`.
- Empirically, we found that SGD converges after observing approx. 10^6 training samples. Thus, a reasonable first guess for the number of iterations is `max_iter = np.ceil(10**6 / n)`, where `n` is the size of the training set.
- If you apply SGD to features extracted using PCA we found that it is often wise to scale the feature values by some constant `c` such that the average L2 norm of the training data equals one.
- We found that Averaged SGD works best with a larger number of features and a higher eta0

Mathematical formulation

Given a set of training examples $(x_1, y_1), \ldots, (x_n, y_n)$ where $x_i \in \mathbf{R}^m$ and $y_i \in \{-1, 1\}$, our goal is to learn a linear scoring function $f(x) = w^T x + b$ with model parameters $w \in \mathbf{R}^m$ and intercept $b \in \mathbf{R}$. In order to make predictions, we simply look at the sign of $f(x)$. A common choice to find the model parameters is by minimizing the regularized training error given by

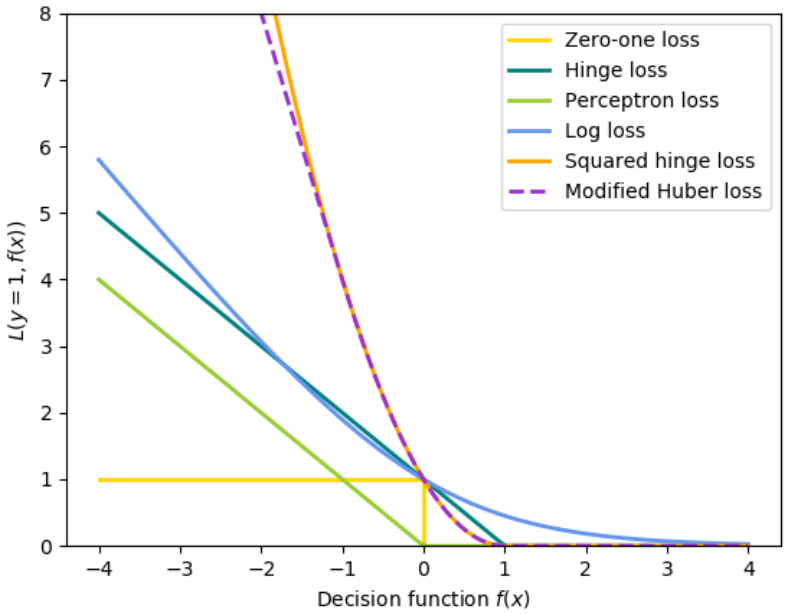
$$E(w, b) = \frac{1}{n} \sum_{i=1}^{n} L(y_i, f(x_i)) + \alpha R(w)$$

where L is a loss function that measures model (mis)fit and R is a regularization term (aka penalty) that penalizes model complexity; $\alpha > 0$ is a non-negative hyperparameter.

Different choices for L entail different classifiers such as

- Hinge: (soft-margin) Support Vector Machines.
- Log: Logistic Regression.
- Least-Squares: Ridge Regression.
- Epsilon-Insensitive: (soft-margin) Support Vector Regression.

All of the above loss functions can be regarded as an upper bound on the misclassification error (Zero-one loss) as shown in the Figure below.



Popular choices for the regularization term R include:

- L2 norm: $R(w) := \frac{1}{2}\sum_{i=1}^{n} w_i^2$,
- L1 norm: $R(w) := \sum_{i=1}^{n} |w_i|$, which leads to sparse solutions.
- Elastic Net: $R(w) := \frac{\rho}{2}\sum_{i=1}^{n} w_i^2 + (1-\rho)\sum_{i=1}^{n} |w_i|$, a convex combination of L2 and L1, where ρ is given by `1 - l1_ratio`.

The Figure below shows the contours of the different regularization terms in the parameter space when $R(w) = 1$.

SGD

Stochastic gradient descent is an optimization method for unconstrained optimization problems. In contrast to (batch) gradient descent, SGD approximates the true gradient of $E(w, b)$ by considering a single training example at a time.

The class *`SGDClassifier`* implements a first-order SGD learning routine. The algorithm iterates over the training examples and for each example updates the model parameters according to the update rule given by

$$w \leftarrow w - \eta(\alpha\frac{\partial R(w)}{\partial w} + \frac{\partial L(w^T x_i + b, y_i)}{\partial w})$$

where η is the learning rate which controls the step-size in the parameter space. The intercept b is updated similarly but without regularization.

The learning rate η can be either constant or gradually decaying. For classification, the default learning rate schedule (`learning_rate='optimal'`) is given by

$$\eta^{(t)} = \frac{1}{\alpha(t_0 + t)}$$

where t is the time step (there are a total of `n_samples * n_iter` time steps), t_0 is determined based on a heuristic proposed by Léon Bottou such that the expected initial updates are comparable with the expected size of the weights (this assuming that the norm of the training samples is approx. 1). The exact definition can be found in `_init_t` in `BaseSGD`.

For regression the default learning rate schedule is inverse scaling (`learning_rate='invscaling'`), given by

$$\eta^{(t)} = \frac{eta_0}{t^{power\_t}}$$

where eta_0 and $power\_t$ are hyperparameters chosen by the user via `eta0` and `power_t`, resp.

For a constant learning rate use `learning_rate='constant'` and use `eta0` to specify the learning rate.

For an adaptively decreasing learning rate, use `learning_rate='adaptive'` and use `eta0` to specify the starting learning rate. When the stopping criterion is reached, the learning rate is divided by 5, and the algorithm does not stop. The algorithm stops when the learning rate goes below 1e-6.

The model parameters can be accessed through the members `coef_` and `intercept_`:

- Member `coef_` holds the weights w
- Member `intercept_` holds b

Implementation details

The implementation of SGD is influenced by the Stochastic Gradient SVM of Léon Bottou. Similar to SvmSGD, the weight vector is represented as the product of a scalar and a vector which allows an efficient weight update in the case of L2 regularization. In the case of sparse feature vectors, the intercept is updated with a smaller learning rate (multiplied by 0.01) to account for the fact that it is updated more frequently. Training examples are picked up sequentially and the learning rate is lowered after each observed example. We adopted the learning rate schedule from Shalev-Shwartz et al. 2007. For multi-class classification, a "one versus all" approach is used. We use the truncated gradient algorithm proposed by Tsuruoka et al. 2009 for L1 regularization (and the Elastic Net). The code is written in Cython.

4.1.6 Nearest Neighbors

`sklearn.neighbors` provides functionality for unsupervised and supervised neighbors-based learning methods. Unsupervised nearest neighbors is the foundation of many other learning methods, notably manifold learning and spectral clustering. Supervised neighbors-based learning comes in two flavors: *classification* for data with discrete labels, and *regression* for data with continuous labels.

The principle behind nearest neighbor methods is to find a predefined number of training samples closest in distance to the new point, and predict the label from these. The number of samples can be a user-defined constant (k-nearest neighbor learning), or vary based on the local density of points (radius-based neighbor learning). The distance can, in general, be any metric measure: standard Euclidean distance is the most common choice. Neighbors-based methods are known as *non-generalizing* machine learning methods, since they simply "remember" all of its training data (possibly transformed into a fast indexing structure such as a *Ball Tree* or *KD Tree*).

Despite its simplicity, nearest neighbors has been successful in a large number of classification and regression problems, including handwritten digits and satellite image scenes. Being a non-parametric method, it is often successful in classification situations where the decision boundary is very irregular.

The classes in `sklearn.neighbors` can handle either NumPy arrays or `scipy.sparse` matrices as input. For dense matrices, a large number of possible distance metrics are supported. For sparse matrices, arbitrary Minkowski metrics are supported for searches.

There are many learning routines which rely on nearest neighbors at their core. One example is *kernel density estimation*, discussed in the *density estimation* section.

Unsupervised Nearest Neighbors

`NearestNeighbors` implements unsupervised nearest neighbors learning. It acts as a uniform interface to three different nearest neighbors algorithms: `BallTree`, `KDTree`, and a brute-force algorithm based on routines in `sklearn.metrics.pairwise`. The choice of neighbors search algorithm is controlled through the keyword `'algorithm'`, which must be one of `['auto', 'ball_tree', 'kd_tree', 'brute']`. When the default value `'auto'` is passed, the algorithm attempts to determine the best approach from the training data. For a discussion of the strengths and weaknesses of each option, see *Nearest Neighbor Algorithms*.

> **Warning:** Regarding the Nearest Neighbors algorithms, if two neighbors $k+1$ and k have identical distances but different labels, the result will depend on the ordering of the training data.

Finding the Nearest Neighbors

For the simple task of finding the nearest neighbors between two sets of data, the unsupervised algorithms within `sklearn.neighbors` can be used:

```
>>> from sklearn.neighbors import NearestNeighbors
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
```

(continues on next page)

(continued from previous page)

```
>>> nbrs = NearestNeighbors(n_neighbors=2, algorithm='ball_tree').fit(X)
>>> distances, indices = nbrs.kneighbors(X)
>>> indices
array([[0, 1],
       [1, 0],
       [2, 1],
       [3, 4],
       [4, 3],
       [5, 4]]...)
>>> distances
array([[0.        , 1.        ],
       [0.        , 1.        ],
       [0.        , 1.41421356],
       [0.        , 1.        ],
       [0.        , 1.        ],
       [0.        , 1.41421356]])
```

Because the query set matches the training set, the nearest neighbor of each point is the point itself, at a distance of zero.

It is also possible to efficiently produce a sparse graph showing the connections between neighboring points:

```
>>> nbrs.kneighbors_graph(X).toarray()
array([[1., 1., 0., 0., 0., 0.],
       [1., 1., 0., 0., 0., 0.],
       [0., 1., 1., 0., 0., 0.],
       [0., 0., 0., 1., 1., 0.],
       [0., 0., 0., 1., 1., 0.],
       [0., 0., 0., 0., 1., 1.]])
```

The dataset is structured such that points nearby in index order are nearby in parameter space, leading to an approximately block-diagonal matrix of K-nearest neighbors. Such a sparse graph is useful in a variety of circumstances which make use of spatial relationships between points for unsupervised learning: in particular, see *sklearn.manifold.Isomap*, *sklearn.manifold.LocallyLinearEmbedding*, and *sklearn.cluster.SpectralClustering*.

KDTree and BallTree Classes

Alternatively, one can use the *KDTree* or *BallTree* classes directly to find nearest neighbors. This is the functionality wrapped by the *NearestNeighbors* class used above. The Ball Tree and KD Tree have the same interface; we'll show an example of using the KD Tree here:

```
>>> from sklearn.neighbors import KDTree
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
>>> kdt = KDTree(X, leaf_size=30, metric='euclidean')
>>> kdt.query(X, k=2, return_distance=False)
array([[0, 1],
       [1, 0],
       [2, 1],
       [3, 4],
       [4, 3],
       [5, 4]]...)
```

Refer to the *KDTree* and *BallTree* class documentation for more information on the options available for nearest

neighbors searches, including specification of query strategies, distance metrics, etc. For a list of available metrics, see the documentation of the `DistanceMetric` class.

Nearest Neighbors Classification

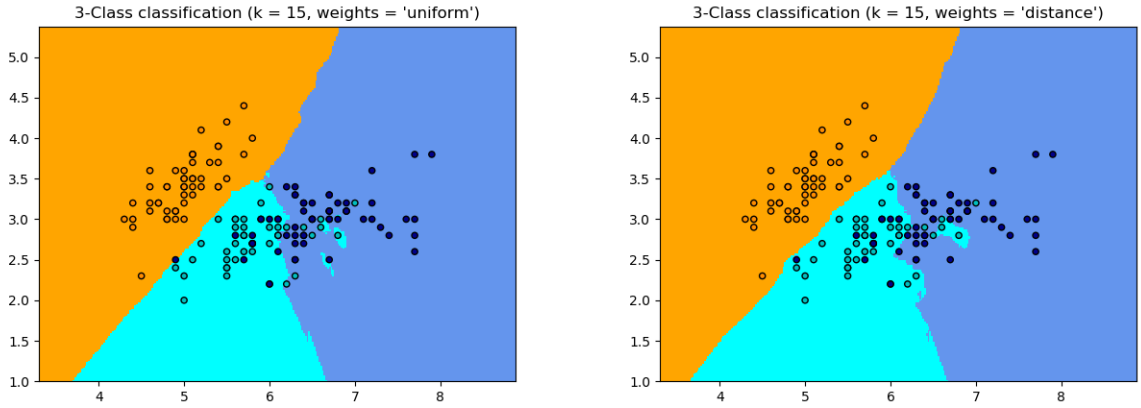
Neighbors-based classification is a type of *instance-based learning* or *non-generalizing learning*: it does not attempt to construct a general internal model, but simply stores instances of the training data. Classification is computed from a simple majority vote of the nearest neighbors of each point: a query point is assigned the data class which has the most representatives within the nearest neighbors of the point.

scikit-learn implements two different nearest neighbors classifiers: `KNeighborsClassifier` implements learning based on the k nearest neighbors of each query point, where k is an integer value specified by the user. `RadiusNeighborsClassifier` implements learning based on the number of neighbors within a fixed radius r of each training point, where r is a floating-point value specified by the user.

The k-neighbors classification in `KNeighborsClassifier` is the most commonly used technique. The optimal choice of the value k is highly data-dependent: in general a larger k suppresses the effects of noise, but makes the classification boundaries less distinct.

In cases where the data is not uniformly sampled, radius-based neighbors classification in `RadiusNeighborsClassifier` can be a better choice. The user specifies a fixed radius r, such that points in sparser neighborhoods use fewer nearest neighbors for the classification. For high-dimensional parameter spaces, this method becomes less effective due to the so-called "curse of dimensionality".

The basic nearest neighbors classification uses uniform weights: that is, the value assigned to a query point is computed from a simple majority vote of the nearest neighbors. Under some circumstances, it is better to weight the neighbors such that nearer neighbors contribute more to the fit. This can be accomplished through the `weights` keyword. The default value, `weights = 'uniform'`, assigns uniform weights to each neighbor. `weights = 'distance'` assigns weights proportional to the inverse of the distance from the query point. Alternatively, a user-defined function of the distance can be supplied to compute the weights.



Examples:

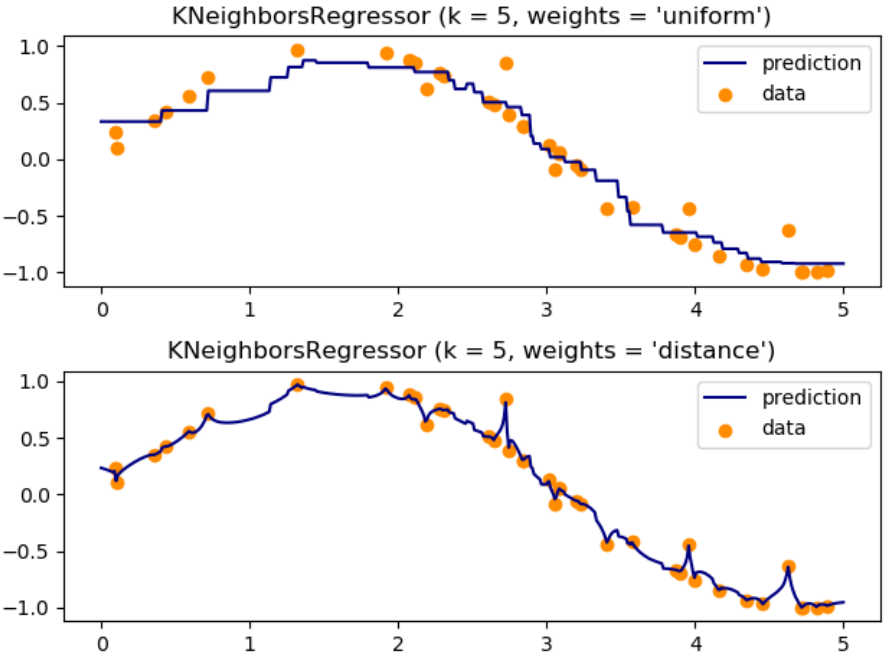
- *Nearest Neighbors Classification*: an example of classification using nearest neighbors.

Nearest Neighbors Regression

Neighbors-based regression can be used in cases where the data labels are continuous rather than discrete variables. The label assigned to a query point is computed based on the mean of the labels of its nearest neighbors.

scikit-learn implements two different neighbors regressors: `KNeighborsRegressor` implements learning based on the k nearest neighbors of each query point, where k is an integer value specified by the user. `RadiusNeighborsRegressor` implements learning based on the neighbors within a fixed radius r of the query point, where r is a floating-point value specified by the user.

The basic nearest neighbors regression uses uniform weights: that is, each point in the local neighborhood contributes uniformly to the classification of a query point. Under some circumstances, it can be advantageous to weight points such that nearby points contribute more to the regression than faraway points. This can be accomplished through the `weights` keyword. The default value, `weights = 'uniform'`, assigns equal weights to all points. `weights = 'distance'` assigns weights proportional to the inverse of the distance from the query point. Alternatively, a user-defined function of the distance can be supplied, which will be used to compute the weights.



The use of multi-output nearest neighbors for regression is demonstrated in *Face completion with a multi-output estimators*. In this example, the inputs X are the pixels of the upper half of faces and the outputs Y are the pixels of the lower half of those faces.

Examples:

- *Nearest Neighbors regression*: an example of regression using nearest neighbors.
- *Face completion with a multi-output estimators*: an example of multi-output regression using nearest neighbors.

Brute Force

Fast computation of nearest neighbors is an active area of research in machine learning. The most naive neighbor search implementation involves the brute-force computation of distances between all pairs of points in the dataset: for N samples in D dimensions, this approach scales as $O[DN^2]$. Efficient brute-force neighbors searches can be very competitive for small data samples. However, as the number of samples N grows, the brute-force approach quickly becomes infeasible. In the classes within *sklearn.neighbors*, brute-force neighbors searches are specified using the keyword `algorithm = 'brute'`, and are computed using the routines available in *sklearn.metrics.pairwise*.

K-D Tree

To address the computational inefficiencies of the brute-force approach, a variety of tree-based data structures have been invented. In general, these structures attempt to reduce the required number of distance calculations by efficiently encoding aggregate distance information for the sample. The basic idea is that if point A is very distant from point B, and point B is very close to point C, then we know that points A and C are very distant, *without having to explicitly calculate their distance*. In this way, the computational cost of a nearest neighbors search can be reduced to $O[DN \log(N)]$ or better. This is a significant improvement over brute-force for large N.

An early approach to taking advantage of this aggregate information was the *KD tree* data structure (short for *K-dimensional tree*), which generalizes two-dimensional *Quad-trees* and 3-dimensional *Oct-trees* to an arbitrary number of dimensions. The KD tree is a binary tree structure which recursively partitions the parameter space along the data axes, dividing it into nested orthotropic regions into which data points are filed. The construction of a KD tree is very fast: because partitioning is performed only along the data axes, no D-dimensional distances need to be computed. Once constructed, the nearest neighbor of a query point can be determined with only $O[\log(N)]$ distance computations. Though the KD tree approach is very fast for low-dimensional ($D < 20$) neighbors searches, it becomes inefficient as D grows very large: this is one manifestation of the so-called "curse of dimensionality". In scikit-learn, KD tree neighbors searches are specified using the keyword `algorithm = 'kd_tree'`, and are computed using the class *KDTree*.

References:

- "Multidimensional binary search trees used for associative searching", Bentley, J.L., Communications of the ACM (1975)

Ball Tree

To address the inefficiencies of KD Trees in higher dimensions, the *ball tree* data structure was developed. Where KD trees partition data along Cartesian axes, ball trees partition data in a series of nesting hyper-spheres. This makes tree construction more costly than that of the KD tree, but results in a data structure which can be very efficient on highly structured data, even in very high dimensions.

A ball tree recursively divides the data into nodes defined by a centroid C and radius r, such that each point in the node lies within the hyper-sphere defined by r and C. The number of candidate points for a neighbor search is reduced through use of the *triangle inequality*:

$$|x + y| \leq |x| + |y|$$

With this setup, a single distance calculation between a test point and the centroid is sufficient to determine a lower and upper bound on the distance to all points within the node. Because of the spherical geometry of the ball tree nodes, it can out-perform a *KD-tree* in high dimensions, though the actual performance is highly dependent on the structure

of the training data. In scikit-learn, ball-tree-based neighbors searches are specified using the keyword `algorithm = 'ball_tree'`, and are computed using the class *`sklearn.neighbors.BallTree`*. Alternatively, the user can work with the *`BallTree`* class directly.

References:

- "Five balltree construction algorithms", Omohundro, S.M., International Computer Science Institute Technical Report (1989)

Choice of Nearest Neighbors Algorithm

The optimal algorithm for a given dataset is a complicated choice, and depends on a number of factors:

- number of samples N (i.e. `n_samples`) and dimensionality D (i.e. `n_features`).
  - *Brute force* query time grows as $O[DN]$
  - *Ball tree* query time grows as approximately $O[D\log(N)]$
  - *KD tree* query time changes with D in a way that is difficult to precisely characterise. For small D (less than 20 or so) the cost is approximately $O[D\log(N)]$, and the KD tree query can be very efficient. For larger D, the cost increases to nearly $O[DN]$, and the overhead due to the tree structure can lead to queries which are slower than brute force.

  For small data sets (N less than 30 or so), $\log(N)$ is comparable to N, and brute force algorithms can be more efficient than a tree-based approach. Both *`KDTree`* and *`BallTree`* address this through providing a *leaf size* parameter: this controls the number of samples at which a query switches to brute-force. This allows both algorithms to approach the efficiency of a brute-force computation for small N.
- data structure: *intrinsic dimensionality* of the data and/or *sparsity* of the data. Intrinsic dimensionality refers to the dimension $d \le D$ of a manifold on which the data lies, which can be linearly or non-linearly embedded in the parameter space. Sparsity refers to the degree to which the data fills the parameter space (this is to be distinguished from the concept as used in "sparse" matrices. The data matrix may have no zero entries, but the **structure** can still be "sparse" in this sense).
  - *Brute force* query time is unchanged by data structure.
  - *Ball tree* and *KD tree* query times can be greatly influenced by data structure. In general, sparser data with a smaller intrinsic dimensionality leads to faster query times. Because the KD tree internal representation is aligned with the parameter axes, it will not generally show as much improvement as ball tree for arbitrarily structured data.

  Datasets used in machine learning tend to be very structured, and are very well-suited for tree-based queries.
- number of neighbors k requested for a query point.
  - *Brute force* query time is largely unaffected by the value of k
  - *Ball tree* and *KD tree* query time will become slower as k increases. This is due to two effects: first, a larger k leads to the necessity to search a larger portion of the parameter space. Second, using $k > 1$ requires internal queueing of results as the tree is traversed.

  As k becomes large compared to N, the ability to prune branches in a tree-based query is reduced. In this situation, Brute force queries can be more efficient.
- number of query points. Both the ball tree and the KD Tree require a construction phase. The cost of this construction becomes negligible when amortized over many queries. If only a small number of queries will

be performed, however, the construction can make up a significant fraction of the total cost. If very few query points will be required, brute force is better than a tree-based method.

Currently, `algorithm = 'auto'` selects `'brute'` if $k >= N/2$, the input data is sparse, or `effective_metric_` isn't in the `VALID_METRICS` list for either `'kd_tree'` or `'ball_tree'`. Otherwise, it selects the first out of `'kd_tree'` and `'ball_tree'` that has `effective_metric_` in its `VALID_METRICS` list. This choice is based on the assumption that the number of query points is at least the same order as the number of training points, and that `leaf_size` is close to its default value of `30`.

Effect of `leaf_size`

As noted above, for small sample sizes a brute force search can be more efficient than a tree-based query. This fact is accounted for in the ball tree and KD tree by internally switching to brute force searches within leaf nodes. The level of this switch can be specified with the parameter `leaf_size`. This parameter choice has many effects:

construction time A larger `leaf_size` leads to a faster tree construction time, because fewer nodes need to be created

query time Both a large or small `leaf_size` can lead to suboptimal query cost. For `leaf_size` approaching 1, the overhead involved in traversing nodes can significantly slow query times. For `leaf_size` approaching the size of the training set, queries become essentially brute force. A good compromise between these is `leaf_size = 30`, the default value of the parameter.

memory As `leaf_size` increases, the memory required to store a tree structure decreases. This is especially important in the case of ball tree, which stores a D-dimensional centroid for each node. The required storage space for *BallTree* is approximately `1 / leaf_size` times the size of the training set.

`leaf_size` is not referenced for brute force queries.

Nearest Centroid Classifier

The *NearestCentroid* classifier is a simple algorithm that represents each class by the centroid of its members. In effect, this makes it similar to the label updating phase of the *sklearn.cluster.KMeans* algorithm. It also has no parameters to choose, making it a good baseline classifier. It does, however, suffer on non-convex classes, as well as when classes have drastically different variances, as equal variance in all dimensions is assumed. See Linear Discriminant Analysis (*sklearn.discriminant_analysis.LinearDiscriminantAnalysis*) and Quadratic Discriminant Analysis (*sklearn.discriminant_analysis.QuadraticDiscriminantAnalysis*) for more complex methods that do not make this assumption. Usage of the default *NearestCentroid* is simple:

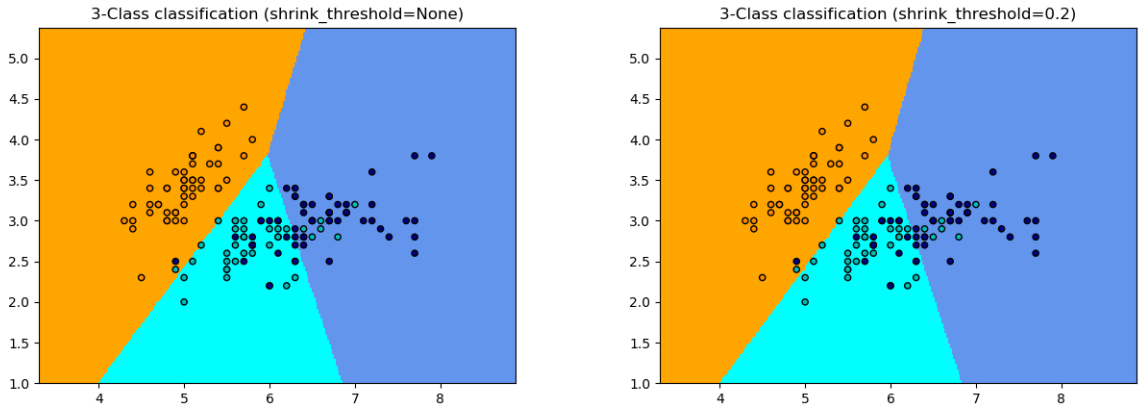
```
>>> from sklearn.neighbors import NearestCentroid
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
>>> y = np.array([1, 1, 1, 2, 2, 2])
>>> clf = NearestCentroid()
>>> clf.fit(X, y)
NearestCentroid()
>>> print(clf.predict([[-0.8, -1]]))
[1]
```

Nearest Shrunken Centroid

The *NearestCentroid* classifier has a `shrink_threshold` parameter, which implements the nearest shrunken centroid classifier. In effect, the value of each feature for each centroid is divided by the within-class variance of that feature. The feature values are then reduced by `shrink_threshold`. Most notably, if a particular feature value

crosses zero, it is set to zero. In effect, this removes the feature from affecting the classification. This is useful, for example, for removing noisy features.

In the example below, using a small shrink threshold increases the accuracy of the model from 0.81 to 0.82.



Examples:

- *Nearest Centroid Classification*: an example of classification using nearest centroid with different shrink thresholds.

Nearest Neighbors Transformer

Many scikit-learn estimators rely on nearest neighbors: Several classifiers and regressors such as `KNeighborsClassifier` and `KNeighborsRegressor`, but also some clustering methods such as `DBSCAN` and `SpectralClustering`, and some manifold embeddings such as `TSNE` and `Isomap`.

All these estimators can compute internally the nearest neighbors, but most of them also accept precomputed nearest neighbors *sparse graph*, as given by `kneighbors_graph` and `radius_neighbors_graph`. With mode `mode='connectivity'`, these functions return a binary adjacency sparse graph as required, for instance, in `SpectralClustering`. Whereas with `mode='distance'`, they return a distance sparse graph as required, for instance, in `DBSCAN`. To include these functions in a scikit-learn pipeline, one can also use the corresponding classes `KNeighborsTransformer` and `RadiusNeighborsTransformer`. The benefits of this sparse graph API are multiple.

First, the precomputed graph can be re-used multiple times, for instance while varying a parameter of the estimator. This can be done manually by the user, or using the caching properties of the scikit-learn pipeline:

```
>>> from sklearn.manifold import Isomap
>>> from sklearn.neighbors import KNeighborsTransformer
>>> from sklearn.pipeline import make_pipeline
>>> estimator = make_pipeline(
...     KNeighborsTransformer(n_neighbors=5, mode='distance'),
...     Isomap(neighbors_algorithm='precomputed'),
...     memory='/path/to/cache')
```

Second, precomputing the graph can give finer control on the nearest neighbors estimation, for instance enabling multiprocessing though the parameter `n_jobs`, which might not be available in all estimators.

Finally, the precomputation can be performed by custom estimators to use different implementations, such as approximate nearest neighbors methods, or implementation with special data types. The precomputed neighbors *sparse graph*

needs to be formatted as in *radius_neighbors_graph* output:

- a CSR matrix (although COO, CSC or LIL will be accepted).
- only explicitly store nearest neighborhoods of each sample with respect to the training data. This should include those at 0 distance from a query point, including the matrix diagonal when computing the nearest neighborhoods between the training data and itself.
- each row's `data` should store the distance in increasing order (optional. Unsorted data will be stable-sorted, adding a computational overhead).
- all values in data should be non-negative.
- there should be no duplicate `indices` in any row (see https://github.com/scipy/scipy/issues/5807).
- if the algorithm being passed the precomputed matrix uses k nearest neighbors (as opposed to radius neighborhood), at least k neighbors must be stored in each row (or k+1, as explained in the following note).

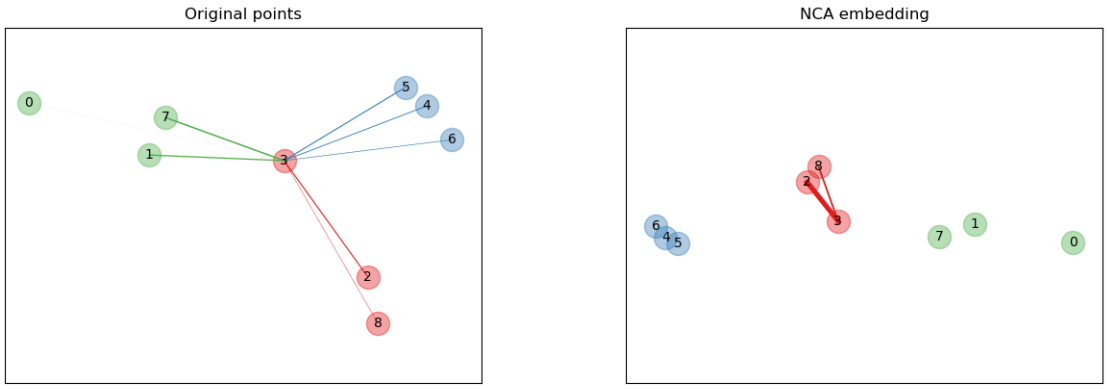
Note: When a specific number of neighbors is queried (using *KNeighborsTransformer*), the definition of `n_neighbors` is ambiguous since it can either include each training point as its own neighbor, or exclude them. Neither choice is perfect, since including them leads to a different number of non-self neighbors during training and testing, while excluding them leads to a difference between `fit(X).transform(X)` and `fit_transform(X)`, which is against scikit-learn API. In *KNeighborsTransformer* we use the definition which includes each training point as its own neighbor in the count of `n_neighbors`. However, for compatibility reasons with other estimators which use the other definition, one extra neighbor will be computed when `mode == 'distance'`. To maximise compatibility with all estimators, a safe choice is to always include one extra neighbor in a custom nearest neighbors estimator, since unnecessary neighbors will be filtered by following estimators.

Examples:

- *Approximate nearest neighbors in TSNE*: an example of pipelining *KNeighborsTransformer* and *TSNE*. Also proposes two custom nearest neighbors estimators based on external packages.
- *Caching nearest neighbors*: an example of pipelining *KNeighborsTransformer* and *KNeighborsClassifier* to enable caching of the neighbors graph during a hyper-parameter grid-search.

Neighborhood Components Analysis

Neighborhood Components Analysis (NCA, *NeighborhoodComponentsAnalysis*) is a distance metric learning algorithm which aims to improve the accuracy of nearest neighbors classification compared to the standard Euclidean distance. The algorithm directly maximizes a stochastic variant of the leave-one-out k-nearest neighbors (KNN) score on the training set. It can also learn a low-dimensional linear projection of data that can be used for data visualization and fast classification.



In the above illustrating figure, we consider some points from a randomly generated dataset. We focus on the stochastic KNN classification of point no. 3. The thickness of a link between sample 3 and another point is proportional to their distance, and can be seen as the relative weight (or probability) that a stochastic nearest neighbor prediction rule would assign to this point. In the original space, sample 3 has many stochastic neighbors from various classes, so the right class is not very likely. However, in the projected space learned by NCA, the only stochastic neighbors with non-negligible weight are from the same class as sample 3, guaranteeing that the latter will be well classified. See the *mathematical formulation* for more details.

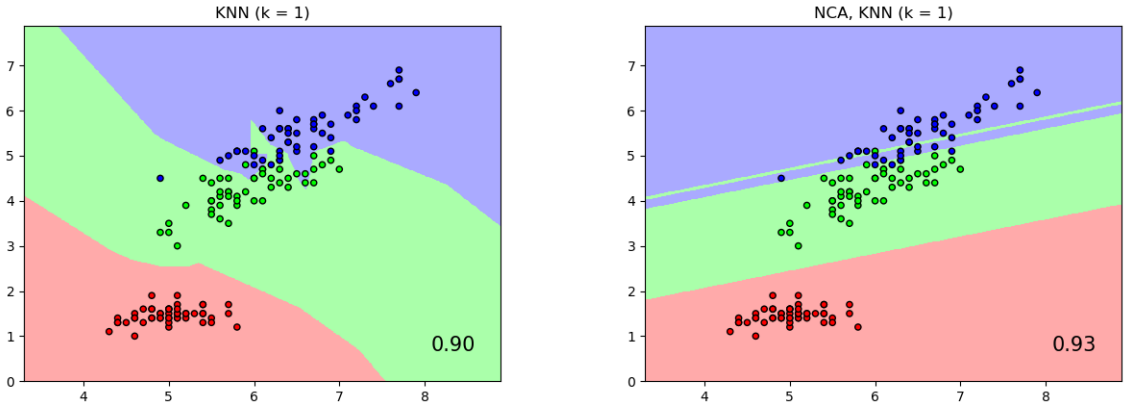
Classification

Combined with a nearest neighbors classifier (`KNeighborsClassifier`), NCA is attractive for classification because it can naturally handle multi-class problems without any increase in the model size, and does not introduce additional parameters that require fine-tuning by the user.

NCA classification has been shown to work well in practice for data sets of varying size and difficulty. In contrast to related methods such as Linear Discriminant Analysis, NCA does not make any assumptions about the class distributions. The nearest neighbor classification can naturally produce highly irregular decision boundaries.

To use this model for classification, one needs to combine a `NeighborhoodComponentsAnalysis` instance that learns the optimal transformation with a `KNeighborsClassifier` instance that performs the classification in the projected space. Here is an example using the two classes:

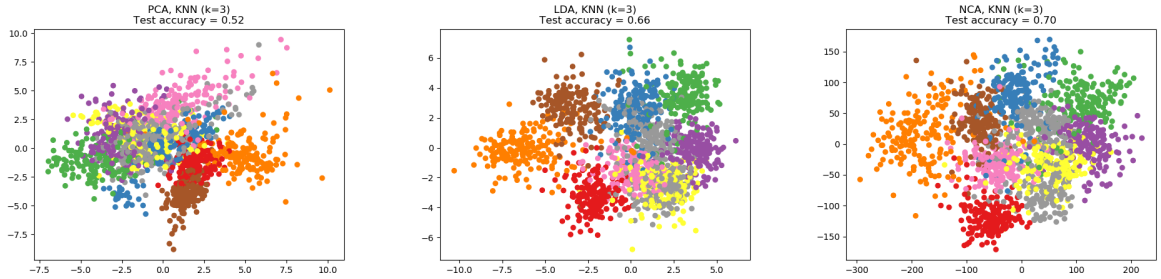
```
>>> from sklearn.neighbors import (NeighborhoodComponentsAnalysis,
... KNeighborsClassifier)
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.pipeline import Pipeline
>>> X, y = load_iris(return_X_y=True)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y,
... stratify=y, test_size=0.7, random_state=42)
>>> nca = NeighborhoodComponentsAnalysis(random_state=42)
>>> knn = KNeighborsClassifier(n_neighbors=3)
>>> nca_pipe = Pipeline([('nca', nca), ('knn', knn)])
>>> nca_pipe.fit(X_train, y_train)
Pipeline(...)
>>> print(nca_pipe.score(X_test, y_test))
0.96190476...
```



The plot shows decision boundaries for Nearest Neighbor Classification and Neighborhood Components Analysis classification on the iris dataset, when training and scoring on only two features, for visualisation purposes.

Dimensionality reduction

NCA can be used to perform supervised dimensionality reduction. The input data are projected onto a linear subspace consisting of the directions which minimize the NCA objective. The desired dimensionality can be set using the parameter `n_components`. For instance, the following figure shows a comparison of dimensionality reduction with Principal Component Analysis (*`sklearn.decomposition.PCA`*), Linear Discriminant Analysis (*`sklearn.discriminant_analysis.LinearDiscriminantAnalysis`*) and Neighborhood Component Analysis (*`NeighborhoodComponentsAnalysis`*) on the Digits dataset, a dataset with size $n_{samples} = 1797$ and $n_{features} = 64$. The data set is split into a training and a test set of equal size, then standardized. For evaluation the 3-nearest neighbor classification accuracy is computed on the 2-dimensional projected points found by each method. Each data sample belongs to one of 10 classes.



Examples:

- *Comparing Nearest Neighbors with and without Neighborhood Components Analysis*
- *Dimensionality Reduction with Neighborhood Components Analysis*
- *Manifold learning on handwritten digits: Locally Linear Embedding, Isomap...*

Mathematical formulation

The goal of NCA is to learn an optimal linear transformation matrix of size `(n_components, n_features)`, which maximises the sum over all samples i of the probability p_i that i is correctly classified, i.e.:

$$\arg\max_{L} \sum_{i=0}^{N-1} p_i$$

with N = `n_samples` and p_i the probability of sample i being correctly classified according to a stochastic nearest neighbors rule in the learned embedded space:

$$p_i = \sum_{j \in C_i} p_{ij}$$

where C_i is the set of points in the same class as sample i, and p_{ij} is the softmax over Euclidean distances in the embedded space:

$$p_{ij} = \frac{\exp(-||Lx_i - Lx_j||^2)}{\sum_{k \neq i} \exp -(||Lx_i - Lx_k||^2)}, \quad p_{ii} = 0$$

Mahalanobis distance

NCA can be seen as learning a (squared) Mahalanobis distance metric:

$$||L(x_i - x_j)||^2 = (x_i - x_j)^T M (x_i - x_j),$$

where $M = L^T L$ is a symmetric positive semi-definite matrix of size `(n_features, n_features)`.

Implementation

This implementation follows what is explained in the original paper[1]. For the optimisation method, it currently uses scipy's L-BFGS-B with a full gradient computation at each iteration, to avoid to tune the learning rate and provide stable learning.

See the examples below and the docstring of *`NeighborhoodComponentsAnalysis.fit`* for further information.

Complexity

Training

NCA stores a matrix of pairwise distances, taking `n_samples ** 2` memory. Time complexity depends on the number of iterations done by the optimisation algorithm. However, one can set the maximum number of iterations with the argument `max_iter`. For each iteration, time complexity is `O(n_components x n_samples x min(n_samples, n_features))`.

[1] "Neighbourhood Components Analysis", J. Goldberger, S. Roweis, G. Hinton, R. Salakhutdinov, Advances in Neural Information Processing Systems, Vol. 17, May 2005, pp. 513-520.

Transform

Here the `transform` operation returns LX^T, therefore its time complexity equals `n_components * n_features * n_samples_test`. There is no added space complexity in the operation.

4.1.7 Gaussian Processes

Gaussian Processes (GP) are a generic supervised learning method designed to solve *regression* and *probabilistic classification* problems.

The advantages of Gaussian processes are:

- The prediction interpolates the observations (at least for regular kernels).
- The prediction is probabilistic (Gaussian) so that one can compute empirical confidence intervals and decide based on those if one should refit (online fitting, adaptive fitting) the prediction in some region of interest.
- Versatile: different *kernels* can be specified. Common kernels are provided, but it is also possible to specify custom kernels.

The disadvantages of Gaussian processes include:

- They are not sparse, i.e., they use the whole samples/features information to perform the prediction.
- They lose efficiency in high dimensional spaces – namely when the number of features exceeds a few dozens.

Gaussian Process Regression (GPR)

The *GaussianProcessRegressor* implements Gaussian processes (GP) for regression purposes. For this, the prior of the GP needs to be specified. The prior mean is assumed to be constant and zero (for `normalize_y=False`) or the training data's mean (for `normalize_y=True`). The prior's covariance is specified by passing a *kernel* object. The hyperparameters of the kernel are optimized during fitting of GaussianProcessRegressor by maximizing the log-marginal-likelihood (LML) based on the passed `optimizer`. As the LML may have multiple local optima, the optimizer can be started repeatedly by specifying `n_restarts_optimizer`. The first run is always conducted starting from the initial hyperparameter values of the kernel; subsequent runs are conducted from hyperparameter values that have been chosen randomly from the range of allowed values. If the initial hyperparameters should be kept fixed, `None` can be passed as optimizer.

The noise level in the targets can be specified by passing it via the parameter `alpha`, either globally as a scalar or per datapoint. Note that a moderate noise level can also be helpful for dealing with numeric issues during fitting as it is effectively implemented as Tikhonov regularization, i.e., by adding it to the diagonal of the kernel matrix. An alternative to specifying the noise level explicitly is to include a WhiteKernel component into the kernel, which can estimate the global noise level from the data (see example below).

The implementation is based on Algorithm 2.1 of [RW2006]. In addition to the API of standard scikit-learn estimators, GaussianProcessRegressor:

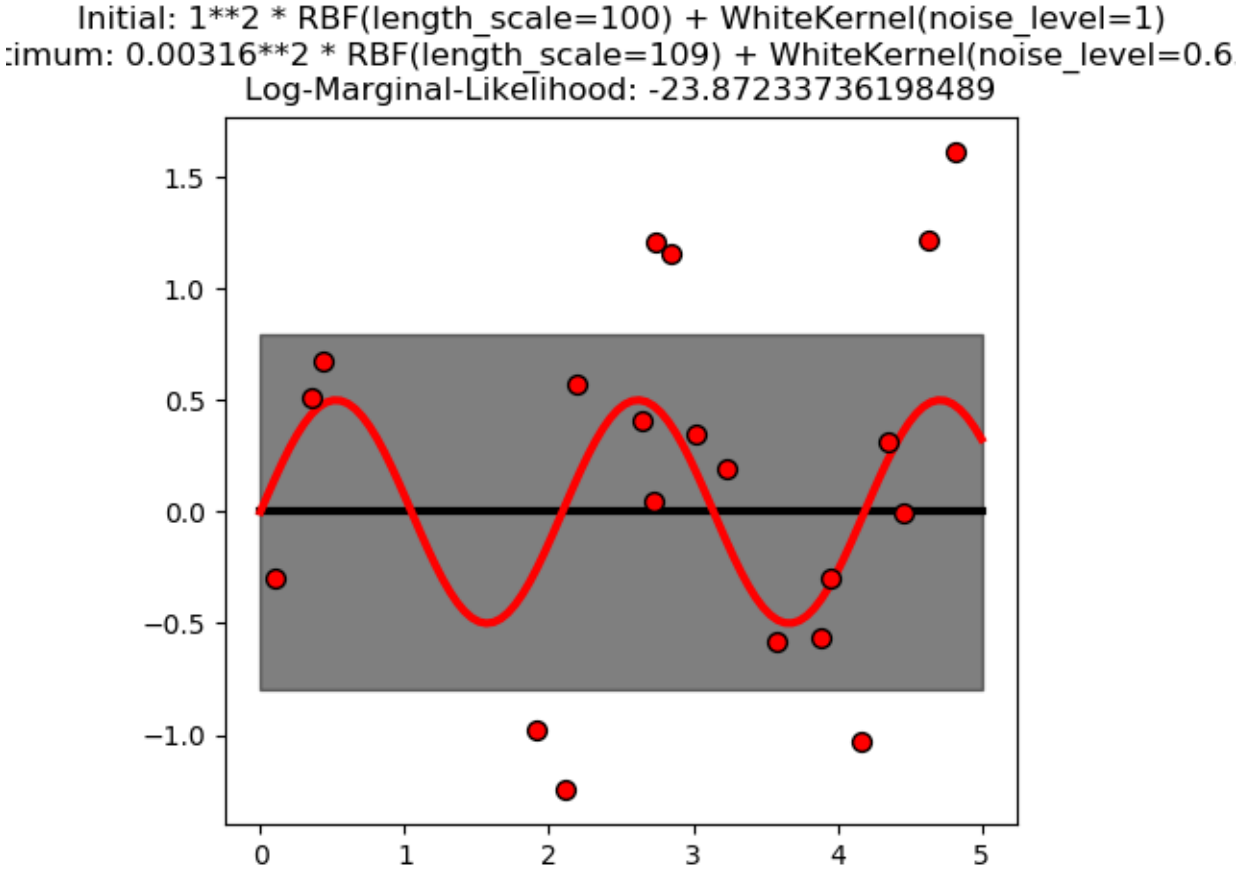
- allows prediction without prior fitting (based on the GP prior)
- provides an additional method `sample_y(X)`, which evaluates samples drawn from the GPR (prior or posterior) at given inputs

- exposes a method `log_marginal_likelihood(theta)`, which can be used externally for other ways of selecting hyperparameters, e.g., via Markov chain Monte Carlo.

GPR examples

GPR with noise-level estimation

This example illustrates that GPR with a sum-kernel including a WhiteKernel can estimate the noise level of data. An illustration of the log-marginal-likelihood (LML) landscape shows that there exist two local maxima of LML.



The first corresponds to a model with a high noise level and a large length scale, which explains all variations in the data by noise.

The second one has a smaller noise level and shorter length scale, which explains most of the variation by the noise-free functional relationship. The second model has a higher likelihood; however, depending on the initial value for the hyperparameters, the gradient-based optimization might also converge to the high-noise solution. It is thus important to repeat the optimization several times for different initializations.

Comparison of GPR and Kernel Ridge Regression

Both kernel ridge regression (KRR) and GPR learn a target function by employing internally the "kernel trick". KRR learns a linear function in the space induced by the respective kernel which corresponds to a non-linear function in the original space. The linear function in the kernel space is chosen based on the mean-squared error loss with ridge

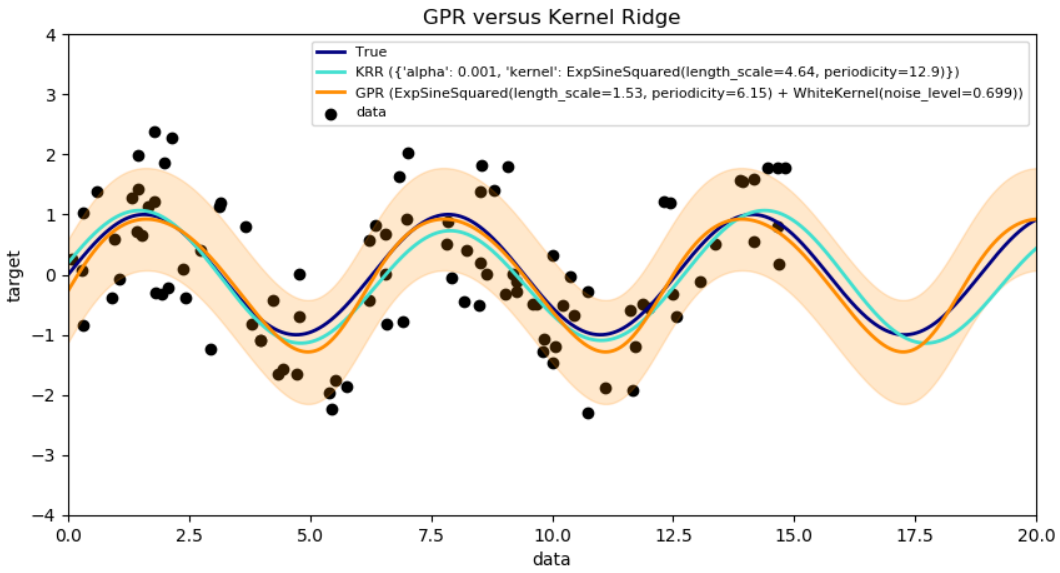
regularization. GPR uses the kernel to define the covariance of a prior distribution over the target functions and uses the observed training data to define a likelihood function. Based on Bayes theorem, a (Gaussian) posterior distribution over target functions is defined, whose mean is used for prediction.

A major difference is that GPR can choose the kernel's hyperparameters based on gradient-ascent on the marginal likelihood function while KRR needs to perform a grid search on a cross-validated loss function (mean-squared error loss). A further difference is that GPR learns a generative, probabilistic model of the target function and can thus provide meaningful confidence intervals and posterior samples along with the predictions while KRR only provides predictions.

The following figure illustrates both methods on an artificial dataset, which consists of a sinusoidal target function and strong noise. The figure compares the learned model of KRR and GPR based on a ExpSineSquared kernel, which is suited for learning periodic functions. The kernel's hyperparameters control the smoothness (length_scale) and periodicity of the kernel (periodicity). Moreover, the noise level of the data is learned explicitly by GPR by an additional WhiteKernel component in the kernel and by the regularization parameter alpha of KRR.



The figure shows that both methods learn reasonable models of the target function. GPR correctly identifies the periodicity of the function to be roughly $2 * \pi$ (6.28), while KRR chooses the doubled periodicity $4 * \pi$. Besides that, GPR provides reasonable confidence bounds on the prediction which are not available for KRR. A major difference between the two methods is the time required for fitting and predicting: while fitting KRR is fast in principle, the grid-search for hyperparameter optimization scales exponentially with the number of hyperparameters ("curse of dimensionality"). The gradient-based optimization of the parameters in GPR does not suffer from this exponential scaling and is thus considerable faster on this example with 3-dimensional hyperparameter space. The time for predicting is similar; however, generating the variance of the predictive distribution of GPR takes considerable longer than just predicting the mean.

GPR on Mauna Loa CO2 data

This example is based on Section 5.4.3 of [RW2006]. It illustrates an example of complex kernel engineering and hyperparameter optimization using gradient ascent on the log-marginal-likelihood. The data consists of the monthly average atmospheric CO2 concentrations (in parts per million by volume (ppmv)) collected at the Mauna Loa Observatory in Hawaii, between 1958 and 1997. The objective is to model the CO2 concentration as a function of the time t.

The kernel is composed of several terms that are responsible for explaining different properties of the signal:

- a long term, smooth rising trend is to be explained by an RBF kernel. The RBF kernel with a large length-scale enforces this component to be smooth; it is not enforced that the trend is rising which leaves this choice to the GP. The specific length-scale and the amplitude are free hyperparameters.
- a seasonal component, which is to be explained by the periodic ExpSineSquared kernel with a fixed periodicity of 1 year. The length-scale of this periodic component, controlling its smoothness, is a free parameter. In order to allow decaying away from exact periodicity, the product with an RBF kernel is taken. The length-scale of this RBF component controls the decay time and is a further free parameter.
- smaller, medium term irregularities are to be explained by a RationalQuadratic kernel component, whose length-scale and alpha parameter, which determines the diffuseness of the length-scales, are to be determined. According to [RW2006], these irregularities can better be explained by a RationalQuadratic than an RBF kernel component, probably because it can accommodate several length-scales.
- a "noise" term, consisting of an RBF kernel contribution, which shall explain the correlated noise components such as local weather phenomena, and a WhiteKernel contribution for the white noise. The relative amplitudes and the RBF's length scale are further free parameters.

Maximizing the log-marginal-likelihood after subtracting the target's mean yields the following kernel with an LML of -83.214:

```
34.4**2 * RBF(length_scale=41.8)
+ 3.27**2 * RBF(length_scale=180) * ExpSineSquared(length_scale=1.44,
                                                   periodicity=1)
+ 0.446**2 * RationalQuadratic(alpha=17.7, length_scale=0.957)
+ 0.197**2 * RBF(length_scale=0.138) + WhiteKernel(noise_level=0.0336)
```

Thus, most of the target signal (34.4ppm) is explained by a long-term rising trend (length-scale 41.8 years). The periodic component has an amplitude of 3.27ppm, a decay time of 180 years and a length-scale of 1.44. The long decay time indicates that we have a locally very close to periodic seasonal component. The correlated noise has an amplitude of 0.197ppm with a length scale of 0.138 years and a white-noise contribution of 0.197ppm. Thus, the overall noise level is very small, indicating that the data can be very well explained by the model. The figure shows also that the model makes very confident predictions until around 2015

Gaussian Process Classification (GPC)

The *GaussianProcessClassifier* implements Gaussian processes (GP) for classification purposes, more specifically for probabilistic classification, where test predictions take the form of class probabilities. GaussianProcessClassifier places a GP prior on a latent function f, which is then squashed through a link function to obtain the probabilistic classification. The latent function f is a so-called nuisance function, whose values are not observed and are not relevant by themselves. Its purpose is to allow a convenient formulation of the model, and f is removed (integrated out) during prediction. GaussianProcessClassifier implements the logistic link function, for which the integral cannot be computed analytically but is easily approximated in the binary case.

In contrast to the regression setting, the posterior of the latent function f is not Gaussian even for a GP prior since a Gaussian likelihood is inappropriate for discrete class labels. Rather, a non-Gaussian likelihood corresponding to the logistic link function (logit) is used. GaussianProcessClassifier approximates the non-Gaussian posterior with a Gaussian based on the Laplace approximation. More details can be found in Chapter 3 of [RW2006].

The GP prior mean is assumed to be zero. The prior's covariance is specified by passing a *kernel* object. The hyperparameters of the kernel are optimized during fitting of GaussianProcessRegressor by maximizing the log-marginal-likelihood (LML) based on the passed `optimizer`. As the LML may have multiple local optima, the optimizer can be started repeatedly by specifying `n_restarts_optimizer`. The first run is always conducted starting from the initial hyperparameter values of the kernel; subsequent runs are conducted from hyperparameter values that have been

chosen randomly from the range of allowed values. If the initial hyperparameters should be kept fixed, `None` can be passed as optimizer.

GaussianProcessClassifier supports multi-class classification by performing either one-versus-rest or one-versus-one based training and prediction. In one-versus-rest, one binary Gaussian process classifier is fitted for each class, which is trained to separate this class from the rest. In "one_vs_one", one binary Gaussian process classifier is fitted for each pair of classes, which is trained to separate these two classes. The predictions of these binary predictors are combined into multi-class predictions. See the section on *multi-class classification* for more details.

In the case of Gaussian process classification, "one_vs_one" might be computationally cheaper since it has to solve many problems involving only a subset of the whole training set rather than fewer problems on the whole dataset. Since Gaussian process classification scales cubically with the size of the dataset, this might be considerably faster. However, note that "one_vs_one" does not support predicting probability estimates but only plain predictions. Moreover, note that *GaussianProcessClassifier* does not (yet) implement a true multi-class Laplace approximation internally, but as discussed above is based on solving several binary classification tasks internally, which are combined using one-versus-rest or one-versus-one.

GPC examples

Probabilistic predictions with GPC

This example illustrates the predicted probability of GPC for an RBF kernel with different choices of the hyperparameters. The first figure shows the predicted probability of GPC with arbitrarily chosen hyperparameters and with the hyperparameters corresponding to the maximum log-marginal-likelihood (LML).

While the hyperparameters chosen by optimizing LML have a considerable larger LML, they perform slightly worse according to the log-loss on test data. The figure shows that this is because they exhibit a steep change of the class probabilities at the class boundaries (which is good) but have predicted probabilities close to 0.5 far away from the class boundaries (which is bad) This undesirable effect is caused by the Laplace approximation used internally by GPC.

The second figure shows the log-marginal-likelihood for different choices of the kernel's hyperparameters, highlighting the two choices of the hyperparameters used in the first figure by black dots.

Illustration of GPC on the XOR dataset

This example illustrates GPC on XOR data. Compared are a stationary, isotropic kernel (*RBF*) and a non-stationary kernel (*DotProduct*). On this particular dataset, the *DotProduct* kernel obtains considerably better results because the class-boundaries are linear and coincide with the coordinate axes. In practice, however, stationary kernels such as *RBF* often obtain better results.

Gaussian process classification (GPC) on iris dataset

This example illustrates the predicted probability of GPC for an isotropic and anisotropic RBF kernel on a two-dimensional version for the iris-dataset. This illustrates the applicability of GPC to non-binary classification. The anisotropic RBF kernel obtains slightly higher log-marginal-likelihood by assigning different length-scales to the two feature dimensions.

Kernels for Gaussian Processes

Kernels (also called "covariance functions" in the context of GPs) are a crucial ingredient of GPs which determine the shape of prior and posterior of the GP. They encode the assumptions on the function being learned by defining the

"similarity" of two datapoints combined with the assumption that similar datapoints should have similar target values. Two categories of kernels can be distinguished: stationary kernels depend only on the distance of two datapoints and not on their absolute values $k(x_i, x_j) = k(d(x_i, x_j))$ and are thus invariant to translations in the input space, while non-stationary kernels depend also on the specific values of the datapoints. Stationary kernels can further be subdivided into isotropic and anisotropic kernels, where isotropic kernels are also invariant to rotations in the input space. For more details, we refer to Chapter 4 of [RW2006].

Gaussian Process Kernel API

The main usage of a *Kernel* is to compute the GP's covariance between datapoints. For this, the method `__call__` of the kernel can be called. This method can either be used to compute the "auto-covariance" of all pairs of datapoints in a 2d array X, or the "cross-covariance" of all combinations of datapoints of a 2d array X with datapoints in a 2d array Y. The following identity holds true for all kernels k (except for the *WhiteKernel*): `k(X) == K(X, Y=X)`

If only the diagonal of the auto-covariance is being used, the method `diag()` of a kernel can be called, which is more computationally efficient than the equivalent call to `__call__`: `np.diag(k(X, X)) == k.diag(X)`

Kernels are parameterized by a vector θ of hyperparameters. These hyperparameters can for instance control length-scales or periodicity of a kernel (see below). All kernels support computing analytic gradients of the kernel's auto-covariance with respect to θ via setting `eval_gradient=True` in the `__call__` method. This gradient is used by the Gaussian process (both regressor and classifier) in computing the gradient of the log-marginal-likelihood, which in turn is used to determine the value of θ, which maximizes the log-marginal-likelihood, via gradient ascent. For each hyperparameter, the initial value and the bounds need to be specified when creating an instance of the kernel. The current value of θ can be get and set via the property `theta` of the kernel object. Moreover, the bounds of the hyperparameters can be accessed by the property `bounds` of the kernel. Note that both properties (theta and bounds) return log-transformed values of the internally used values since those are typically more amenable to gradient-based optimization. The specification of each hyperparameter is stored in the form of an instance of *Hyperparameter* in the respective kernel. Note that a kernel using a hyperparameter with name "x" must have the attributes self.x and self.x_bounds.

The abstract base class for all kernels is *Kernel*. Kernel implements a similar interface as `Estimator`, providing the methods `get_params()`, `set_params()`, and `clone()`. This allows setting kernel values also via meta-estimators such as `Pipeline` or `GridSearch`. Note that due to the nested structure of kernels (by applying kernel

operators, see below), the names of kernel parameters might become relatively complicated. In general, for a binary kernel operator, parameters of the left operand are prefixed with `k1__` and parameters of the right operand with `k2__`. An additional convenience method is `clone_with_theta(theta)`, which returns a cloned version of the kernel but with the hyperparameters set to `theta`. An illustrative example:

```
>>> from sklearn.gaussian_process.kernels import ConstantKernel, RBF
>>> kernel = ConstantKernel(constant_value=1.0, constant_value_bounds=(0.0, 10.0)) *␣

All Gaussian process kernels are interoperable with *sklearn.metrics.pairwise* and vice versa: instances of subclasses of *Kernel* can be passed as `metric` to `pairwise_kernels` from *sklearn.metrics.pairwise*. Moreover, kernel functions from pairwise can be used as GP kernels by using the wrapper class *PairwiseKernel*. The only caveat is that the gradient of the hyperparameters is not analytic but numeric and all those kernels support only isotropic distances. The parameter `gamma` is considered to be a hyperparameter and may be optimized. The other kernel parameters are set directly at initialization and are kept fixed.

Basic kernels

The *ConstantKernel* kernel can be used as part of a *Product* kernel where it scales the magnitude of the other factor (kernel) or as part of a *Sum* kernel, where it modifies the mean of the Gaussian process. It depends on a parameter $constant\_value$. It is defined as:

$$k(x_i, x_j) = constant\_value \;\forall\; x_1, x_2$$

The main use-case of the *WhiteKernel* kernel is as part of a sum-kernel where it explains the noise-component of the signal. Tuning its parameter $noise\_level$ corresponds to estimating the noise-level. It is defined as:

$$k(x_i, x_j) = noise\_level \text{ if } x_i == x_j \text{ else } 0$$

Kernel operators

Kernel operators take one or two base kernels and combine them into a new kernel. The `Sum` kernel takes two kernels $k1$ and $k2$ and combines them via $k_{sum}(X, Y) = k1(X, Y) + k2(X, Y)$. The `Product` kernel takes two kernels $k1$ and $k2$ and combines them via $k_{product}(X, Y) = k1(X, Y) * k2(X, Y)$. The `Exponentiation` kernel takes one base kernel and a scalar parameter $exponent$ and combines them via $k_{exp}(X, Y) = k(X, Y)^{\text{exponent}}$.

Radial-basis function (RBF) kernel

The `RBF` kernel is a stationary kernel. It is also known as the "squared exponential" kernel. It is parameterized by a length-scale parameter $l > 0$, which can either be a scalar (isotropic variant of the kernel) or a vector with the same number of dimensions as the inputs x (anisotropic variant of the kernel). The kernel is given by:

$$k(x_i, x_j) = \exp\left(-\frac{1}{2} d(x_i/l, x_j/l)^2\right)$$

This kernel is infinitely differentiable, which implies that GPs with this kernel as covariance function have mean square derivatives of all orders, and are thus very smooth. The prior and posterior of a GP resulting from an RBF kernel are shown in the following figure:

Matérn kernel

The `Matern` kernel is a stationary kernel and a generalization of the `RBF` kernel. It has an additional parameter ν which controls the smoothness of the resulting function. It is parameterized by a length-scale parameter $l > 0$, which can either be a scalar (isotropic variant of the kernel) or a vector with the same number of dimensions as the inputs x (anisotropic variant of the kernel). The kernel is given by:

$$k(x_i, x_j) = \sigma^2 \frac{1}{\Gamma(\nu)2^{\nu-1}} \left(\gamma\sqrt{2\nu} d(x_i/l, x_j/l)\right)^{\nu} K_{\nu}\left(\gamma\sqrt{2\nu} d(x_i/l, x_j/l)\right),$$

As $\nu \to \infty$, the Matérn kernel converges to the RBF kernel. When $\nu = 1/2$, the Matérn kernel becomes identical to the absolute exponential kernel, i.e.,

$$k(x_i, x_j) = \sigma^2 \exp\left(-\gamma d(x_i/l, x_j/l)\right) \qquad \nu = \tfrac{1}{2}$$

In particular, $\nu = 3/2$:

$$k(x_i, x_j) = \sigma^2 \left(1 + \gamma\sqrt{3} d(x_i/l, x_j/l)\right) \exp\left(-\gamma\sqrt{3} d(x_i/l, x_j/l)\right) \qquad \nu = \tfrac{3}{2}$$

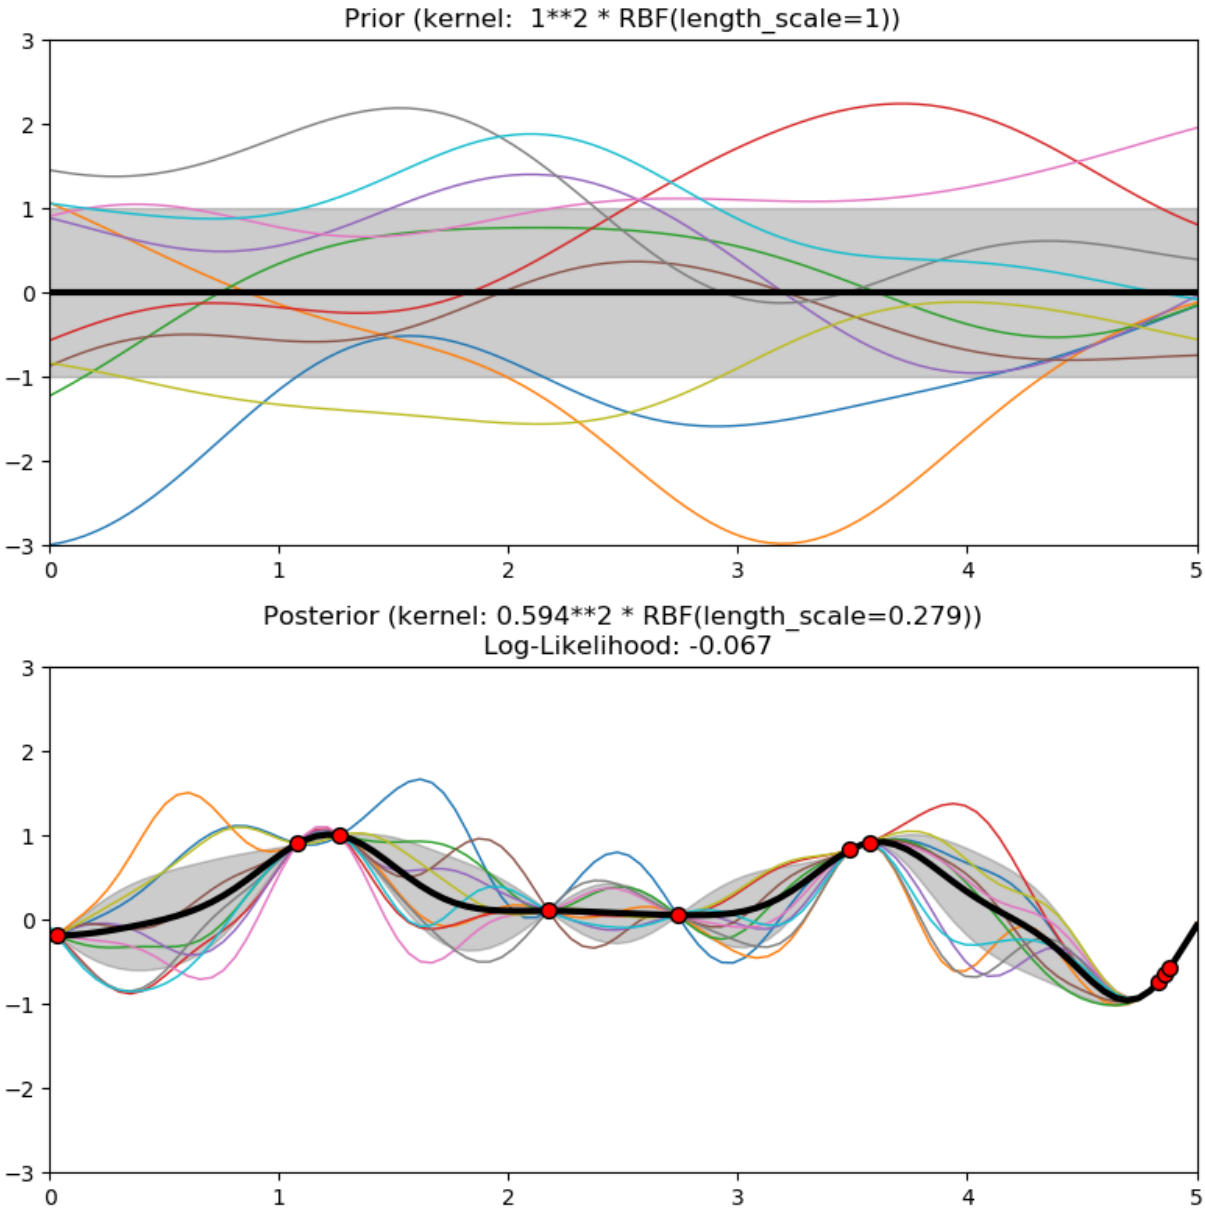
and $\nu = 5/2$:

$$k(x_i, x_j) = \sigma^2 \left(1 + \gamma\sqrt{5} d(x_i/l, x_j/l) + \frac{5}{3}\gamma^2 d(x_i/l, x_j/l)^2\right) \exp\left(-\gamma\sqrt{5} d(x_i/l, x_j/l)\right) \qquad \nu = \tfrac{5}{2}$$

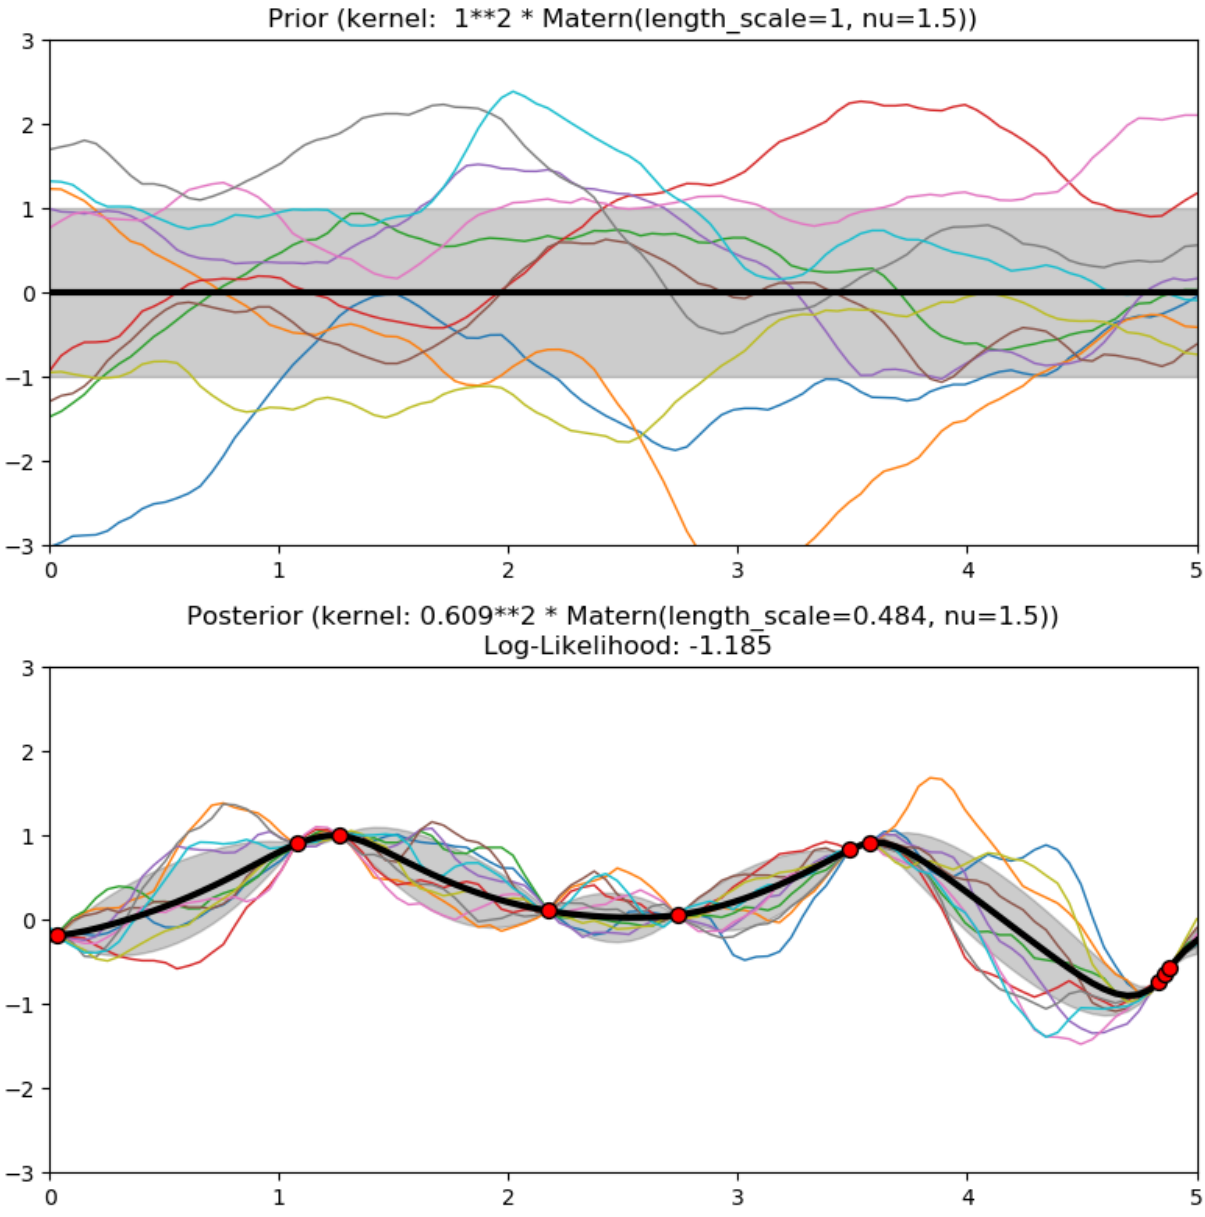
are popular choices for learning functions that are not infinitely differentiable (as assumed by the RBF kernel) but at least once ($\nu = 3/2$) or twice differentiable ($\nu = 5/2$).

The flexibility of controlling the smoothness of the learned function via ν allows adapting to the properties of the true underlying functional relation. The prior and posterior of a GP resulting from a Matérn kernel are shown in the following figure:

See [RW2006], pp84 for further details regarding the different variants of the Matérn kernel.



Prior (kernel: 1**2 * RBF(length_scale=1))
Posterior (kernel: 0.594**2 * RBF(length_scale=0.279))
Log-Likelihood: -0.067



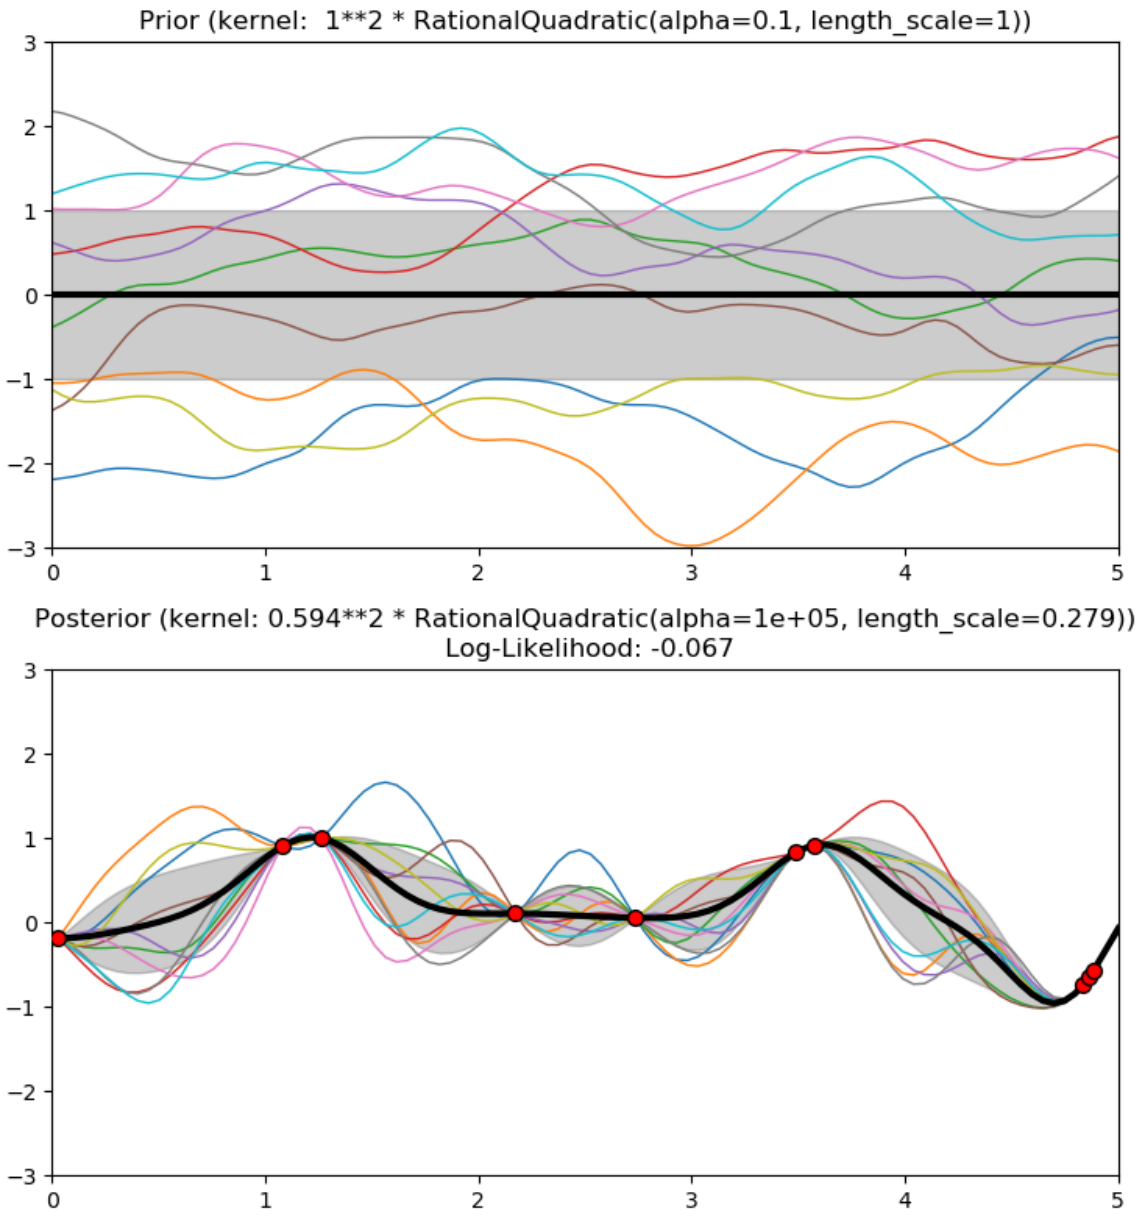
Prior (kernel: 1**2 * Matern(length_scale=1, nu=1.5))
Posterior (kernel: 0.609**2 * Matern(length_scale=0.484, nu=1.5))
Log-Likelihood: -1.185

Rational quadratic kernel

The `RationalQuadratic` kernel can be seen as a scale mixture (an infinite sum) of `RBF` kernels with different characteristic length-scales. It is parameterized by a length-scale parameter $l > 0$ and a scale mixture parameter $\alpha > 0$ Only the isotropic variant where l is a scalar is supported at the moment. The kernel is given by:

$$k(x_i, x_j) = \left(1 + \frac{d(x_i, x_j)^2}{2\alpha l^2}\right)^{-\alpha}$$

The prior and posterior of a GP resulting from a `RationalQuadratic` kernel are shown in the following figure:

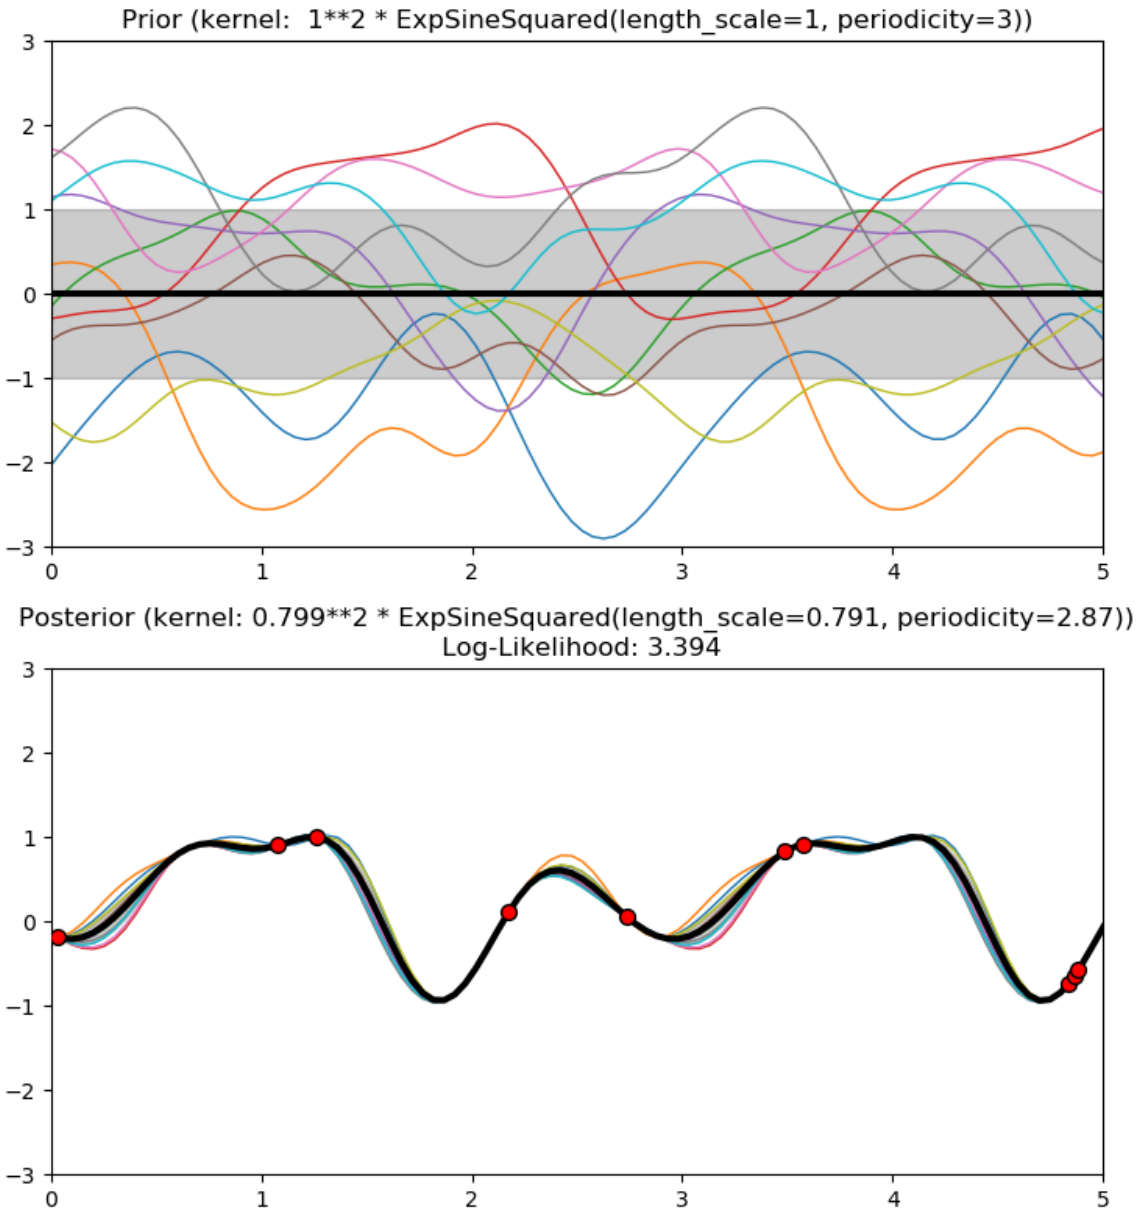


Exp-Sine-Squared kernel

The `ExpSineSquared` kernel allows modeling periodic functions. It is parameterized by a length-scale parameter $l > 0$ and a periodicity parameter $p > 0$. Only the isotropic variant where l is a scalar is supported at the moment. The kernel is given by:

$$k(x_i, x_j) = \exp\left(-2\left(\sin(\pi/p * d(x_i, x_j))/l\right)^2\right)$$

The prior and posterior of a GP resulting from an ExpSineSquared kernel are shown in the following figure:



Dot-Product kernel

The `DotProduct` kernel is non-stationary and can be obtained from linear regression by putting $N(0, 1)$ priors on the coefficients of $x_d(d = 1, ..., D)$ and a prior of $N(0, \sigma_0^2)$ on the bias. The `DotProduct` kernel is invariant to a rotation of the coordinates about the origin, but not translations. It is parameterized by a parameter σ_0^2. For $\sigma_0^2 = 0$, the kernel is called the homogeneous linear kernel, otherwise it is inhomogeneous. The kernel is given by

$$k(x_i, x_j) = \sigma_0^2 + x_i \cdot x_j$$

The `DotProduct` kernel is commonly combined with exponentiation. An example with exponent 2 is shown in the following figure:

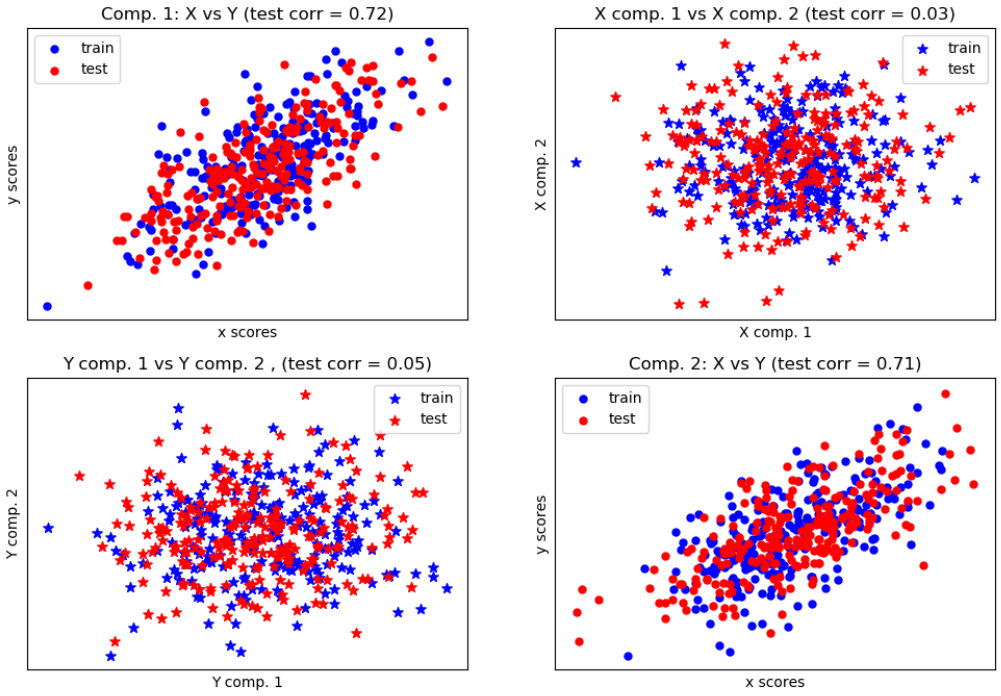
4.1.8 Cross decomposition

The cross decomposition module contains two main families of algorithms: the partial least squares (PLS) and the canonical correlation analysis (CCA).

These families of algorithms are useful to find linear relations between two multivariate datasets: the `X` and `Y` arguments of the `fit` method are 2D arrays.



Cross decomposition algorithms find the fundamental relations between two matrices (X and Y). They are latent variable approaches to modeling the covariance structures in these two spaces. They will try to find the multidimensional direction in the X space that explains the maximum multidimensional variance direction in the Y space. PLS-regression is particularly suited when the matrix of predictors has more variables than observations, and when there is multicollinearity among X values. By contrast, standard regression will fail in these cases.

Classes included in this module are *`PLSRegression`* *`PLSCanonical`*, *`CCA`* and *`PLSSVD`*

4.1.9 Naive Bayes

Naive Bayes methods are a set of supervised learning algorithms based on applying Bayes' theorem with the "naive" assumption of conditional independence between every pair of features given the value of the class variable. Bayes' theorem states the following relationship, given class variable y and dependent feature vector x_1 through x_n, :

$$P(y \mid x_1, \ldots, x_n) = \frac{P(y)P(x_1, \ldots x_n \mid y)}{P(x_1, \ldots, x_n)}$$

Using the naive conditional independence assumption that

$$P(x_i|y, x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n) = P(x_i|y),$$

for all i, this relationship is simplified to

$$P(y \mid x_1, \ldots, x_n) = \frac{P(y) \prod_{i=1}^{n} P(x_i \mid y)}{P(x_1, \ldots, x_n)}$$

Since $P(x_1, \ldots, x_n)$ is constant given the input, we can use the following classification rule:

$$P(y \mid x_1, \ldots, x_n) \propto P(y) \prod_{i=1}^{n} P(x_i \mid y)$$

$$\Downarrow$$

$$\hat{y} = \arg\max_y P(y) \prod_{i=1}^{n} P(x_i \mid y),$$

and we can use Maximum A Posteriori (MAP) estimation to estimate $P(y)$ and $P(x_i \mid y)$; the former is then the relative frequency of class y in the training set.

The different naive Bayes classifiers differ mainly by the assumptions they make regarding the distribution of $P(x_i \mid y)$.

In spite of their apparently over-simplified assumptions, naive Bayes classifiers have worked quite well in many real-world situations, famously document classification and spam filtering. They require a small amount of training data to estimate the necessary parameters. (For theoretical reasons why naive Bayes works well, and on which types of data it does, see the references below.)

Naive Bayes learners and classifiers can be extremely fast compared to more sophisticated methods. The decoupling of the class conditional feature distributions means that each distribution can be independently estimated as a one dimensional distribution. This in turn helps to alleviate problems stemming from the curse of dimensionality.

On the flip side, although naive Bayes is known as a decent classifier, it is known to be a bad estimator, so the probability outputs from `predict_proba` are not to be taken too seriously.

References:

- H. Zhang (2004). The optimality of Naive Bayes. Proc. FLAIRS.

Gaussian Naive Bayes

`GaussianNB` implements the Gaussian Naive Bayes algorithm for classification. The likelihood of the features is assumed to be Gaussian:

$$P(x_i \mid y) = \frac{1}{\sqrt{2\pi\sigma_y^2}} \exp\left(-\frac{(x_i - \mu_y)^2}{2\sigma_y^2}\right)$$

The parameters σ_y and μ_y are estimated using maximum likelihood.

```
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.naive_bayes import GaussianNB
>>> X, y = load_iris(return_X_y=True)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, test_size=0.5, random_
↪state=0)
>>> gnb = GaussianNB()
>>> y_pred = gnb.fit(X_train, y_train).predict(X_test)
>>> print("Number of mislabeled points out of a total %d points : %d"
...       % (X_test.shape[0], (y_test != y_pred).sum()))
Number of mislabeled points out of a total 75 points : 4
```

Multinomial Naive Bayes

MultinomialNB implements the naive Bayes algorithm for multinomially distributed data, and is one of the two classic naive Bayes variants used in text classification (where the data are typically represented as word vector counts, although tf-idf vectors are also known to work well in practice). The distribution is parametrized by vectors $\theta_y = (\theta_{y1}, \ldots, \theta_{yn})$ for each class y, where n is the number of features (in text classification, the size of the vocabulary) and θ_{yi} is the probability $P(x_i \mid y)$ of feature i appearing in a sample belonging to class y.

The parameters θ_y is estimated by a smoothed version of maximum likelihood, i.e. relative frequency counting:

$$\hat{\theta}_{yi} = \frac{N_{yi} + \alpha}{N_y + \alpha n}$$

where $N_{yi} = \sum_{x \in T} x_i$ is the number of times feature i appears in a sample of class y in the training set T, and $N_y = \sum_{i=1}^{n} N_{yi}$ is the total count of all features for class y.

The smoothing priors $\alpha \geq 0$ accounts for features not present in the learning samples and prevents zero probabilities in further computations. Setting $\alpha = 1$ is called Laplace smoothing, while $\alpha < 1$ is called Lidstone smoothing.

Complement Naive Bayes

ComplementNB implements the complement naive Bayes (CNB) algorithm. CNB is an adaptation of the standard multinomial naive Bayes (MNB) algorithm that is particularly suited for imbalanced data sets. Specifically, CNB uses statistics from the *complement* of each class to compute the model's weights. The inventors of CNB show empirically that the parameter estimates for CNB are more stable than those for MNB. Further, CNB regularly outperforms MNB (often by a considerable margin) on text classification tasks. The procedure for calculating the weights is as follows:

$$\hat{\theta}_{ci} = \frac{\alpha_i + \sum_{j:y_j \neq c} d_{ij}}{\alpha + \sum_{j:y_j \neq c} \sum_k d_{kj}}$$

$$w_{ci} = \log \hat{\theta}_{ci}$$

$$w_{ci} = \frac{w_{ci}}{\sum_j |w_{cj}|}$$

where the summations are over all documents j not in class c, d_{ij} is either the count or tf-idf value of term i in document j, α_i is a smoothing hyperparameter like that found in MNB, and $\alpha = \sum_i \alpha_i$. The second normalization addresses the tendency for longer documents to dominate parameter estimates in MNB. The classification rule is:

$$\hat{c} = \arg\min_c \sum_i t_i w_{ci}$$

i.e., a document is assigned to the class that is the *poorest* complement match.

- Rennie, J. D., Shih, L., Teevan, J., & Karger, D. R. (2003). Tackling the poor assumptions of naive bayes text classifiers. In ICML (Vol. 3, pp. 616-623).

Bernoulli Naive Bayes

`BernoulliNB` implements the naive Bayes training and classification algorithms for data that is distributed according to multivariate Bernoulli distributions; i.e., there may be multiple features but each one is assumed to be a binary-valued (Bernoulli, boolean) variable. Therefore, this class requires samples to be represented as binary-valued feature vectors; if handed any other kind of data, a `BernoulliNB` instance may binarize its input (depending on the `binarize` parameter).

The decision rule for Bernoulli naive Bayes is based on

$$P(x_i \mid y) = P(i \mid y)x_i + (1 - P(i \mid y))(1 - x_i)$$

which differs from multinomial NB's rule in that it explicitly penalizes the non-occurrence of a feature i that is an indicator for class y, where the multinomial variant would simply ignore a non-occurring feature.

In the case of text classification, word occurrence vectors (rather than word count vectors) may be used to train and use this classifier. `BernoulliNB` might perform better on some datasets, especially those with shorter documents. It is advisable to evaluate both models, if time permits.

Categorical Naive Bayes

`CategoricalNB` implements the categorical naive Bayes algorithm for categorically distributed data. It assumes that each feature, which is described by the index i, has its own categorical distribution.

For each feature i in the training set X, `CategoricalNB` estimates a categorical distribution for each feature i of X conditioned on the class y. The index set of the samples is defined as $J = \{1, \ldots, m\}$, with m as the number of samples.

The probability of category t in feature i given class c is estimated as:

$$P(x_i = t \mid y = c \,;\, \alpha) = \frac{N_{tic} + \alpha}{N_c + \alpha n_i},$$

where $N_{tic} = |\{j \in J \mid x_{ij} = t, y_j = c\}|$ is the number of times category t appears in the samples x_i, which belong to class c, $N_c = |\{j \in J \mid y_j = c\}|$ is the number of samples with class c, α is a smoothing parameter and n_i is the number of available categories of feature i.

CategoricalNB assumes that the sample matrix X is encoded (for instance with the help of `OrdinalEncoder`) such that all categories for each feature i are represented with numbers $0, ..., n_i - 1$ where n_i is the number of available categories of feature i.

Out-of-core naive Bayes model fitting

Naive Bayes models can be used to tackle large scale classification problems for which the full training set might not fit in memory. To handle this case, *MultinomialNB*, *BernoulliNB*, and *GaussianNB* expose a `partial_fit` method that can be used incrementally as done with other classifiers as demonstrated in *Out-of-core classification of text documents*. All naive Bayes classifiers support sample weighting.

Contrary to the `fit` method, the first call to `partial_fit` needs to be passed the list of all the expected class labels.

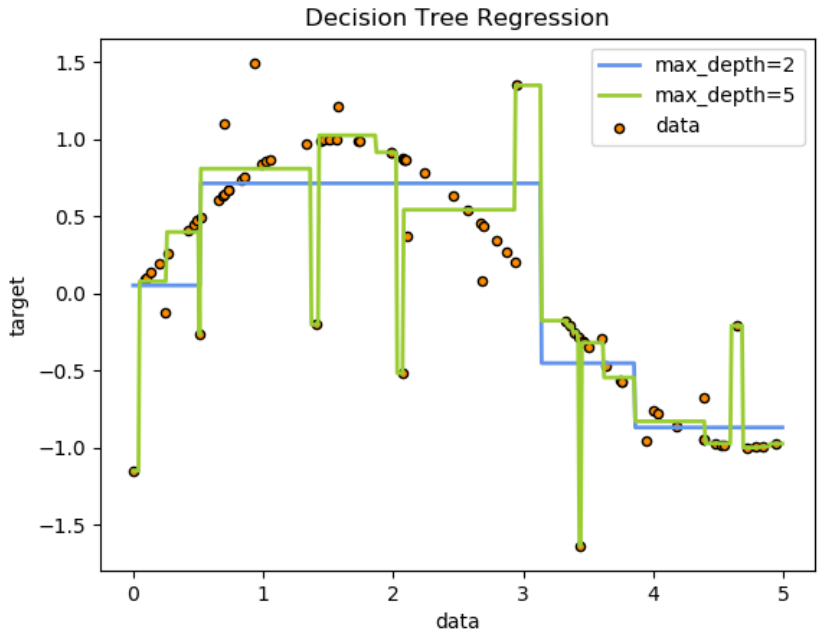
For an overview of available strategies in scikit-learn, see also the *out-of-core learning* documentation.

Note: The `partial_fit` method call of naive Bayes models introduces some computational overhead. It is recommended to use data chunk sizes that are as large as possible, that is as the available RAM allows.

4.1.10 Decision Trees

Decision Trees (DTs) are a non-parametric supervised learning method used for *classification* and *regression*. The goal is to create a model that predicts the value of a target variable by learning simple decision rules inferred from the data features.

For instance, in the example below, decision trees learn from data to approximate a sine curve with a set of if-then-else decision rules. The deeper the tree, the more complex the decision rules and the fitter the model.



Some advantages of decision trees are:

- Simple to understand and to interpret. Trees can be visualised.

- Requires little data preparation. Other techniques often require data normalisation, dummy variables need to be created and blank values to be removed. Note however that this module does not support missing values.
- The cost of using the tree (i.e., predicting data) is logarithmic in the number of data points used to train the tree.
- Able to handle both numerical and categorical data. Other techniques are usually specialised in analysing datasets that have only one type of variable. See *algorithms* for more information.
- Able to handle multi-output problems.
- Uses a white box model. If a given situation is observable in a model, the explanation for the condition is easily explained by boolean logic. By contrast, in a black box model (e.g., in an artificial neural network), results may be more difficult to interpret.
- Possible to validate a model using statistical tests. That makes it possible to account for the reliability of the model.
- Performs well even if its assumptions are somewhat violated by the true model from which the data were generated.

The disadvantages of decision trees include:

- Decision-tree learners can create over-complex trees that do not generalise the data well. This is called overfitting. Mechanisms such as pruning (not currently supported), setting the minimum number of samples required at a leaf node or setting the maximum depth of the tree are necessary to avoid this problem.
- Decision trees can be unstable because small variations in the data might result in a completely different tree being generated. This problem is mitigated by using decision trees within an ensemble.
- The problem of learning an optimal decision tree is known to be NP-complete under several aspects of optimality and even for simple concepts. Consequently, practical decision-tree learning algorithms are based on heuristic algorithms such as the greedy algorithm where locally optimal decisions are made at each node. Such algorithms cannot guarantee to return the globally optimal decision tree. This can be mitigated by training multiple trees in an ensemble learner, where the features and samples are randomly sampled with replacement.
- There are concepts that are hard to learn because decision trees do not express them easily, such as XOR, parity or multiplexer problems.
- Decision tree learners create biased trees if some classes dominate. It is therefore recommended to balance the dataset prior to fitting with the decision tree.

Classification

DecisionTreeClassifier is a class capable of performing multi-class classification on a dataset.

As with other classifiers, *DecisionTreeClassifier* takes as input two arrays: an array X, sparse or dense, of size `[n_samples, n_features]` holding the training samples, and an array Y of integer values, size `[n_samples]`, holding the class labels for the training samples:

```
>>> from sklearn import tree
>>> X = [[0, 0], [1, 1]]
>>> Y = [0, 1]
>>> clf = tree.DecisionTreeClassifier()
>>> clf = clf.fit(X, Y)
```

After being fitted, the model can then be used to predict the class of samples:

```
>>> clf.predict([[2., 2.]])
array([1])
```

Alternatively, the probability of each class can be predicted, which is the fraction of training samples of the same class in a leaf:

```
>>> clf.predict_proba([[2., 2.]])
array([[0., 1.]])
```

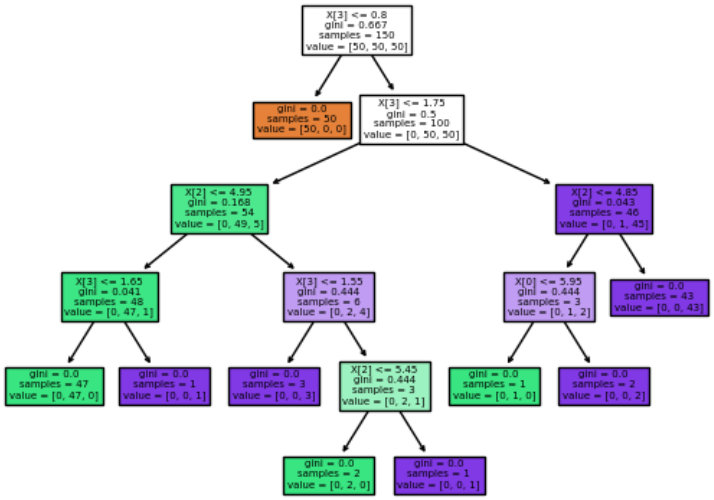
DecisionTreeClassifier is capable of both binary (where the labels are [-1, 1]) classification and multiclass (where the labels are [0, . . . , K-1]) classification.

Using the Iris dataset, we can construct a tree as follows:

```
>>> from sklearn.datasets import load_iris
>>> from sklearn import tree
>>> X, y = load_iris(return_X_y=True)
>>> clf = tree.DecisionTreeClassifier()
>>> clf = clf.fit(X, y)
```

Once trained, you can plot the tree with the plot_tree function:

```
>>> tree.plot_tree(clf.fit(iris.data, iris.target))
```



We can also export the tree in Graphviz format using the *export_graphviz* exporter. If you use the conda package manager, the graphviz binaries

and the python package can be installed with

    conda install python-graphviz

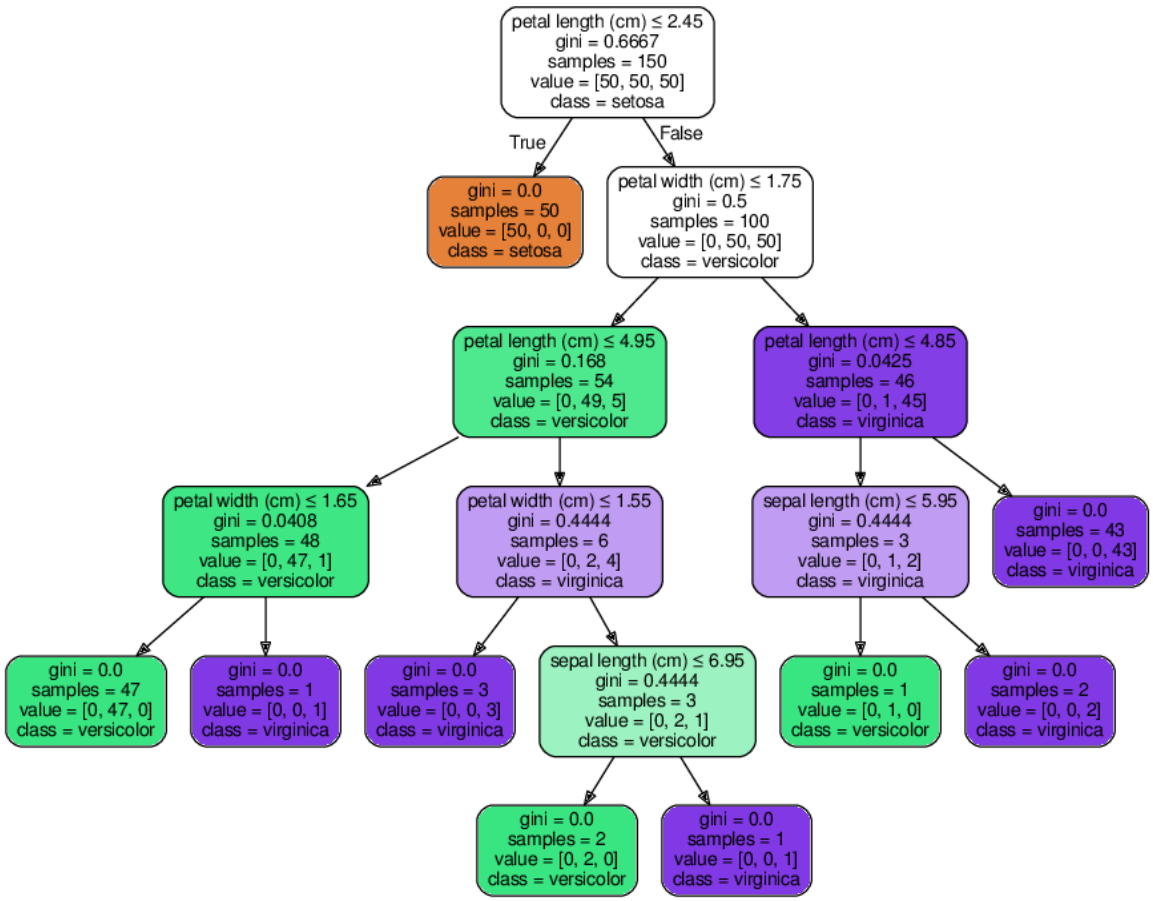
Alternatively binaries for graphviz can be downloaded from the graphviz project homepage, and the Python wrapper installed from pypi with `pip install graphviz`.

Below is an example graphviz export of the above tree trained on the entire iris dataset; the results are saved in an output file `iris.pdf`:

```
>>> import graphviz
>>> dot_data = tree.export_graphviz(clf, out_file=None)
>>> graph = graphviz.Source(dot_data)
>>> graph.render("iris")
```

The *export_graphviz* exporter also supports a variety of aesthetic options, including coloring nodes by their class (or value for regression) and using explicit variable and class names if desired. Jupyter notebooks also render these plots inline automatically:

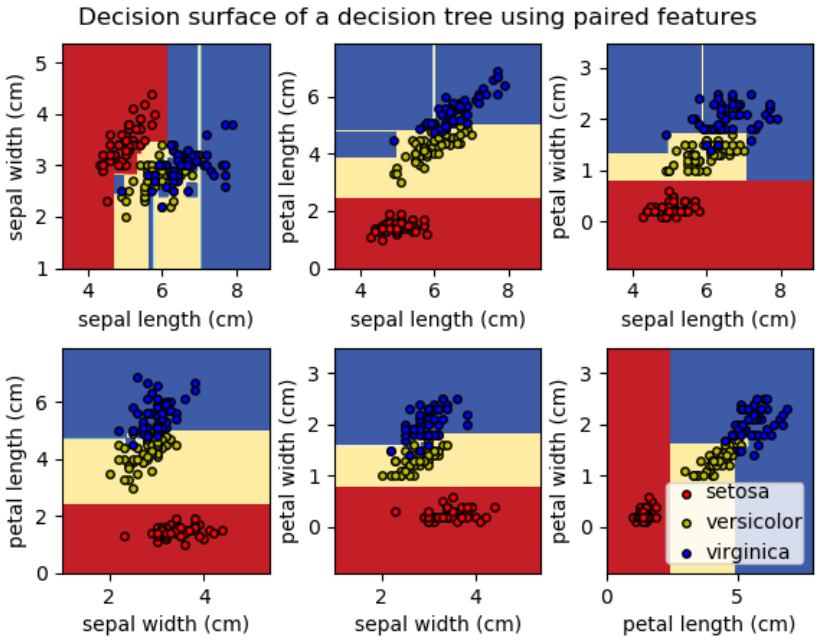
```
>>> dot_data = tree.export_graphviz(clf, out_file=None,
...                                 feature_names=iris.feature_names,
...                                 class_names=iris.target_names,
...                                 filled=True, rounded=True,
...                                 special_characters=True)
>>> graph = graphviz.Source(dot_data)
>>> graph
```



Alternatively, the tree can also be exported in textual format with the function *export_text*. This method doesn't require the installation of external libraries and is more compact:

```
>>> from sklearn.datasets import load_iris
>>> from sklearn.tree import DecisionTreeClassifier
```

(continues on next page)



(continued from previous page)

```
>>> from sklearn.tree.export import export_text
>>> iris = load_iris()
>>> decision_tree = DecisionTreeClassifier(random_state=0, max_depth=2)
>>> decision_tree = decision_tree.fit(iris.data, iris.target)
>>> r = export_text(decision_tree, feature_names=iris['feature_names'])
>>> print(r)
|--- petal width (cm) <= 0.80
|   |--- class: 0
|--- petal width (cm) >  0.80
|   |--- petal width (cm) <= 1.75
|   |   |--- class: 1
|   |--- petal width (cm) >  1.75
|   |   |--- class: 2
<BLANKLINE>
```

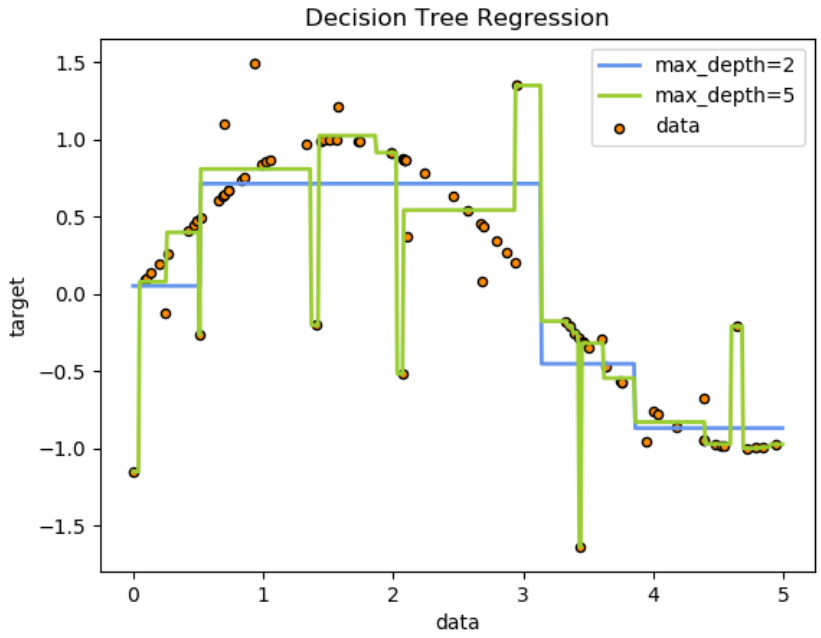
Examples:

- *Plot the decision surface of a decision tree on the iris dataset*
- *Understanding the decision tree structure*

Regression

Decision trees can also be applied to regression problems, using the `DecisionTreeRegressor` class.

As in the classification setting, the fit method will take as argument arrays X and y, only that in this case y is expected to have floating point values instead of integer values:



```
>>> from sklearn import tree
>>> X = [[0, 0], [2, 2]]
>>> y = [0.5, 2.5]
>>> clf = tree.DecisionTreeRegressor()
>>> clf = clf.fit(X, y)
>>> clf.predict([[1, 1]])
array([0.5])
```

Examples:

- *Decision Tree Regression*

Multi-output problems

A multi-output problem is a supervised learning problem with several outputs to predict, that is when Y is a 2d array of size `[n_samples, n_outputs]`.

When there is no correlation between the outputs, a very simple way to solve this kind of problem is to build n independent models, i.e. one for each output, and then to use those models to independently predict each one of the n outputs. However, because it is likely that the output values related to the same input are themselves correlated, an often better way is to build a single model capable of predicting simultaneously all n outputs. First, it requires lower training time since only a single estimator is built. Second, the generalization accuracy of the resulting estimator may often be increased.

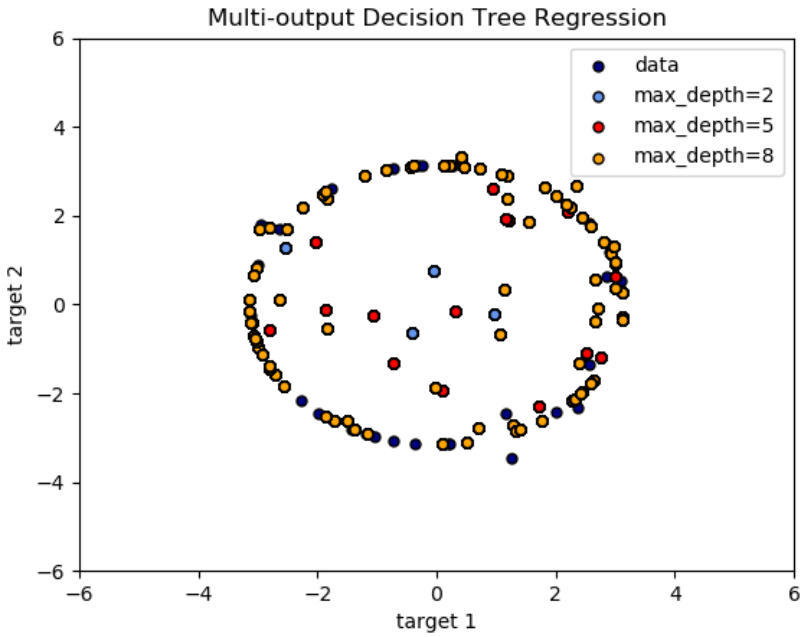
With regard to decision trees, this strategy can readily be used to support multi-output problems. This requires the following changes:

- Store n output values in leaves, instead of 1;
- Use splitting criteria that compute the average reduction across all n outputs.

This module offers support for multi-output problems by implementing this strategy in both `DecisionTreeClassifier` and `DecisionTreeRegressor`. If a decision tree is fit on an output array Y of size `[n_samples, n_outputs]` then the resulting estimator will:

- Output n_output values upon `predict`;
- Output a list of n_output arrays of class probabilities upon `predict_proba`.

The use of multi-output trees for regression is demonstrated in *Multi-output Decision Tree Regression*. In this example, the input X is a single real value and the outputs Y are the sine and cosine of X.



The use of multi-output trees for classification is demonstrated in *Face completion with a multi-output estimators*. In this example, the inputs X are the pixels of the upper half of faces and the outputs Y are the pixels of the lower half of those faces.

Examples:

- *Multi-output Decision Tree Regression*
- *Face completion with a multi-output estimators*

Complexity

In general, the run time cost to construct a balanced binary tree is $O(n_{samples}n_{features}\log(n_{samples}))$ and query time $O(\log(n_{samples}))$. Although the tree construction algorithm attempts to generate balanced trees, they will not

Face completion with multi-output estimators
true faces
Extra trees
K-nn
Linear regression
Ridge

always be balanced. Assuming that the subtrees remain approximately balanced, the cost at each node consists of searching through $O(n_{features})$ to find the feature that offers the largest reduction in entropy. This has a cost of $O(n_{features}n_{samples}\log(n_{samples}))$ at each node, leading to a total cost over the entire trees (by summing the cost at each node) of $O(n_{features}n^2_{samples}\log(n_{samples}))$.

Tips on practical use

- Decision trees tend to overfit on data with a large number of features. Getting the right ratio of samples to number of features is important, since a tree with few samples in high dimensional space is very likely to overfit.
- Consider performing dimensionality reduction (*PCA*, *ICA*, or *Feature selection*) beforehand to give your tree a better chance of finding features that are discriminative.
- *Understanding the decision tree structure* will help in gaining more insights about how the decision tree makes predictions, which is important for understanding the important features in the data.
- Visualise your tree as you are training by using the `export` function. Use `max_depth=3` as an initial tree depth to get a feel for how the tree is fitting to your data, and then increase the depth.
- Remember that the number of samples required to populate the tree doubles for each additional level the tree grows to. Use `max_depth` to control the size of the tree to prevent overfitting.
- Use `min_samples_split` or `min_samples_leaf` to ensure that multiple samples inform every decision in the tree, by controlling which splits will be considered. A very small number will usually mean the tree will overfit, whereas a large number will prevent the tree from learning the data. Try `min_samples_leaf=5` as an initial value. If the sample size varies greatly, a float number can be used as percentage in these two parameters. While `min_samples_split` can create arbitrarily small leaves, `min_samples_leaf` guarantees that each leaf has a minimum size, avoiding low-variance, over-fit leaf nodes in regression problems. For classification with few classes, `min_samples_leaf=1` is often the best choice.
- Balance your dataset before training to prevent the tree from being biased toward the classes that are dominant. Class balancing can be done by sampling an equal number of samples from each class, or preferably by normalizing the sum of the sample weights (`sample_weight`) for each class to the same value. Also note that weight-based pre-pruning criteria, such as `min_weight_fraction_leaf`, will then be less biased toward dominant classes than criteria that are not aware of the sample weights, like `min_samples_leaf`.
- If the samples are weighted, it will be easier to optimize the tree structure using weight-based pre-pruning criterion such as `min_weight_fraction_leaf`, which ensure that leaf nodes contain at least a fraction of the overall sum of the sample weights.
- All decision trees use `np.float32` arrays internally. If training data is not in this format, a copy of the dataset will be made.
- If the input matrix X is very sparse, it is recommended to convert to sparse `csc_matrix` before calling fit and sparse `csr_matrix` before calling predict. Training time can be orders of magnitude faster for a sparse matrix input compared to a dense matrix when features have zero values in most of the samples.

Tree algorithms: ID3, C4.5, C5.0 and CART

What are all the various decision tree algorithms and how do they differ from each other? Which one is implemented in scikit-learn?

ID3 (Iterative Dichotomiser 3) was developed in 1986 by Ross Quinlan. The algorithm creates a multiway tree, finding for each node (i.e. in a greedy manner) the categorical feature that will yield the largest information gain for categorical targets. Trees are grown to their maximum size and then a pruning step is usually applied to improve the ability of the tree to generalise to unseen data.

C4.5 is the successor to ID3 and removed the restriction that features must be categorical by dynamically defining a discrete attribute (based on numerical variables) that partitions the continuous attribute value into a discrete set of intervals. C4.5 converts the trained trees (i.e. the output of the ID3 algorithm) into sets of if-then rules. These accuracy of each rule is then evaluated to determine the order in which they should be applied. Pruning is done by removing a rule's precondition if the accuracy of the rule improves without it.

C5.0 is Quinlan's latest version release under a proprietary license. It uses less memory and builds smaller rulesets than C4.5 while being more accurate.

CART (Classification and Regression Trees) is very similar to C4.5, but it differs in that it supports numerical target variables (regression) and does not compute rule sets. CART constructs binary trees using the feature and threshold that yield the largest information gain at each node.

scikit-learn uses an optimised version of the CART algorithm; however, scikit-learn implementation does not support categorical variables for now.

Mathematical formulation

Given training vectors $x_i \in R^n$, i=1,..., l and a label vector $y \in R^l$, a decision tree recursively partitions the space such that the samples with the same labels are grouped together.

Let the data at node m be represented by Q. For each candidate split $\theta = (j, t_m)$ consisting of a feature j and threshold t_m, partition the data into $Q_{left}(\theta)$ and $Q_{right}(\theta)$ subsets

$$Q_{left}(\theta) = (x, y)|x_j <= t_m$$
$$Q_{right}(\theta) = Q \setminus Q_{left}(\theta)$$

The impurity at m is computed using an impurity function $H()$, the choice of which depends on the task being solved (classification or regression)

$$G(Q, \theta) = \frac{n_{left}}{N_m} H(Q_{left}(\theta)) + \frac{n_{right}}{N_m} H(Q_{right}(\theta))$$

Select the parameters that minimises the impurity

$$\theta^* = \operatorname{argmin}_\theta G(Q, \theta)$$

Recurse for subsets $Q_{left}(\theta^*)$ and $Q_{right}(\theta^*)$ until the maximum allowable depth is reached, $N_m < \min_{samples}$ or $N_m = 1$.

Classification criteria

If a target is a classification outcome taking on values 0,1,...,K-1, for node m, representing a region R_m with N_m observations, let

$$p_{mk} = 1/N_m \sum_{x_i \in R_m} I(y_i = k)$$

be the proportion of class k observations in node m

Common measures of impurity are Gini

$$H(X_m) = \sum_k p_{mk}(1 - p_{mk})$$

Entropy

$$H(X_m) = -\sum_k p_{mk} \log(p_{mk})$$

and Misclassification

$$H(X_m) = 1 - \max(p_{mk})$$

where X_m is the training data in node m

Regression criteria

If the target is a continuous value, then for node m, representing a region R_m with N_m observations, common criteria to minimise as for determining locations for future splits are Mean Squared Error, which minimizes the L2 error using mean values at terminal nodes, and Mean Absolute Error, which minimizes the L1 error using median values at terminal nodes.

Mean Squared Error:

$$\bar{y}_m = \frac{1}{N_m} \sum_{i \in N_m} y_i$$

$$H(X_m) = \frac{1}{N_m} \sum_{i \in N_m} (y_i - \bar{y}_m)^2$$

Mean Absolute Error:

$$\bar{y}_m = \frac{1}{N_m} \sum_{i \in N_m} y_i$$

$$H(X_m) = \frac{1}{N_m} \sum_{i \in N_m} |y_i - \bar{y}_m|$$

where X_m is the training data in node m

Minimal Cost-Complexity Pruning

Minimal cost-complexity pruning is an algorithm used to prune a tree to avoid over-fitting, described in Chapter 3 of [BRE]. This algorithm is parameterized by $\alpha \geq 0$ known as the complexity parameter. The complexity parameter is used to define the cost-complexity measure, $R_\alpha(T)$ of a given tree T:

$$R_\alpha(T) = R(T) + \alpha|T|$$

where $|T|$ is the number of terminal nodes in T and $R(T)$ is traditionally defined as the total misclassification rate of the terminal nodes. Alternatively, scikit-learn uses the total sample weighted impurity of the terminal nodes for $R(T)$. As shown above, the impurity of a node depends on the criterion. Minimal cost-complexity pruning finds the subtree of T that minimizes $R_\alpha(T)$.

The cost complexity measure of a single node is $R_\alpha(t) = R(t) + \alpha$. The branch, T_t, is defined to be a tree where node t is its root. In general, the impurity of a node is greater than the sum of impurities of its terminal nodes, $R(T_t) < R(t)$. However, the cost complexity measure of a node, t, and its branch, T_t, can be equal depending on α. We define the effective α of a node to be the value where they are equal, $R_\alpha(T_t) = R_\alpha(t)$ or $\alpha_{eff}(t) = \frac{R(t) - R(T_t)}{|T| - 1}$. A non-terminal node with the smallest value of α_{eff} is the weakest link and will be pruned. This process stops when the pruned tree's minimal α_{eff} is greater than the `ccp_alpha` parameter.

Examples:

4.1.11 Ensemble methods

The goal of **ensemble methods** is to combine the predictions of several base estimators built with a given learning algorithm in order to improve generalizability / robustness over a single estimator.

Two families of ensemble methods are usually distinguished:

- In **averaging methods**, the driving principle is to build several estimators independently and then to average their predictions. On average, the combined estimator is usually better than any of the single base estimator because its variance is reduced.

  Examples: *Bagging methods*, *Forests of randomized trees*, ...

- By contrast, in **boosting methods**, base estimators are built sequentially and one tries to reduce the bias of the combined estimator. The motivation is to combine several weak models to produce a powerful ensemble.

  Examples: *AdaBoost*, *Gradient Tree Boosting*, ...

Bagging meta-estimator

In ensemble algorithms, bagging methods form a class of algorithms which build several instances of a black-box estimator on random subsets of the original training set and then aggregate their individual predictions to form a final prediction. These methods are used as a way to reduce the variance of a base estimator (e.g., a decision tree), by introducing randomization into its construction procedure and then making an ensemble out of it. In many cases, bagging methods constitute a very simple way to improve with respect to a single model, without making it necessary to adapt the underlying base algorithm. As they provide a way to reduce overfitting, bagging methods work best with strong and complex models (e.g., fully developed decision trees), in contrast with boosting methods which usually work best with weak models (e.g., shallow decision trees).

Bagging methods come in many flavours but mostly differ from each other by the way they draw random subsets of the training set:

- When random subsets of the dataset are drawn as random subsets of the samples, then this algorithm is known as Pasting [B1999].
- When samples are drawn with replacement, then the method is known as Bagging [B1996].
- When random subsets of the dataset are drawn as random subsets of the features, then the method is known as Random Subspaces [H1998].
- Finally, when base estimators are built on subsets of both samples and features, then the method is known as Random Patches [LG2012].

In scikit-learn, bagging methods are offered as a unified `BaggingClassifier` meta-estimator (resp. `BaggingRegressor`), taking as input a user-specified base estimator along with parameters specifying the strategy to draw random subsets. In particular, `max_samples` and `max_features` control the size of the subsets (in terms of samples and features), while `bootstrap` and `bootstrap_features` control whether samples and features

are drawn with or without replacement. When using a subset of the available samples the generalization accuracy can be estimated with the out-of-bag samples by setting `oob_score=True`. As an example, the snippet below illustrates how to instantiate a bagging ensemble of `KNeighborsClassifier` base estimators, each built on random subsets of 50% of the samples and 50% of the features.

```
>>> from sklearn.ensemble import BaggingClassifier
>>> from sklearn.neighbors import KNeighborsClassifier
>>> bagging = BaggingClassifier(KNeighborsClassifier(),
...                             max_samples=0.5, max_features=0.5)
```

Forests of randomized trees

The *sklearn.ensemble* module includes two averaging algorithms based on randomized *decision trees*: the RandomForest algorithm and the Extra-Trees method. Both algorithms are perturb-and-combine techniques [B1998] specifically designed for trees. This means a diverse set of classifiers is created by introducing randomness in the classifier construction. The prediction of the ensemble is given as the averaged prediction of the individual classifiers.

As other classifiers, forest classifiers have to be fitted with two arrays: a sparse or dense array X of size `[n_samples, n_features]` holding the training samples, and an array Y of size `[n_samples]` holding the target values (class labels) for the training samples:

```
>>> from sklearn.ensemble import RandomForestClassifier
>>> X = [[0, 0], [1, 1]]
>>> Y = [0, 1]
>>> clf = RandomForestClassifier(n_estimators=10)
>>> clf = clf.fit(X, Y)
```

Like *decision trees*, forests of trees also extend to *multi-output problems* (if Y is an array of size `[n_samples, n_outputs]`).

Random Forests

In random forests (see *RandomForestClassifier* and *RandomForestRegressor* classes), each tree in the ensemble is built from a sample drawn with replacement (i.e., a bootstrap sample) from the training set.

Furthermore, when splitting each node during the construction of a tree, the best split is found either from all input features or a random subset of size `max_features`. (See the *parameter tuning guidelines* for more details).

The purpose of these two sources of randomness is to decrease the variance of the forest estimator. Indeed, individual decision trees typically exhibit high variance and tend to overfit. The injected randomness in forests yield decision trees with somewhat decoupled prediction errors. By taking an average of those predictions, some errors can cancel out. Random forests achieve a reduced variance by combining diverse trees, sometimes at the cost of a slight increase in bias. In practice the variance reduction is often significant hence yielding an overall better model.

In contrast to the original publication [B2001], the scikit-learn implementation combines classifiers by averaging their probabilistic prediction, instead of letting each classifier vote for a single class.

Extremely Randomized Trees

In extremely randomized trees (see *ExtraTreesClassifier* and *ExtraTreesRegressor* classes), randomness goes one step further in the way splits are computed. As in random forests, a random subset of candidate features is used, but instead of looking for the most discriminative thresholds, thresholds are drawn at random for each candidate feature and the best of these randomly-generated thresholds is picked as the splitting rule. This usually allows to reduce the variance of the model a bit more, at the expense of a slightly greater increase in bias:

```
>>> from sklearn.model_selection import cross_val_score
>>> from sklearn.datasets import make_blobs
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.ensemble import ExtraTreesClassifier
>>> from sklearn.tree import DecisionTreeClassifier

>>> X, y = make_blobs(n_samples=10000, n_features=10, centers=100,
...     random_state=0)

>>> clf = DecisionTreeClassifier(max_depth=None, min_samples_split=2,
...     random_state=0)
>>> scores = cross_val_score(clf, X, y, cv=5)
>>> scores.mean()
0.98...

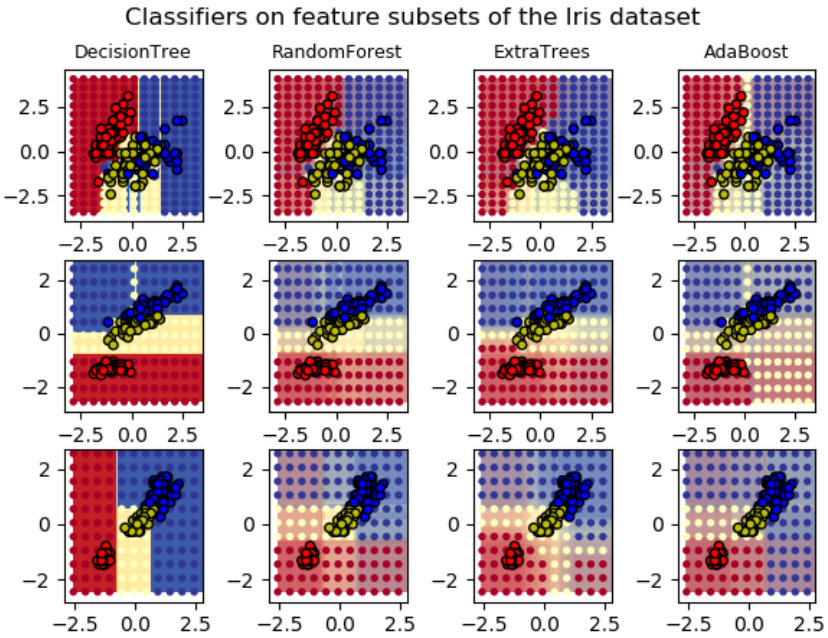
>>> clf = RandomForestClassifier(n_estimators=10, max_depth=None,
...     min_samples_split=2, random_state=0)
>>> scores = cross_val_score(clf, X, y, cv=5)
>>> scores.mean()
0.999...

>>> clf = ExtraTreesClassifier(n_estimators=10, max_depth=None,
...     min_samples_split=2, random_state=0)
>>> scores = cross_val_score(clf, X, y, cv=5)
>>> scores.mean() > 0.999
True
```

Parameters

The main parameters to adjust when using these methods is `n_estimators` and `max_features`. The former is the number of trees in the forest. The larger the better, but also the longer it will take to compute. In addition, note that results will stop getting significantly better beyond a critical number of trees. The latter is the size of the random subsets of features to consider when splitting a node. The lower the greater the reduction of variance, but also the greater the increase in bias. Empirical good default values are `max_features=None` (always considering all features instead of a random subset) for regression problems, and `max_features="sqrt"` (using a random subset of size `sqrt(n_features)`) for classification tasks (where `n_features` is the number of features in the data). Good results are often achieved when setting `max_depth=None` in combination with `min_samples_split=2` (i.e., when fully developing the trees). Bear in mind though that these values are usually not optimal, and might result in models that consume a lot of RAM. The best parameter values should always be cross-validated. In addition, note that in random forests, bootstrap samples are used by default (`bootstrap=True`) while the default strategy for extra-trees is to use the whole dataset (`bootstrap=False`). When using bootstrap sampling the generalization accuracy can be estimated on the left out or out-of-bag samples. This can be enabled by setting `oob_score=True`.

Note: The size of the model with the default parameters is $O(M * N * log(N))$, where M is the number of trees and N is the number of samples. In order to reduce the size of the model, you can change these parameters:



`min_samples_split`, `max_leaf_nodes`, `max_depth` and `min_samples_leaf`.

Parallelization

Finally, this module also features the parallel construction of the trees and the parallel computation of the predictions through the `n_jobs` parameter. If `n_jobs=k` then computations are partitioned into `k` jobs, and run on `k` cores of the machine. If `n_jobs=-1` then all cores available on the machine are used. Note that because of inter-process communication overhead, the speedup might not be linear (i.e., using `k` jobs will unfortunately not be `k` times as fast). Significant speedup can still be achieved though when building a large number of trees, or when building a single tree requires a fair amount of time (e.g., on large datasets).

Examples:

- *Plot the decision surfaces of ensembles of trees on the iris dataset*
- *Pixel importances with a parallel forest of trees*
- *Face completion with a multi-output estimators*

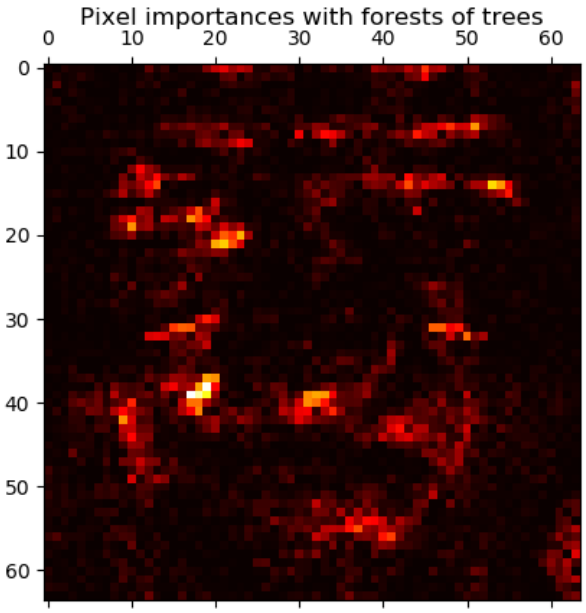
Feature importance evaluation

The relative rank (i.e. depth) of a feature used as a decision node in a tree can be used to assess the relative importance of that feature with respect to the predictability of the target variable. Features used at the top of the tree contribute to the final prediction decision of a larger fraction of the input samples. The **expected fraction of the samples** they contribute to can thus be used as an estimate of the **relative importance of the features**. In scikit-learn, the fraction of samples a feature contributes to is combined with the decrease in impurity from splitting them to create a normalized estimate of the predictive power of that feature.

By **averaging** the estimates of predictive ability over several randomized trees one can **reduce the variance** of such an estimate and use it for feature selection. This is known as the mean decrease in impurity, or MDI. Refer to [L2014] for more information on MDI and feature importance evaluation with Random Forests.

The following example shows a color-coded representation of the relative importances of each individual pixel for a face recognition task using a `ExtraTreesClassifier` model.



In practice those estimates are stored as an attribute named `feature_importances_` on the fitted model. This is an array with shape `(n_features,)` whose values are positive and sum to 1.0. The higher the value, the more important is the contribution of the matching feature to the prediction function.

Examples:

- *Pixel importances with a parallel forest of trees*
- *Feature importances with forests of trees*

Totally Random Trees Embedding

`RandomTreesEmbedding` implements an unsupervised transformation of the data. Using a forest of completely random trees, `RandomTreesEmbedding` encodes the data by the indices of the leaves a data point ends up in. This index is then encoded in a one-of-K manner, leading to a high dimensional, sparse binary coding. This coding can be computed very efficiently and can then be used as a basis for other learning tasks. The size and sparsity of the code can be influenced by choosing the number of trees and the maximum depth per tree. For each tree in the ensemble, the coding contains one entry of one. The size of the coding is at most `n_estimators * 2 ** max_depth`, the maximum number of leaves in the forest.

As neighboring data points are more likely to lie within the same leaf of a tree, the transformation performs an implicit, non-parametric density estimation.

Examples:

- *Hashing feature transformation using Totally Random Trees*
- *Manifold learning on handwritten digits: Locally Linear Embedding, Isomap...* compares non-linear dimensionality reduction techniques on handwritten digits.
- *Feature transformations with ensembles of trees* compares supervised and unsupervised tree based feature transformations.

See also:

Manifold learning techniques can also be useful to derive non-linear representations of feature space, also these approaches focus also on dimensionality reduction.

AdaBoost

The module `sklearn.ensemble` includes the popular boosting algorithm AdaBoost, introduced in 1995 by Freund and Schapire [FS1995].

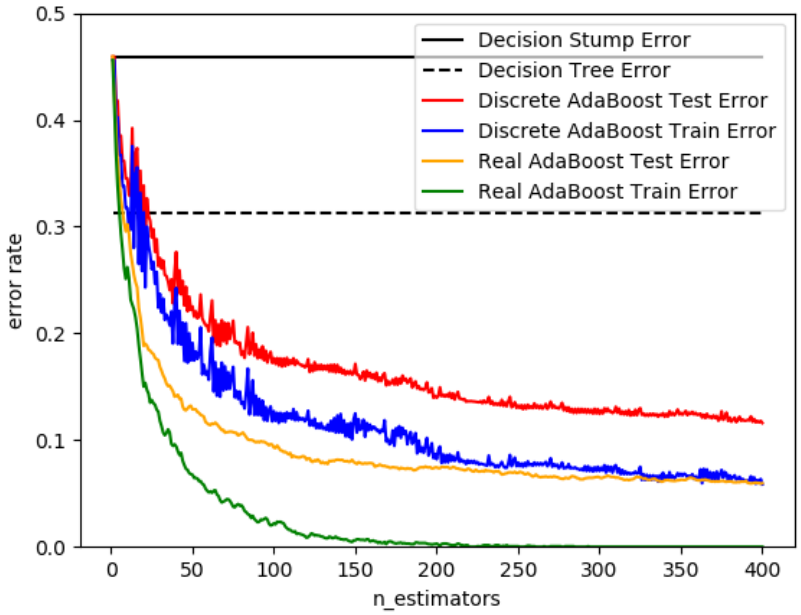
The core principle of AdaBoost is to fit a sequence of weak learners (i.e., models that are only slightly better than random guessing, such as small decision trees) on repeatedly modified versions of the data. The predictions from all of them are then combined through a weighted majority vote (or sum) to produce the final prediction. The data modifications at each so-called boosting iteration consist of applying weights w_1, w_2, ..., w_N to each of the training samples. Initially, those weights are all set to $w_i = 1/N$, so that the first step simply trains a weak learner on the original data. For each successive iteration, the sample weights are individually modified and the learning algorithm is reapplied to the reweighted data. At a given step, those training examples that were incorrectly predicted by the boosted model induced at the previous step have their weights increased, whereas the weights are decreased for those that were predicted correctly. As iterations proceed, examples that are difficult to predict receive ever-increasing influence. Each subsequent weak learner is thereby forced to concentrate on the examples that are missed by the previous ones in the sequence [HTF].

AdaBoost can be used both for classification and regression problems:

- For multi-class classification, `AdaBoostClassifier` implements AdaBoost-SAMME and AdaBoost-SAMME.R [ZZRH2009].
- For regression, `AdaBoostRegressor` implements AdaBoost.R2 [D1997].

Usage

The following example shows how to fit an AdaBoost classifier with 100 weak learners:



```
>>> from sklearn.model_selection import cross_val_score
>>> from sklearn.datasets import load_iris
>>> from sklearn.ensemble import AdaBoostClassifier

>>> X, y = load_iris(return_X_y=True)
>>> clf = AdaBoostClassifier(n_estimators=100)
>>> scores = cross_val_score(clf, X, y, cv=5)
>>> scores.mean()
0.9...
```

The number of weak learners is controlled by the parameter `n_estimators`. The `learning_rate` parameter controls the contribution of the weak learners in the final combination. By default, weak learners are decision stumps. Different weak learners can be specified through the `base_estimator` parameter. The main parameters to tune to obtain good results are `n_estimators` and the complexity of the base estimators (e.g., its depth `max_depth` or minimum required number of samples to consider a split `min_samples_split`).

Examples:

- *Discrete versus Real AdaBoost* compares the classification error of a decision stump, decision tree, and a boosted decision stump using AdaBoost-SAMME and AdaBoost-SAMME.R.
- *Multi-class AdaBoosted Decision Trees* shows the performance of AdaBoost-SAMME and AdaBoost-SAMME.R on a multi-class problem.
- *Two-class AdaBoost* shows the decision boundary and decision function values for a non-linearly separable two-class problem using AdaBoost-SAMME.
- *Decision Tree Regression with AdaBoost* demonstrates regression with the AdaBoost.R2 algorithm.

Gradient Tree Boosting

Gradient Tree Boosting or Gradient Boosted Decision Trees (GBDT) is a generalization of boosting to arbitrary differentiable loss functions. GBDT is an accurate and effective off-the-shelf procedure that can be used for both regression and classification problems in a variety of areas including Web search ranking and ecology.

The module *sklearn.ensemble* provides methods for both classification and regression via gradient boosted decision trees.

Note: Scikit-learn 0.21 introduces two new experimental implementations of gradient boosting trees, namely *HistGradientBoostingClassifier* and *HistGradientBoostingRegressor*, inspired by LightGBM (See [LightGBM]).

These histogram-based estimators can be **orders of magnitude faster** than *GradientBoostingClassifier* and *GradientBoostingRegressor* when the number of samples is larger than tens of thousands of samples.

They also have built-in support for missing values, which avoids the need for an imputer.

These estimators are described in more detail below in *Histogram-Based Gradient Boosting*.

The following guide focuses on *GradientBoostingClassifier* and *GradientBoostingRegressor*, which might be preferred for small sample sizes since binning may lead to split points that are too approximate in this setting.

Classification

GradientBoostingClassifier supports both binary and multi-class classification. The following example shows how to fit a gradient boosting classifier with 100 decision stumps as weak learners:

```
>>> from sklearn.datasets import make_hastie_10_2
>>> from sklearn.ensemble import GradientBoostingClassifier

>>> X, y = make_hastie_10_2(random_state=0)
>>> X_train, X_test = X[:2000], X[2000:]
>>> y_train, y_test = y[:2000], y[2000:]

>>> clf = GradientBoostingClassifier(n_estimators=100, learning_rate=1.0,
...     max_depth=1, random_state=0).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.913...
```

The number of weak learners (i.e. regression trees) is controlled by the parameter `n_estimators`; *The size of each tree* can be controlled either by setting the tree depth via `max_depth` or by setting the number of leaf nodes via `max_leaf_nodes`. The `learning_rate` is a hyper-parameter in the range (0.0, 1.0] that controls overfitting via *shrinkage* .

Note: Classification with more than 2 classes requires the induction of `n_classes` regression trees at each iteration, thus, the total number of induced trees equals `n_classes * n_estimators`. For datasets with a large number of classes we strongly recommend to use *HistGradientBoostingClassifier* as an alternative to *GradientBoostingClassifier* .

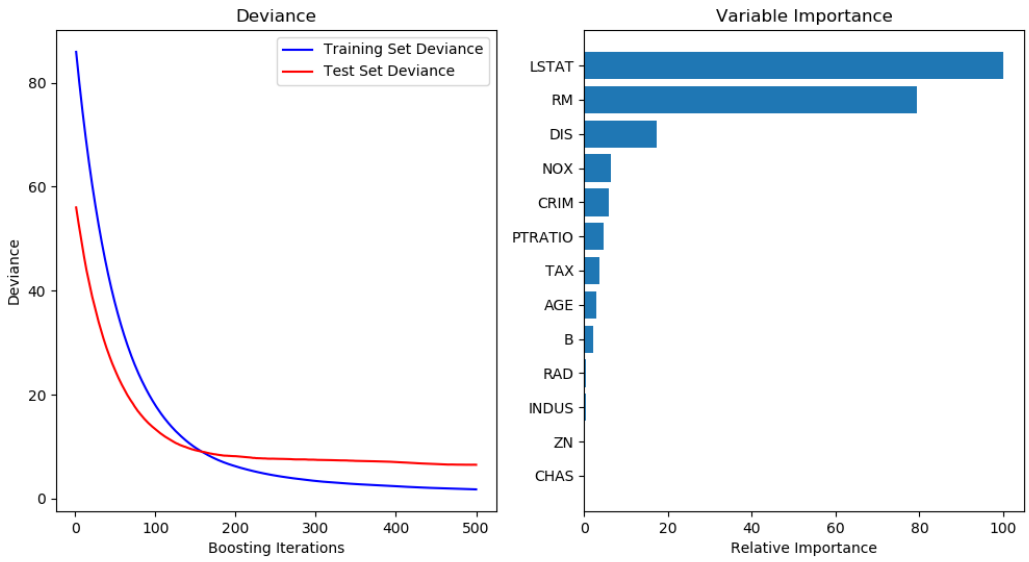
Regression

GradientBoostingRegressor supports a number of *different loss functions* for regression which can be specified via the argument `loss`; the default loss function for regression is least squares (`'ls'`).

```
>>> import numpy as np
>>> from sklearn.metrics import mean_squared_error
>>> from sklearn.datasets import make_friedman1
>>> from sklearn.ensemble import GradientBoostingRegressor

>>> X, y = make_friedman1(n_samples=1200, random_state=0, noise=1.0)
>>> X_train, X_test = X[:200], X[200:]
>>> y_train, y_test = y[:200], y[200:]
>>> est = GradientBoostingRegressor(n_estimators=100, learning_rate=0.1,
...     max_depth=1, random_state=0, loss='ls').fit(X_train, y_train)
>>> mean_squared_error(y_test, est.predict(X_test))
5.00...
```

The figure below shows the results of applying *GradientBoostingRegressor* with least squares loss and 500 base learners to the Boston house price dataset (*sklearn.datasets.load_boston*). The plot on the left shows the train and test error at each iteration. The train error at each iteration is stored in the `train_score_` attribute of the gradient boosting model. The test error at each iterations can be obtained via the *staged_predict* method which returns a generator that yields the predictions at each stage. Plots like these can be used to determine the optimal number of trees (i.e. `n_estimators`) by early stopping. The plot on the right shows the feature importances which can be obtained via the `feature_importances_` property.



Examples:

- *Gradient Boosting regression*
- *Gradient Boosting Out-of-Bag estimates*

Fitting additional weak-learners

Both *GradientBoostingRegressor* and *GradientBoostingClassifier* support `warm_start=True` which allows you to add more estimators to an already fitted model.

```
>>> _ = est.set_params(n_estimators=200, warm_start=True)  # set warm_start and new␣
↪nr of trees
>>> _ = est.fit(X_train, y_train) # fit additional 100 trees to est
>>> mean_squared_error(y_test, est.predict(X_test))
3.84...
```

Controlling the tree size

The size of the regression tree base learners defines the level of variable interactions that can be captured by the gradient boosting model. In general, a tree of depth `h` can capture interactions of order `h` . There are two ways in which the size of the individual regression trees can be controlled.

If you specify `max_depth=h` then complete binary trees of depth `h` will be grown. Such trees will have (at most) `2**h` leaf nodes and `2**h - 1` split nodes.

Alternatively, you can control the tree size by specifying the number of leaf nodes via the parameter `max_leaf_nodes`. In this case, trees will be grown using best-first search where nodes with the highest improvement in impurity will be expanded first. A tree with `max_leaf_nodes=k` has `k - 1` split nodes and thus can model interactions of up to order `max_leaf_nodes - 1` .

We found that `max_leaf_nodes=k` gives comparable results to `max_depth=k-1` but is significantly faster to train at the expense of a slightly higher training error. The parameter `max_leaf_nodes` corresponds to the variable `J` in the chapter on gradient boosting in [F2001] and is related to the parameter `interaction.depth` in R's gbm package where `max_leaf_nodes == interaction.depth + 1` .

Mathematical formulation

GBRT considers additive models of the following form:

$$F(x) = \sum_{m=1}^{M} \gamma_m h_m(x)$$

where $h_m(x)$ are the basis functions which are usually called *weak learners* in the context of boosting. Gradient Tree Boosting uses *decision trees* of fixed size as weak learners. Decision trees have a number of abilities that make them valuable for boosting, namely the ability to handle data of mixed type and the ability to model complex functions.

Similar to other boosting algorithms, GBRT builds the additive model in a greedy fashion:

$$F_m(x) = F_{m-1}(x) + \gamma_m h_m(x),$$

where the newly added tree h_m tries to minimize the loss L, given the previous ensemble F_{m-1}:

$$h_m = \arg\min_{h} \sum_{i=1}^{n} L(y_i, F_{m-1}(x_i) + h(x_i)).$$

The initial model F_0 is problem specific, for least-squares regression one usually chooses the mean of the target values.

Note: The initial model can also be specified via the `init` argument. The passed object has to implement `fit` and `predict`.

Gradient Boosting attempts to solve this minimization problem numerically via steepest descent: The steepest descent direction is the negative gradient of the loss function evaluated at the current model F_{m-1} which can be calculated for any differentiable loss function:

$$F_m(x) = F_{m-1}(x) - \gamma_m \sum_{i=1}^{n} \nabla_F L(y_i, F_{m-1}(x_i))$$

Where the step length γ_m is chosen using line search:

$$\gamma_m = \arg\min_{\gamma} \sum_{i=1}^{n} L(y_i, F_{m-1}(x_i) - \gamma \frac{\partial L(y_i, F_{m-1}(x_i))}{\partial F_{m-1}(x_i)})$$

The algorithms for regression and classification only differ in the concrete loss function used.

Loss Functions

The following loss functions are supported and can be specified using the parameter `loss`:

- Regression
  - Least squares (`'ls'`): The natural choice for regression due to its superior computational properties. The initial model is given by the mean of the target values.
  - Least absolute deviation (`'lad'`): A robust loss function for regression. The initial model is given by the median of the target values.
  - Huber (`'huber'`): Another robust loss function that combines least squares and least absolute deviation; use `alpha` to control the sensitivity with regards to outliers (see [F2001] for more details).
  - Quantile (`'quantile'`): A loss function for quantile regression. Use `0 < alpha < 1` to specify the quantile. This loss function can be used to create prediction intervals (see *Prediction Intervals for Gradient Boosting Regression*).
- Classification
  - Binomial deviance (`'deviance'`): The negative binomial log-likelihood loss function for binary classification (provides probability estimates). The initial model is given by the log odds-ratio.
  - Multinomial deviance (`'deviance'`): The negative multinomial log-likelihood loss function for multi-class classification with `n_classes` mutually exclusive classes. It provides probability estimates. The initial model is given by the prior probability of each class. At each iteration `n_classes` regression trees have to be constructed which makes GBRT rather inefficient for data sets with a large number of classes.
  - Exponential loss (`'exponential'`): The same loss function as `AdaBoostClassifier`. Less robust to mislabeled examples than `'deviance'`; can only be used for binary classification.

Regularization

Shrinkage

[F2001] proposed a simple regularization strategy that scales the contribution of each weak learner by a factor ν:

$$F_m(x) = F_{m-1}(x) + \nu\gamma_m h_m(x)$$

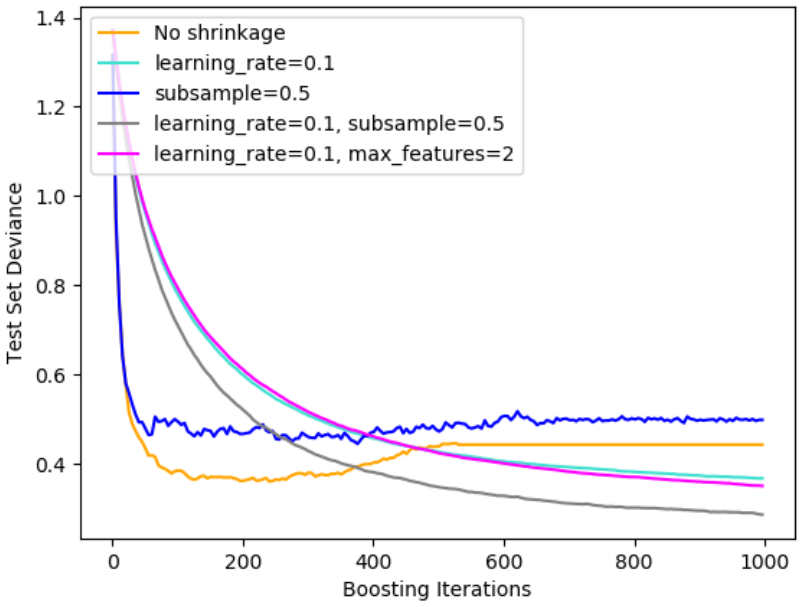
The parameter ν is also called the **learning rate** because it scales the step length the gradient descent procedure; it can be set via the `learning_rate` parameter.

The parameter `learning_rate` strongly interacts with the parameter `n_estimators`, the number of weak learners to fit. Smaller values of `learning_rate` require larger numbers of weak learners to maintain a constant training error. Empirical evidence suggests that small values of `learning_rate` favor better test error. [HTF] recommend to set the learning rate to a small constant (e.g. `learning_rate <= 0.1`) and choose `n_estimators` by early stopping. For a more detailed discussion of the interaction between `learning_rate` and `n_estimators` see [R2007].

Subsampling

[F1999] proposed stochastic gradient boosting, which combines gradient boosting with bootstrap averaging (bagging). At each iteration the base classifier is trained on a fraction `subsample` of the available training data. The subsample is drawn without replacement. A typical value of `subsample` is 0.5.

The figure below illustrates the effect of shrinkage and subsampling on the goodness-of-fit of the model. We can clearly see that shrinkage outperforms no-shrinkage. Subsampling with shrinkage can further increase the accuracy of the model. Subsampling without shrinkage, on the other hand, does poorly.



Another strategy to reduce the variance is by subsampling the features analogous to the random splits in `RandomForestClassifier`. The number of subsampled features can be controlled via the `max_features` parameter.

Note: Using a small `max_features` value can significantly decrease the runtime.

Stochastic gradient boosting allows to compute out-of-bag estimates of the test deviance by computing the improvement in deviance on the examples that are not included in the bootstrap sample (i.e. the out-of-bag examples). The improvements are stored in the attribute `oob_improvement_`. `oob_improvement_[i]` holds the improvement in terms of the loss on the OOB samples if you add the i-th stage to the current predictions. Out-of-bag estimates can be used for model selection, for example to determine the optimal number of iterations. OOB estimates are usually very pessimistic thus we recommend to use cross-validation instead and only use OOB if cross-validation is too time consuming.

Examples:

- *Gradient Boosting regularization*
- *Gradient Boosting Out-of-Bag estimates*
- *OOB Errors for Random Forests*

Interpretation

Individual decision trees can be interpreted easily by simply visualizing the tree structure. Gradient boosting models, however, comprise hundreds of regression trees thus they cannot be easily interpreted by visual inspection of the individual trees. Fortunately, a number of techniques have been proposed to summarize and interpret gradient boosting models.

Feature importance

Often features do not contribute equally to predict the target response; in many situations the majority of the features are in fact irrelevant. When interpreting a model, the first question usually is: what are those important features and how do they contributing in predicting the target response?

Individual decision trees intrinsically perform feature selection by selecting appropriate split points. This information can be used to measure the importance of each feature; the basic idea is: the more often a feature is used in the split points of a tree the more important that feature is. This notion of importance can be extended to decision tree ensembles by simply averaging the feature importance of each tree (see *Feature importance evaluation* for more details).

The feature importance scores of a fit gradient boosting model can be accessed via the `feature_importances_` property:

```
>>> from sklearn.datasets import make_hastie_10_2
>>> from sklearn.ensemble import GradientBoostingClassifier

>>> X, y = make_hastie_10_2(random_state=0)
>>> clf = GradientBoostingClassifier(n_estimators=100, learning_rate=1.0,
...     max_depth=1, random_state=0).fit(X, y)
>>> clf.feature_importances_
array([0.10..., 0.10..., 0.11..., ...
```

Examples:

- *Gradient Boosting regression*

Histogram-Based Gradient Boosting

Scikit-learn 0.21 introduces two new experimental implementations of gradient boosting trees, namely `HistGradientBoostingClassifier` and `HistGradientBoostingRegressor`, inspired by LightGBM (See [LightGBM]).

These histogram-based estimators can be **orders of magnitude faster** than `GradientBoostingClassifier` and `GradientBoostingRegressor` when the number of samples is larger than tens of thousands of samples.

They also have built-in support for missing values, which avoids the need for an imputer.

These fast estimators first bin the input samples `X` into integer-valued bins (typically 256 bins) which tremendously reduces the number of splitting points to consider, and allows the algorithm to leverage integer-based data structures (histograms) instead of relying on sorted continuous values when building the trees. The API of these estimators is slightly different, and some of the features from `GradientBoostingClassifier` and `GradientBoostingRegressor` are not yet supported: in particular sample weights, and some loss functions.

These estimators are still **experimental**: their predictions and their API might change without any deprecation cycle. To use them, you need to explicitly import `enable_hist_gradient_boosting`:

```
>>> # explicitly require this experimental feature
>>> from sklearn.experimental import enable_hist_gradient_boosting  # noqa
>>> # now you can import normally from ensemble
>>> from sklearn.ensemble import HistGradientBoostingClassifier
```

Examples:

- *Partial Dependence Plots*

Usage

Most of the parameters are unchanged from `GradientBoostingClassifier` and `GradientBoostingRegressor`. One exception is the `max_iter` parameter that replaces `n_estimators`, and controls the number of iterations of the boosting process:

```
>>> from sklearn.experimental import enable_hist_gradient_boosting
>>> from sklearn.ensemble import HistGradientBoostingClassifier
>>> from sklearn.datasets import make_hastie_10_2

>>> X, y = make_hastie_10_2(random_state=0)
>>> X_train, X_test = X[:2000], X[2000:]
>>> y_train, y_test = y[:2000], y[2000:]

>>> clf = HistGradientBoostingClassifier(max_iter=100).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.8965
```

Available losses for regression are 'least_squares' and 'least_absolute_deviation', which is less sensitive to outliers. For classification, 'binary_crossentropy' is used for binary classification and 'categorical_crossentropy' is used for multiclass classification. By default the loss is 'auto' and will select the appropriate loss depending on *y* passed to *fit*.

The size of the trees can be controlled through the `max_leaf_nodes`, `max_depth`, and `min_samples_leaf` parameters.

The number of bins used to bin the data is controlled with the `max_bins` parameter. Using less bins acts as a form of regularization. It is generally recommended to use as many bins as possible, which is the default.

The `l2_regularization` parameter is a regularizer on the loss function and corresponds to λ in equation (2) of [XGBoost].

The early-stopping behaviour is controlled via the `scoring`, `validation_fraction`, `n_iter_no_change`, and `tol` parameters. It is possible to early-stop using an arbitrary *scorer*, or just the training or validation loss. By default, early-stopping is performed using the default *scorer* of the estimator on a validation set but it is also possible to perform early-stopping based on the loss value, which is significantly faster.

Missing values support

HistGradientBoostingClassifier and *HistGradientBoostingRegressor* have built-in support for missing values (NaNs).

During training, the tree grower learns at each split point whether samples with missing values should go to the left or right child, based on the potential gain. When predicting, samples with missing values are assigned to the left or right child consequently:

```
>>> from sklearn.experimental import enable_hist_gradient_boosting  # noqa
>>> from sklearn.ensemble import HistGradientBoostingClassifier
>>> import numpy as np

>>> X = np.array([0, 1, 2, np.nan]).reshape(-1, 1)
>>> y = [0, 0, 1, 1]

>>> gbdt = HistGradientBoostingClassifier(min_samples_leaf=1).fit(X, y)
>>> gbdt.predict(X)
array([0, 0, 1, 1])
```

When the missingness pattern is predictive, the splits can be done on whether the feature value is missing or not:

```
>>> X = np.array([0, np.nan, 1, 2, np.nan]).reshape(-1, 1)
>>> y = [0, 1, 0, 0, 1]
>>> gbdt = HistGradientBoostingClassifier(min_samples_leaf=1,
...                                       max_depth=2,
...                                       learning_rate=1,
...                                       max_iter=1).fit(X, y)
>>> gbdt.predict(X)
array([0, 1, 0, 0, 1])
```

If no missing values were encountered for a given feature during training, then samples with missing values are mapped to whichever child has the most samples.

Low-level parallelism

HistGradientBoostingClassifier and *HistGradientBoostingRegressor* have implementations that use OpenMP for parallelization through Cython. For more details on how to control the number of threads, please refer to our *Parallelism* notes.

The following parts are parallelized:

- mapping samples from real values to integer-valued bins (finding the bin thresholds is however sequential)

- building histograms is parallelized over features
- finding the best split point at a node is parallelized over features
- during fit, mapping samples into the left and right children is parallelized over samples
- gradient and hessians computations are parallelized over samples
- predicting is parallelized over samples

Why it's faster

The bottleneck of a gradient boosting procedure is building the decision trees. Building a traditional decision tree (as in the other GBDTs *GradientBoostingClassifier* and *GradientBoostingRegressor*) requires sorting the samples at each node (for each feature). Sorting is needed so that the potential gain of a split point can be computed efficiently. Splitting a single node has thus a complexity of $\mathcal{O}(n_{\text{features}} \times n \log(n))$ where n is the number of samples at the node.

HistGradientBoostingClassifier and *HistGradientBoostingRegressor*, in contrast, do not require sorting the feature values and instead use a data-structure called a histogram, where the samples are implicitly ordered. Building a histogram has a $\mathcal{O}(n)$ complexity, so the node splitting procedure has a $\mathcal{O}(n_{\text{features}} \times n)$ complexity, much smaller than the previous one. In addition, instead of considering n split points, we here consider only `max_bins` split points, which is much smaller.

In order to build histograms, the input data `X` needs to be binned into integer-valued bins. This binning procedure does require sorting the feature values, but it only happens once at the very beginning of the boosting process (not at each node, like in *GradientBoostingClassifier* and *GradientBoostingRegressor*).

Finally, many parts of the implementation of *HistGradientBoostingClassifier* and *HistGradientBoostingRegressor* are parallelized.

References

Voting Classifier

The idea behind the *VotingClassifier* is to combine conceptually different machine learning classifiers and use a majority vote or the average predicted probabilities (soft vote) to predict the class labels. Such a classifier can be useful for a set of equally well performing model in order to balance out their individual weaknesses.

Majority Class Labels (Majority/Hard Voting)

In majority voting, the predicted class label for a particular sample is the class label that represents the majority (mode) of the class labels predicted by each individual classifier.

E.g., if the prediction for a given sample is

- classifier 1 -> class 1
- classifier 2 -> class 1
- classifier 3 -> class 2

the VotingClassifier (with `voting='hard'`) would classify the sample as "class 1" based on the majority class label.

In the cases of a tie, the *VotingClassifier* will select the class based on the ascending sort order. E.g., in the following scenario

- classifier 1 -> class 2
- classifier 2 -> class 1

the class label 1 will be assigned to the sample.

Usage

The following example shows how to fit the majority rule classifier:

```
>>> from sklearn import datasets
>>> from sklearn.model_selection import cross_val_score
>>> from sklearn.linear_model import LogisticRegression
>>> from sklearn.naive_bayes import GaussianNB
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.ensemble import VotingClassifier

>>> iris = datasets.load_iris()
>>> X, y = iris.data[:, 1:3], iris.target

>>> clf1 = LogisticRegression(random_state=1)
>>> clf2 = RandomForestClassifier(n_estimators=50, random_state=1)
>>> clf3 = GaussianNB()

>>> eclf = VotingClassifier(
...     estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)],
...     voting='hard')

>>> for clf, label in zip([clf1, clf2, clf3, eclf], ['Logistic Regression', 'Random␣
↪Forest', 'naive Bayes', 'Ensemble']):
...     scores = cross_val_score(clf, X, y, scoring='accuracy', cv=5)
...     print("Accuracy: %0.2f (+/- %0.2f) [%s]" % (scores.mean(), scores.std(),␣
↪label))
Accuracy: 0.95 (+/- 0.04) [Logistic Regression]
Accuracy: 0.94 (+/- 0.04) [Random Forest]
Accuracy: 0.91 (+/- 0.04) [naive Bayes]
Accuracy: 0.95 (+/- 0.04) [Ensemble]
```

Weighted Average Probabilities (Soft Voting)

In contrast to majority voting (hard voting), soft voting returns the class label as argmax of the sum of predicted probabilities.

Specific weights can be assigned to each classifier via the `weights` parameter. When weights are provided, the predicted class probabilities for each classifier are collected, multiplied by the classifier weight, and averaged. The final class label is then derived from the class label with the highest average probability.

To illustrate this with a simple example, let's assume we have 3 classifiers and a 3-class classification problems where we assign equal weights to all classifiers: w1=1, w2=1, w3=1.

The weighted average probabilities for a sample would then be calculated as follows:

classifier	class 1	class 2	class 3
classifier 1	w1 * 0.2	w1 * 0.5	w1 * 0.3
classifier 2	w2 * 0.6	w2 * 0.3	w2 * 0.1
classifier 3	w3 * 0.3	w3 * 0.4	w3 * 0.3
weighted average	0.37	0.4	0.23

Here, the predicted class label is 2, since it has the highest average probability.

The following example illustrates how the decision regions may change when a soft *VotingClassifier* is used based on an linear Support Vector Machine, a Decision Tree, and a K-nearest neighbor classifier:

```
>>> from sklearn import datasets
>>> from sklearn.tree import DecisionTreeClassifier
>>> from sklearn.neighbors import KNeighborsClassifier
>>> from sklearn.svm import SVC
>>> from itertools import product
>>> from sklearn.ensemble import VotingClassifier

>>> # Loading some example data
>>> iris = datasets.load_iris()
>>> X = iris.data[:, [0, 2]]
>>> y = iris.target

>>> # Training classifiers
>>> clf1 = DecisionTreeClassifier(max_depth=4)
>>> clf2 = KNeighborsClassifier(n_neighbors=7)
>>> clf3 = SVC(kernel='rbf', probability=True)
>>> eclf = VotingClassifier(estimators=[('dt', clf1), ('knn', clf2), ('svc', clf3)],
...                         voting='soft', weights=[2, 1, 2])

>>> clf1 = clf1.fit(X, y)
>>> clf2 = clf2.fit(X, y)
>>> clf3 = clf3.fit(X, y)
>>> eclf = eclf.fit(X, y)
```

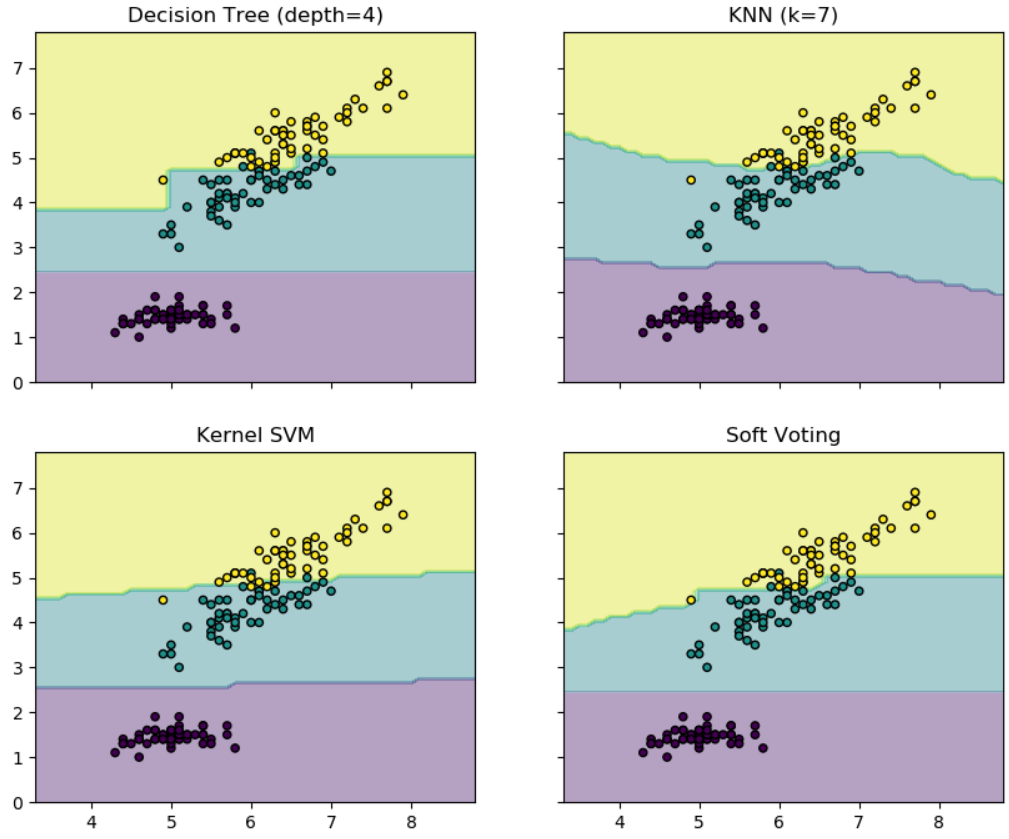
Using the `VotingClassifier` with `GridSearchCV`

The *VotingClassifier* can also be used together with *GridSearchCV* in order to tune the hyperparameters of the individual estimators:

```
>>> from sklearn.model_selection import GridSearchCV
>>> clf1 = LogisticRegression(random_state=1)
>>> clf2 = RandomForestClassifier(random_state=1)
>>> clf3 = GaussianNB()
>>> eclf = VotingClassifier(
...     estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)],
...     voting='soft'
... )

>>> params = {'lr__C': [1.0, 100.0], 'rf__n_estimators': [20, 200]}

>>> grid = GridSearchCV(estimator=eclf, param_grid=params, cv=5)
>>> grid = grid.fit(iris.data, iris.target)
```



Decision Tree (depth=4)
KNN (k=7)
Kernel SVM
Soft Voting
0
1
2
3
4
5
6
7
4
5
6
7
8

Usage

In order to predict the class labels based on the predicted class-probabilities (scikit-learn estimators in the VotingClassifier must support `predict_proba` method):

```
>>> eclf = VotingClassifier(
...     estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)],
...     voting='soft'
... )
```

Optionally, weights can be provided for the individual classifiers:

```
>>> eclf = VotingClassifier(
...     estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)],
...     voting='soft', weights=[2,5,1]
... )
```

Voting Regressor

The idea behind the *VotingRegressor* is to combine conceptually different machine learning regressors and return the average predicted values. Such a regressor can be useful for a set of equally well performing models in order to balance out their individual weaknesses.

Usage

The following example shows how to fit the VotingRegressor:

```
>>> from sklearn.datasets import load_boston
>>> from sklearn.ensemble import GradientBoostingRegressor
>>> from sklearn.ensemble import RandomForestRegressor
>>> from sklearn.linear_model import LinearRegression
>>> from sklearn.ensemble import VotingRegressor

>>> # Loading some example data
>>> X, y = load_boston(return_X_y=True)

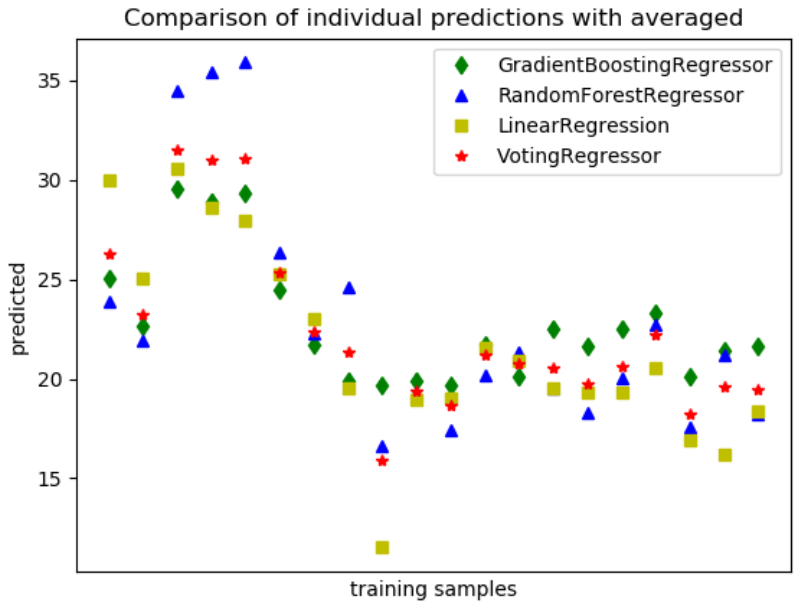
>>> # Training classifiers
>>> reg1 = GradientBoostingRegressor(random_state=1, n_estimators=10)
>>> reg2 = RandomForestRegressor(random_state=1, n_estimators=10)
>>> reg3 = LinearRegression()
>>> ereg = VotingRegressor(estimators=[('gb', reg1), ('rf', reg2), ('lr', reg3)])
>>> ereg = ereg.fit(X, y)
```

Examples:

- *Plot individual and voting regression predictions*

Stacked generalization

Stacked generalization is a method for combining estimators to reduce their biases [W1992] [HTF]. More precisely, the predictions of each individual estimator are stacked together and used as input to a final estimator to compute the prediction. This final estimator is trained through cross-validation.



The *StackingClassifier* and *StackingRegressor* provide such strategies which can be applied to classification and regression problems.

The `estimators` parameter corresponds to the list of the estimators which are stacked together in parallel on the input data. It should be given as a list of names and estimators:

```
>>> from sklearn.linear_model import RidgeCV, LassoCV
>>> from sklearn.svm import SVR
>>> estimators = [('ridge', RidgeCV()),
...               ('lasso', LassoCV(random_state=42)),
...               ('svr', SVR(C=1, gamma=1e-6))]
```

The `final_estimator` will use the predictions of the `estimators` as input. It needs to be a classifier or a regressor when using *StackingClassifier* or *StackingRegressor*, respectively:

```
>>> from sklearn.ensemble import GradientBoostingRegressor
>>> from sklearn.ensemble import StackingRegressor
>>> reg = StackingRegressor(
...     estimators=estimators,
...     final_estimator=GradientBoostingRegressor(random_state=42))
```

To train the `estimators` and `final_estimator`, the `fit` method needs to be called on the training data:

```
>>> from sklearn.datasets import load_boston
>>> X, y = load_boston(return_X_y=True)
>>> from sklearn.model_selection import train_test_split
>>> X_train, X_test, y_train, y_test = train_test_split(X, y,
...                                                     random_state=42)
>>> reg.fit(X_train, y_train)
StackingRegressor(...)
```

During training, the `estimators` are fitted on the whole training data `X_train`. They will be used when calling `predict` or `predict_proba`. To generalize and avoid over-fitting, the `final_estimator` is trained on out-

samples using *sklearn.model_selection.cross_val_predict* internally.

For *StackingClassifier*, note that the output of the `estimators` is controlled by the parameter `stack_method` and it is called by each estimator. This parameter is either a string, being estimator method names, or `'auto'` which will automatically identify an available method depending on the availability, tested in the order of preference: `predict_proba`, `decision_function` and `predict`.

A *StackingRegressor* and *StackingClassifier* can be used as any other regressor or classifier, exposing a `predict`, `predict_proba`, and `decision_function` methods, e.g.:

```
>>> y_pred = reg.predict(X_test)
>>> from sklearn.metrics import r2_score
>>> print('R2 score: {:.2f}'.format(r2_score(y_test, y_pred)))
R2 score: 0.81
```

Note that it is also possible to get the output of the stacked outputs of the `estimators` using the `transform` method:

```
>>> reg.transform(X_test[:5])
array([[28.78..., 28.43...  , 22.62...],
       [35.96..., 32.58..., 23.68...],
       [14.97..., 14.05..., 16.45...],
       [25.19..., 25.54..., 22.92...],
       [18.93..., 19.26..., 17.03... ]])
```

In practise, a stacking predictor predict as good as the best predictor of the base layer and even sometimes outputperform it by combining the different strength of the these predictors. However, training a stacking predictor is computationally expensive.

Note: For *StackingClassifier*, when using `stack_method_='predict_proba'`, the first column is dropped when the problem is a binary classification problem. Indeed, both probability columns predicted by each estimator are perfectly collinear.

Note: Multiple stacking layers can be achieved by assigning `final_estimator` to a *StackingClassifier* or *StackingRegressor*:

```
>>> final_layer = StackingRegressor(
...     estimators=[('rf', RandomForestRegressor(random_state=42)),
...                 ('gbrt', GradientBoostingRegressor(random_state=42))],
...     final_estimator=RidgeCV()
...     )
>>> multi_layer_regressor = StackingRegressor(
...     estimators=[('ridge', RidgeCV()),
...                 ('lasso', LassoCV(random_state=42)),
...                 ('svr', SVR(C=1, gamma=1e-6, kernel='rbf'))],
...     final_estimator=final_layer
... )
>>> multi_layer_regressor.fit(X_train, y_train)
StackingRegressor(...)
>>> print('R2 score: {:.2f}'
...       .format(multi_layer_regressor.score(X_test, y_test)))
R2 score: 0.82
```

4.1.12 Multiclass and multilabel algorithms

Warning: All classifiers in scikit-learn do multiclass classification out-of-the-box. You don't need to use the *sklearn.multiclass* module unless you want to experiment with different multiclass strategies.

The *sklearn.multiclass* module implements *meta-estimators* to solve `multiclass` and `multilabel` classification problems by decomposing such problems into binary classification problems. `multioutput` regression is also supported.

- **Multiclass classification**: classification task with more than two classes. Each sample can only be labelled as one class.

  For example, classification using features extracted from a set of images of fruit, where each image may either be of an orange, an apple, or a pear. Each image is one sample and is labelled as one of the 3 possible classes. Multiclass classification makes the assumption that each sample is assigned to one and only one label - one sample cannot, for example, be both a pear and an apple.

  Valid *multiclass* representations for `type_of_target` (`y`) are:

  – 1d or column vector containing more than two discrete values. An example of a vector `y` for 3 samples:

  ```
  >>> import numpy as np
  >>> y = np.array(['apple', 'pear', 'apple'])
  >>> print(y)
  ['apple' 'pear' 'apple']
  ```

  – sparse *binary* matrix of shape `(n_samples, n_classes)` with a single element per row, where each column represents one class. An example of a sparse *binary* matrix `y` for 3 samples, where the columns, in order, are orange, apple and pear:

  ```
  >>> from scipy import sparse
  >>> row_ind = np.array([0, 1, 2])
  >>> col_ind = np.array([1, 2, 1])
  >>> y_sparse = sparse.csr_matrix((np.ones(3), (row_ind, col_ind)))
  >>> print(y_sparse)
    (0, 1)        1.0
    (1, 2)        1.0
    (2, 1)        1.0
  ```

- **Multilabel classification**: classification task labelling each sample with `x` labels from `n_classes` possible classes, where `x` can be 0 to `n_classes` inclusive. This can be thought of as predicting properties of a sample that are not mutually exclusive. Formally, a binary output is assigned to each class, for every sample. Positive classes are indicated with 1 and negative classes with 0 or -1. It is thus comparable to running `n_classes` binary classification tasks, for example with *sklearn.multioutput.MultiOutputClassifier*. This approach treats each label independently whereas multilabel classifiers *may* treat the multiple classes simultaneously, accounting for correlated behaviour amoung them.

  For example, prediction of the topics relevant to a text document or video. The document or video may be about one of 'religion', 'politics', 'finance' or 'education', several of the topic classes or all of the topic classes.

  Valid representation of *multilabel* `y` is either dense (or sparse) *binary* matrix of shape `(n_samples, n_classes)`. Each column represents a class. The `1`'s in each row denote the positive classes a sample

has been labelled with. An example of a dense matrix `y` for 3 samples:

```
>>> y = np.array([[1, 0, 0, 1], [0, 0, 1, 1], [0, 0, 0, 0]])
>>> print(y)
[[1 0 0 1]
 [0 0 1 1]
 [0 0 0 0]]
```

An example of the same `y` in sparse matrix form:

```
>>> y_sparse = sparse.csr_matrix(y)
>>> print(y_sparse)
  (0, 0)    1
  (0, 3)    1
  (1, 2)    1
  (1, 3)    1
```

- **Multioutput regression**: predicts multiple numerical properties for each sample. Each property is a numerical variable and the number of properties to be predicted for each sample is greater than or equal to 2. Some estimators that support multioutput regression are faster than just running `n_output` estimators.

  For example, prediction of both wind speed and wind direction, in degrees, using data obtained at a certain location. Each sample would be data obtained at one location and both wind speed and directtion would be output for each sample.

  Valid representation of *multilabel* `y` is dense matrix of shape `(n_samples, n_classes)` of floats. A column wise concatenation of *continuous* variables. An example of `y` for 3 samples:

```
>>> y = np.array([[31.4, 94], [40.5, 109], [25.0, 30]])
>>> print(y)
[[ 31.4  94. ]
 [ 40.5 109. ]
 [ 25.   30. ]]
```

- **Multioutput-multiclass classification** (also known as **multitask classification**): classification task which labels each sample with a set of **non-binary** properties. Both the number of properties and the number of classes per property is greater than 2. A single estimator thus handles several joint classification tasks. This is both a generalization of the multi*label* classification task, which only considers binary attributes, as well as a generalization of the multi*class* classification task, where only one property is considered.

  For example, classification of the properties "type of fruit" and "colour" for a set of images of fruit. The property "type of fruit" has the possible classes: "apple", "pear" and "orange". The property "colour" has the possible classes: "green", "red", "yellow" and "orange". Each sample is an image of a fruit, a label is output for both properties and each label is one of the possible classes of the corresponding property.

  Valid representation of *multilabel* `y` is dense matrix of shape `(n_samples, n_classes)` of floats. A column wise concatenation of 1d *multiclass* variables. An example of `y` for 3 samples:

```
>>> y = np.array([['apple', 'green'], ['orange', 'orange'], ['pear', 'green']])
>>> print(y)
[['apple' 'green']
 ['orange' 'orange']
 ['pear' 'green']]
```

  Note that any classifiers handling multioutput-multiclass (also known as multitask classification) tasks, support the multilabel classification task as a special case. Multitask classification is similar to the multioutput classification task with different model formulations. For more information, see the relevant estimator documentation.

All scikit-learn classifiers are capable of multiclass classification, but the meta-estimators offered by *sklearn.multiclass* permit changing the way they handle more than two classes because this may have an effect on classifier performance (either in terms of generalization error or required computational resources).

Summary

	Number of targets	Target cardinality	Valid `type_of_target`
Multiclass classification	1	>2	• 'multiclass'
Multilabel classification	>1	2 (0 or 1)	• 'multilabel-indicator'
Multioutput regression	>1	Continuous	• 'continuous-multioutput'
Multioutput- multiclass classification	>1	>2	• 'multiclass-multioutput'

Below is a summary of the classifiers supported by scikit-learn grouped by strategy; you don't need the meta-estimators in this class if you're using one of these, unless you want custom multiclass behavior:

- **Inherently multiclass:**
  - *sklearn.naive_bayes.BernoulliNB*
  - *sklearn.tree.DecisionTreeClassifier*
  - *sklearn.tree.ExtraTreeClassifier*
  - *sklearn.ensemble.ExtraTreesClassifier*
  - *sklearn.naive_bayes.GaussianNB*
  - *sklearn.neighbors.KNeighborsClassifier*
  - *sklearn.semi_supervised.LabelPropagation*
  - *sklearn.semi_supervised.LabelSpreading*
  - *sklearn.discriminant_analysis.LinearDiscriminantAnalysis*
  - *sklearn.svm.LinearSVC* (setting multi_class="crammer_singer")
  - *sklearn.linear_model.LogisticRegression* (setting multi_class="multinomial")
  - *sklearn.linear_model.LogisticRegressionCV* (setting multi_class="multinomial")
  - *sklearn.neural_network.MLPClassifier*
  - *sklearn.neighbors.NearestCentroid*
  - *sklearn.discriminant_analysis.QuadraticDiscriminantAnalysis*
  - *sklearn.neighbors.RadiusNeighborsClassifier*
  - *sklearn.ensemble.RandomForestClassifier*
  - *sklearn.linear_model.RidgeClassifier*
  - *sklearn.linear_model.RidgeClassifierCV*

- **Multiclass as One-Vs-One:**
  - *sklearn.svm.NuSVC*
  - *sklearn.svm.SVC*.
  - *sklearn.gaussian_process.GaussianProcessClassifier* (setting multi_class = "one_vs_one")
- **Multiclass as One-Vs-The-Rest:**
  - *sklearn.ensemble.GradientBoostingClassifier*
  - *sklearn.gaussian_process.GaussianProcessClassifier* (setting multi_class = "one_vs_rest")
  - *sklearn.svm.LinearSVC* (setting multi_class="ovr")
  - *sklearn.linear_model.LogisticRegression* (setting multi_class="ovr")
  - *sklearn.linear_model.LogisticRegressionCV* (setting multi_class="ovr")
  - *sklearn.linear_model.SGDClassifier*
  - *sklearn.linear_model.Perceptron*
  - *sklearn.linear_model.PassiveAggressiveClassifier*
- **Support multilabel:**
  - *sklearn.tree.DecisionTreeClassifier*
  - *sklearn.tree.ExtraTreeClassifier*
  - *sklearn.ensemble.ExtraTreesClassifier*
  - *sklearn.neighbors.KNeighborsClassifier*
  - *sklearn.neural_network.MLPClassifier*
  - *sklearn.neighbors.RadiusNeighborsClassifier*
  - *sklearn.ensemble.RandomForestClassifier*
  - *sklearn.linear_model.RidgeClassifierCV*
- **Support multiclass-multioutput:**
  - *sklearn.tree.DecisionTreeClassifier*
  - *sklearn.tree.ExtraTreeClassifier*
  - *sklearn.ensemble.ExtraTreesClassifier*
  - *sklearn.neighbors.KNeighborsClassifier*
  - *sklearn.neighbors.RadiusNeighborsClassifier*
  - *sklearn.ensemble.RandomForestClassifier*

Warning: At present, no metric in *sklearn.metrics* supports the multioutput-multiclass classification task.

Multilabel classification format

In multilabel learning, the joint set of binary classification tasks is expressed with label binary indicator array: each sample is one row of a 2d array of shape (n_samples, n_classes) with binary values: the one, i.e. the non zero elements, corresponds to the subset of labels. An array such as `np.array([[1, 0, 0], [0, 1, 1], [0, 0, 0]])` represents label 0 in the first sample, labels 1 and 2 in the second sample, and no labels in the third sample.

Producing multilabel data as a list of sets of labels may be more intuitive. The *MultiLabelBinarizer* transformer can be used to convert between a collection of collections of labels and the indicator format.

```
>>> from sklearn.preprocessing import MultiLabelBinarizer
>>> y = [[2, 3, 4], [2], [0, 1, 3], [0, 1, 2, 3, 4], [0, 1, 2]]
>>> MultiLabelBinarizer().fit_transform(y)
array([[0, 0, 1, 1, 1],
       [0, 0, 1, 0, 0],
       [1, 1, 0, 1, 0],
       [1, 1, 1, 1, 1],
       [1, 1, 1, 0, 0]])
```

One-Vs-The-Rest

This strategy, also known as **one-vs-all**, is implemented in *OneVsRestClassifier*. The strategy consists in fitting one classifier per class. For each classifier, the class is fitted against all the other classes. In addition to its computational efficiency (only `n_classes` classifiers are needed), one advantage of this approach is its interpretability. Since each class is represented by one and only one classifier, it is possible to gain knowledge about the class by inspecting its corresponding classifier. This is the most commonly used strategy and is a fair default choice.

Multiclass learning

Below is an example of multiclass learning using OvR:

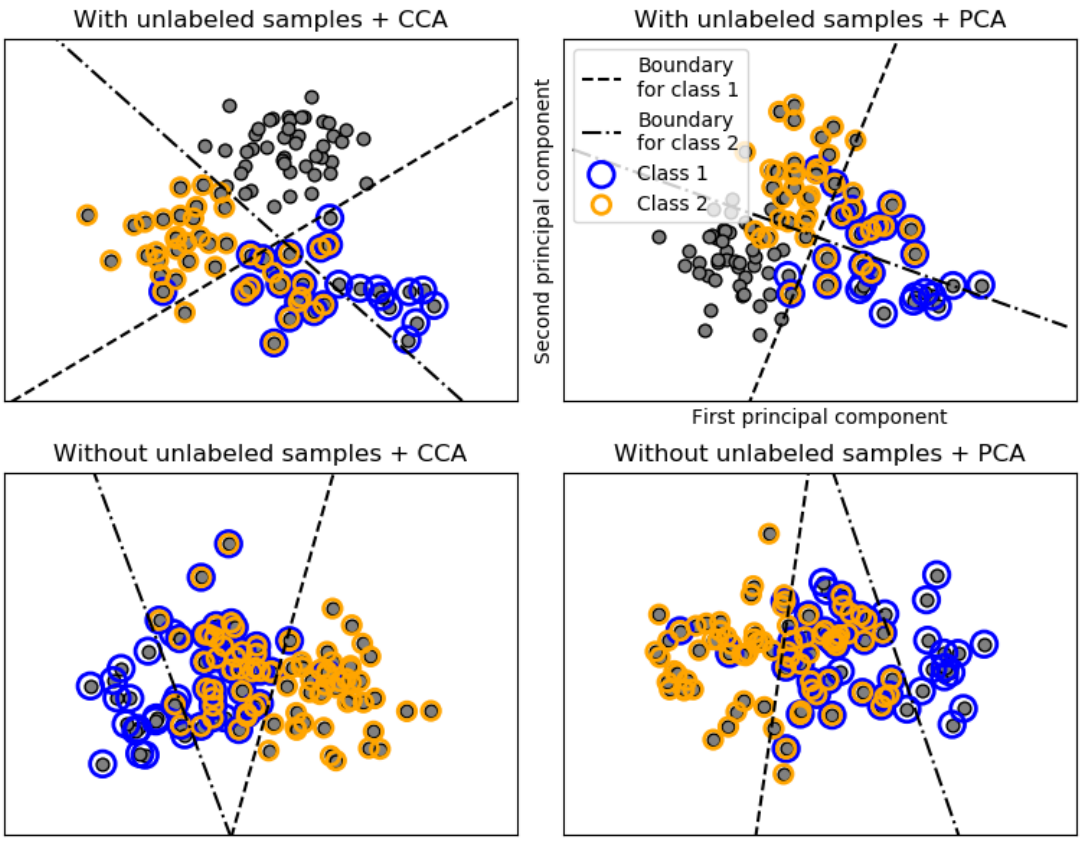
```
>>> from sklearn import datasets
>>> from sklearn.multiclass import OneVsRestClassifier
>>> from sklearn.svm import LinearSVC
>>> X, y = datasets.load_iris(return_X_y=True)
>>> OneVsRestClassifier(LinearSVC(random_state=0)).fit(X, y).predict(X)
array([0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
       1, 2, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 1, 1, 1, 1, 1, 1, 1,
       1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
       2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 1, 2, 2, 2, 1, 2, 2, 2, 2,
       2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2])
```

Multilabel learning

OneVsRestClassifier also supports multilabel classification. To use this feature, feed the classifier an indicator matrix, in which cell [i, j] indicates the presence of label j in sample i.

Examples:

- *Multilabel classification*



One-Vs-One

OneVsOneClassifier constructs one classifier per pair of classes. At prediction time, the class which received the most votes is selected. In the event of a tie (among two classes with an equal number of votes), it selects the class with the highest aggregate classification confidence by summing over the pair-wise classification confidence levels computed by the underlying binary classifiers.

Since it requires to fit `n_classes * (n_classes - 1) / 2` classifiers, this method is usually slower than one-vs-the-rest, due to its O(n_classes^2) complexity. However, this method may be advantageous for algorithms such as kernel algorithms which don't scale well with `n_samples`. This is because each individual learning problem only involves a small subset of the data whereas, with one-vs-the-rest, the complete dataset is used `n_classes` times. The decision function is the result of a monotonic transformation of the one-versus-one classification.

Multiclass learning

Below is an example of multiclass learning using OvO:

```
>>> from sklearn import datasets
>>> from sklearn.multiclass import OneVsOneClassifier
>>> from sklearn.svm import LinearSVC
>>> X, y = datasets.load_iris(return_X_y=True)
>>> OneVsOneClassifier(LinearSVC(random_state=0)).fit(X, y).predict(X)
array([0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
```

(continues on next page)

(continued from previous page)

```
       1, 2, 1, 2, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 2, 1, 1, 1, 1, 1, 1, 1, 1,
       1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
       2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
       2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2])
```

Error-Correcting Output-Codes

Output-code based strategies are fairly different from one-vs-the-rest and one-vs-one. With these strategies, each class is represented in a Euclidean space, where each dimension can only be 0 or 1. Another way to put it is that each class is represented by a binary code (an array of 0 and 1). The matrix which keeps track of the location/code of each class is called the code book. The code size is the dimensionality of the aforementioned space. Intuitively, each class should be represented by a code as unique as possible and a good code book should be designed to optimize classification accuracy. In this implementation, we simply use a randomly-generated code book as advocated in[3] although more elaborate methods may be added in the future.

At fitting time, one binary classifier per bit in the code book is fitted. At prediction time, the classifiers are used to project new points in the class space and the class closest to the points is chosen.

In *`OutputCodeClassifier`*, the `code_size` attribute allows the user to control the number of classifiers which will be used. It is a percentage of the total number of classes.

A number between 0 and 1 will require fewer classifiers than one-vs-the-rest. In theory, `log2(n_classes) / n_classes` is sufficient to represent each class unambiguously. However, in practice, it may not lead to good accuracy since `log2(n_classes)` is much smaller than n_classes.

A number greater than 1 will require more classifiers than one-vs-the-rest. In this case, some classifiers will in theory correct for the mistakes made by other classifiers, hence the name "error-correcting". In practice, however, this may not happen as classifier mistakes will typically be correlated. The error-correcting output codes have a similar effect to bagging.

Multiclass learning

Below is an example of multiclass learning using Output-Codes:

```
>>> from sklearn import datasets
>>> from sklearn.multiclass import OutputCodeClassifier
>>> from sklearn.svm import LinearSVC
>>> X, y = datasets.load_iris(return_X_y=True)
>>> clf = OutputCodeClassifier(LinearSVC(random_state=0),
...                            code_size=2, random_state=0)
>>> clf.fit(X, y).predict(X)
array([0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 2, 1, 1, 1, 1, 1, 1, 1, 1, 2, 1, 1,
       1, 2, 1, 1, 1, 1, 1, 1, 2, 1, 1, 1, 1, 1, 2, 2, 2, 1, 1, 1, 1, 1, 1,
       1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
```

Multioutput regression

Multioutput regression support can be added to any regressor with `MultiOutputRegressor`. This strategy consists of fitting one regressor per target. Since each target is represented by exactly one regressor it is possible to gain knowledge about the target by inspecting its corresponding regressor. As `MultiOutputRegressor` fits one regressor per target it can not take advantage of correlations between targets.

Below is an example of multioutput regression:

```
>>> from sklearn.datasets import make_regression
>>> from sklearn.multioutput import MultiOutputRegressor
>>> from sklearn.ensemble import GradientBoostingRegressor
>>> X, y = make_regression(n_samples=10, n_targets=3, random_state=1)
>>> MultiOutputRegressor(GradientBoostingRegressor(random_state=0)).fit(X, y).
↪predict(X)
array([[-154.75474165, -147.03498585,  -50.03812219],
       [   7.12165031,    5.12914884,  -81.46081961],
       [-187.8948621 , -100.44373091,   13.88978285],
       [-141.62745778,   95.02891072, -191.48204257],
       [  97.03260883,  165.34867495,  139.52003279],
       [ 123.92529176,   21.25719016,   -7.84253   ],
       [-122.25193977,  -85.16443186, -107.12274212],
       [ -30.170388  ,  -94.80956739,   12.16979946],
       [ 140.72667194,  176.50941682,  -17.50447799],
       [ 149.37967282,  -81.15699552,   -5.72850319]])
```

Multioutput classification

Multioutput classification support can be added to any classifier with `MultiOutputClassifier`. This strategy consists of fitting one classifier per target. This allows multiple target variable classifications. The purpose of this class is to extend estimators to be able to estimate a series of target functions (f1,f2,f3...,fn) that are trained on a single X predictor matrix to predict a series of responses (y1,y2,y3...,yn).

Below is an example of multioutput classification:

```
>>> from sklearn.datasets import make_classification
>>> from sklearn.multioutput import MultiOutputClassifier
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.utils import shuffle
>>> import numpy as np
>>> X, y1 = make_classification(n_samples=10, n_features=100, n_informative=30, n_
↪classes=3, random_state=1)
```

(continues on next page)

(continued from previous page)

```
>>> y2 = shuffle(y1, random_state=1)
>>> y3 = shuffle(y1, random_state=2)
>>> Y = np.vstack((y1, y2, y3)).T
>>> n_samples, n_features = X.shape # 10,100
>>> n_outputs = Y.shape[1] # 3
>>> n_classes = 3
>>> forest = RandomForestClassifier(random_state=1)
>>> multi_target_forest = MultiOutputClassifier(forest, n_jobs=-1)
>>> multi_target_forest.fit(X, Y).predict(X)
array([[2, 2, 0],
       [1, 2, 1],
       [2, 1, 0],
       [0, 0, 2],
       [0, 2, 1],
       [0, 0, 2],
       [1, 1, 0],
       [1, 1, 1],
       [0, 0, 2],
       [2, 0, 0]])
```

Classifier Chain

Classifier chains (see `ClassifierChain`) are a way of combining a number of binary classifiers into a single multi-label model that is capable of exploiting correlations among targets.

For a multi-label classification problem with N classes, N binary classifiers are assigned an integer between 0 and N-1. These integers define the order of models in the chain. Each classifier is then fit on the available training data plus the true labels of the classes whose models were assigned a lower number.

When predicting, the true labels will not be available. Instead the predictions of each model are passed on to the subsequent models in the chain to be used as features.

Clearly the order of the chain is important. The first model in the chain has no information about the other labels while the last model in the chain has features indicating the presence of all of the other labels. In general one does not know the optimal ordering of the models in the chain so typically many randomly ordered chains are fit and their predictions are averaged together.

References:

Jesse Read, Bernhard Pfahringer, Geoff Holmes, Eibe Frank, "Classifier Chains for Multi-label Classification", 2009.

Regressor Chain

Regressor chains (see `RegressorChain`) is analogous to ClassifierChain as a way of combining a number of regressions into a single multi-target model that is capable of exploiting correlations among targets.

4.1.13 Feature selection

The classes in the *sklearn.feature_selection* module can be used for feature selection/dimensionality reduction on sample sets, either to improve estimators' accuracy scores or to boost their performance on very high-dimensional datasets.

Removing features with low variance

VarianceThreshold is a simple baseline approach to feature selection. It removes all features whose variance doesn't meet some threshold. By default, it removes all zero-variance features, i.e. features that have the same value in all samples.

As an example, suppose that we have a dataset with boolean features, and we want to remove all features that are either one or zero (on or off) in more than 80% of the samples. Boolean features are Bernoulli random variables, and the variance of such variables is given by

$$\mathrm{Var}[X] = p(1-p)$$

so we can select using the threshold `.8 * (1 - .8)`:

```
>>> from sklearn.feature_selection import VarianceThreshold
>>> X = [[0, 0, 1], [0, 1, 0], [1, 0, 0], [0, 1, 1], [0, 1, 0], [0, 1, 1]]
>>> sel = VarianceThreshold(threshold=(.8 * (1 - .8)))
>>> sel.fit_transform(X)
array([[0, 1],
       [1, 0],
       [0, 0],
       [1, 1],
       [1, 0],
       [1, 1]])
```

As expected, `VarianceThreshold` has removed the first column, which has a probability $p = 5/6 > .8$ of containing a zero.

Univariate feature selection

Univariate feature selection works by selecting the best features based on univariate statistical tests. It can be seen as a preprocessing step to an estimator. Scikit-learn exposes feature selection routines as objects that implement the `transform` method:

- *SelectKBest* removes all but the k highest scoring features
- *SelectPercentile* removes all but a user-specified highest scoring percentage of features
- using common univariate statistical tests for each feature: false positive rate *SelectFpr*, false discovery rate *SelectFdr*, or family wise error *SelectFwe*.
- *GenericUnivariateSelect* allows to perform univariate feature selection with a configurable strategy. This allows to select the best univariate selection strategy with hyper-parameter search estimator.

For instance, we can perform a χ^2 test to the samples to retrieve only the two best features as follows:

```
>>> from sklearn.datasets import load_iris
>>> from sklearn.feature_selection import SelectKBest
>>> from sklearn.feature_selection import chi2
>>> X, y = load_iris(return_X_y=True)
>>> X.shape
(150, 4)
>>> X_new = SelectKBest(chi2, k=2).fit_transform(X, y)
>>> X_new.shape
(150, 2)
```

These objects take as input a scoring function that returns univariate scores and p-values (or only scores for *SelectKBest* and *SelectPercentile*):

- For regression: *f_regression*, *mutual_info_regression*
- For classification: *chi2*, *f_classif*, *mutual_info_classif*

The methods based on F-test estimate the degree of linear dependency between two random variables. On the other hand, mutual information methods can capture any kind of statistical dependency, but being nonparametric, they require more samples for accurate estimation.

Feature selection with sparse data

If you use sparse data (i.e. data represented as sparse matrices), *chi2*, *mutual_info_regression*, *mutual_info_classif* will deal with the data without making it dense.

Warning: Beware not to use a regression scoring function with a classification problem, you will get useless results.

Examples:

- *Univariate Feature Selection*
- *Comparison of F-test and mutual information*

Recursive feature elimination

Given an external estimator that assigns weights to features (e.g., the coefficients of a linear model), recursive feature elimination (*RFE*) is to select features by recursively considering smaller and smaller sets of features. First, the estimator is trained on the initial set of features and the importance of each feature is obtained either through a `coef_` attribute or through a `feature_importances_` attribute. Then, the least important features are pruned from current set of features.That procedure is recursively repeated on the pruned set until the desired number of features to select is eventually reached.

RFECV performs RFE in a cross-validation loop to find the optimal number of features.

Examples:

- *Recursive feature elimination*: A recursive feature elimination example showing the relevance of pixels in a digit classification task.
- *Recursive feature elimination with cross-validation*: A recursive feature elimination example with automatic tuning of the number of features selected with cross-validation.

Feature selection using SelectFromModel

SelectFromModel is a meta-transformer that can be used along with any estimator that has a `coef_` or `feature_importances_` attribute after fitting. The features are considered unimportant and removed, if the corresponding `coef_` or `feature_importances_` values are below the provided `threshold` parameter. Apart from specifying the threshold numerically, there are built-in heuristics for finding a threshold using a string argument. Available heuristics are “mean”, “median” and float multiples of these like “0.1*mean”.

For examples on how it is to be used refer to the sections below.

Examples

- *Feature selection using SelectFromModel and LassoCV*: Selecting the two most important features from the Boston dataset without knowing the threshold beforehand.

L1-based feature selection

Linear models penalized with the L1 norm have sparse solutions: many of their estimated coefficients are zero. When the goal is to reduce the dimensionality of the data to use with another classifier, they can be used along with `feature_selection.SelectFromModel` to select the non-zero coefficients. In particular, sparse estimators useful for this purpose are the `linear_model.Lasso` for regression, and of `linear_model.LogisticRegression` and `svm.LinearSVC` for classification:

```
>>> from sklearn.svm import LinearSVC
>>> from sklearn.datasets import load_iris
>>> from sklearn.feature_selection import SelectFromModel
>>> X, y = load_iris(return_X_y=True)
>>> X.shape
(150, 4)
>>> lsvc = LinearSVC(C=0.01, penalty="l1", dual=False).fit(X, y)
>>> model = SelectFromModel(lsvc, prefit=True)
>>> X_new = model.transform(X)
>>> X_new.shape
(150, 3)
```

With SVMs and logistic-regression, the parameter C controls the sparsity: the smaller C the fewer features selected. With Lasso, the higher the alpha parameter, the fewer features selected.

Examples:

- *Classification of text documents using sparse features*: Comparison of different algorithms for document classification including L1-based feature selection.

L1-recovery and compressive sensing

For a good choice of alpha, the *Lasso* can fully recover the exact set of non-zero variables using only few observations, provided certain specific conditions are met. In particular, the number of samples should be "sufficiently large", or L1 models will perform at random, where "sufficiently large" depends on the number of non-zero coefficients, the logarithm of the number of features, the amount of noise, the smallest absolute value of non-zero coefficients, and the structure of the design matrix X. In addition, the design matrix must display certain specific properties, such as not being too correlated.

There is no general rule to select an alpha parameter for recovery of non-zero coefficients. It can by set by cross-validation (`LassoCV` or `LassoLarsCV`), though this may lead to under-penalized models: including a small number of non-relevant variables is not detrimental to prediction score. BIC (`LassoLarsIC`) tends, on the opposite, to set high values of alpha.

Reference Richard G. Baraniuk "Compressive Sensing", IEEE Signal Processing Magazine [120] July 2007 http://users.isr.ist.utl.pt/~aguiar/CS_notes.pdf

Tree-based feature selection

Tree-based estimators (see the *sklearn.tree* module and forest of trees in the *sklearn.ensemble* module) can be used to compute feature importances, which in turn can be used to discard irrelevant features (when coupled with the *sklearn.feature_selection.SelectFromModel* meta-transformer):

```
>>> from sklearn.ensemble import ExtraTreesClassifier
>>> from sklearn.datasets import load_iris
>>> from sklearn.feature_selection import SelectFromModel
>>> X, y = load_iris(return_X_y=True)
>>> X.shape
(150, 4)
>>> clf = ExtraTreesClassifier(n_estimators=50)
>>> clf = clf.fit(X, y)
>>> clf.feature_importances_
array([ 0.04...,  0.05...,  0.4...,  0.4...])
>>> model = SelectFromModel(clf, prefit=True)
>>> X_new = model.transform(X)
>>> X_new.shape
(150, 2)
```

Examples:

- *Feature importances with forests of trees*: example on synthetic data showing the recovery of the actually meaningful features.
- *Pixel importances with a parallel forest of trees*: example on face recognition data.

Feature selection as part of a pipeline

Feature selection is usually used as a pre-processing step before doing the actual learning. The recommended way to do this in scikit-learn is to use a *sklearn.pipeline.Pipeline*:

```
clf = Pipeline([
  ('feature_selection', SelectFromModel(LinearSVC(penalty="l1"))),
  ('classification', RandomForestClassifier())
])
clf.fit(X, y)
```

In this snippet we make use of a *sklearn.svm.LinearSVC* coupled with *sklearn.feature_selection.SelectFromModel* to evaluate feature importances and select the most relevant features. Then, a *sklearn.ensemble.RandomForestClassifier* is trained on the transformed output, i.e. using only relevant features. You can perform similar operations with the other feature selection methods and also classifiers that provide a way to evaluate feature importances of course. See the *sklearn.pipeline.Pipeline* examples for more details.

4.1.14 Semi-Supervised

Semi-supervised learning is a situation in which in your training data some of the samples are not labeled. The semi-supervised estimators in *sklearn.semi_supervised* are able to make use of this additional unlabeled data to better capture the shape of the underlying data distribution and generalize better to new samples. These algorithms can perform well when we have a very small amount of labeled points and a large amount of unlabeled points.

Unlabeled entries in y

It is important to assign an identifier to unlabeled points along with the labeled data when training the model with the `fit` method. The identifier that this implementation uses is the integer value -1.

Label Propagation

Label propagation denotes a few variations of semi-supervised graph inference algorithms.

A few features available in this model:

- Can be used for classification and regression tasks
- Kernel methods to project data into alternate dimensional spaces

`scikit-learn` provides two label propagation models: *`LabelPropagation`* and *`LabelSpreading`*. Both work by constructing a similarity graph over all items in the input dataset.

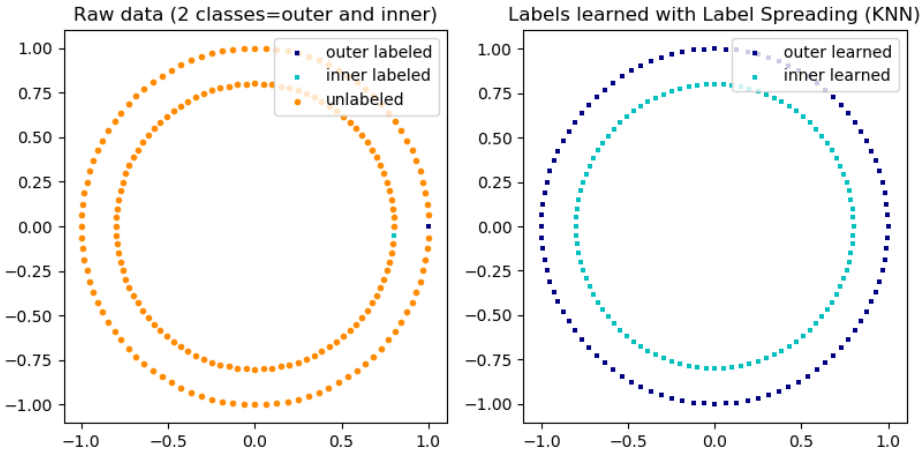

Fig. 1: **An illustration of label-propagation:** *the structure of unlabeled observations is consistent with the class structure, and thus the class label can be propagated to the unlabeled observations of the training set.*

`LabelPropagation` and *`LabelSpreading`* differ in modifications to the similarity matrix that graph and the clamping effect on the label distributions. Clamping allows the algorithm to change the weight of the true ground labeled data to some degree. The *`LabelPropagation`* algorithm performs hard clamping of input labels, which means $\alpha = 0$. This clamping factor can be relaxed, to say $\alpha = 0.2$, which means that we will always retain 80 percent of our original label distribution, but the algorithm gets to change its confidence of the distribution within 20 percent.

`LabelPropagation` uses the raw similarity matrix constructed from the data with no modifications. In contrast, *`LabelSpreading`* minimizes a loss function that has regularization properties, as such it is often more robust to noise. The algorithm iterates on a modified version of the original graph and normalizes the edge weights by computing the normalized graph Laplacian matrix. This procedure is also used in *Spectral clustering*.

Label propagation models have two built-in kernel methods. Choice of kernel effects both scalability and performance of the algorithms. The following are available:

- rbf ($\exp(-\gamma|x - y|^2), \gamma > 0$). γ is specified by keyword gamma.
- knn ($1[x' \in kNN(x)]$). k is specified by keyword n_neighbors.

The RBF kernel will produce a fully connected graph which is represented in memory by a dense matrix. This matrix may be very large and combined with the cost of performing a full matrix multiplication calculation for each iteration

of the algorithm can lead to prohibitively long running times. On the other hand, the KNN kernel will produce a much more memory-friendly sparse matrix which can drastically reduce running times.

4.1.15 Isotonic regression

The class `IsotonicRegression` fits a non-decreasing function to data. It solves the following problem:

minimize $\sum_i w_i(y_i - \hat{y}_i)^2$

subject to $\hat{y}_{min} = \hat{y}_1 \leq \hat{y}_2 ... \leq \hat{y}_n = \hat{y}_{max}$

where each w_i is strictly positive and each y_i is an arbitrary real number. It yields the vector which is composed of non-decreasing elements the closest in terms of mean squared error. In practice this list of elements forms a function that is piecewise linear.

4.1.16 Probability calibration

When performing classification you often want not only to predict the class label, but also obtain a probability of the respective label. This probability gives you some kind of confidence on the prediction. Some models can give you poor estimates of the class probabilities and some even do not support probability prediction. The calibration module allows you to better calibrate the probabilities of a given model, or to add support for probability prediction.

Well calibrated classifiers are probabilistic classifiers for which the output of the predict_proba method can be directly interpreted as a confidence level. For instance, a well calibrated (binary) classifier should classify the samples such that among the samples to which it gave a predict_proba value close to 0.8, approximately 80% actually belong to the positive class. The following plot compares how well the probabilistic predictions of different classifiers are calibrated:

`LogisticRegression` returns well calibrated predictions by default as it directly optimizes log-loss. In contrast, the other methods return biased probabilities; with different biases per method:

- `GaussianNB` tends to push probabilities to 0 or 1 (note the counts in the histograms). This is mainly because it makes the assumption that features are conditionally independent given the class, which is not the case in this dataset which contains 2 redundant features.
- `RandomForestClassifier` shows the opposite behavior: the histograms show peaks at approximately 0.2 and 0.9 probability, while probabilities close to 0 or 1 are very rare. An explanation for this is given by

Niculescu-Mizil and Caruana[4]: "Methods such as bagging and random forests that average predictions from a base set of models can have difficulty making predictions near 0 and 1 because variance in the underlying base models will bias predictions that should be near zero or one away from these values. Because predictions are restricted to the interval [0,1], errors caused by variance tend to be one-sided near zero and one. For example, if a model should predict p = 0 for a case, the only way bagging can achieve this is if all bagged trees predict zero. If we add noise to the trees that bagging is averaging over, this noise will cause some trees to predict values larger than 0 for this case, thus moving the average prediction of the bagged ensemble away from 0. We observe this effect most strongly with random forests because the base-level trees trained with random forests have relatively high variance due to feature subsetting." As a result, the calibration curve also referred to as the reliability diagram (Wilks 1995[5]) shows a characteristic sigmoid shape, indicating that the classifier could trust its "intuition" more and return probabilities closer to 0 or 1 typically.

- Linear Support Vector Classification (`LinearSVC`) shows an even more sigmoid curve as the RandomForestClassifier, which is typical for maximum-margin methods (compare Niculescu-Mizil and Caruana[4]), which focus on hard samples that are close to the decision boundary (the support vectors).

Two approaches for performing calibration of probabilistic predictions are provided: a parametric approach based on Platt's sigmoid model and a non-parametric approach based on isotonic regression (`sklearn.isotonic`). Probability calibration should be done on new data not used for model fitting. The class `CalibratedClassifierCV` uses a cross-validation generator and estimates for each split the model parameter on the train samples and the calibration of the test samples. The probabilities predicted for the folds are then averaged. Already fitted classifiers can be calibrated by `CalibratedClassifierCV` via the parameter cv="prefit". In this case, the user has to take care manually that data for model fitting and calibration are disjoint.

The following images demonstrate the benefit of probability calibration. The first image present a dataset with 2 classes and 3 blobs of data. The blob in the middle contains random samples of each class. The probability for the samples in this blob should be 0.5.

The following image shows on the data above the estimated probability using a Gaussian naive Bayes classifier without calibration, with a sigmoid calibration and with a non-parametric isotonic calibration. One can observe that the non-parametric model provides the most accurate probability estimates for samples in the middle, i.e., 0.5.

The following experiment is performed on an artificial dataset for binary classification with 100,000 samples (1,000 of them are used for model fitting) with 20 features. Of the 20 features, only 2 are informative and 10 are redundant. The figure shows the estimated probabilities obtained with logistic regression, a linear support-vector classifier (SVC), and linear SVC with both isotonic calibration and sigmoid calibration. The Brier score is a metric which is a combination of calibration loss and refinement loss, `brier_score_loss`, reported in the legend (the smaller the better). Calibration loss is defined as the mean squared deviation from empirical probabilities derived from the slope of ROC segments. Refinement loss can be defined as the expected optimal loss as measured by the area under the optimal cost curve.

One can observe here that logistic regression is well calibrated as its curve is nearly diagonal. Linear SVC's calibration curve or reliability diagram has a sigmoid curve, which is typical for an under-confident classifier. In the case of LinearSVC, this is caused by the margin property of the hinge loss, which lets the model focus on hard samples that are close to the decision boundary (the support vectors). Both kinds of calibration can fix this issue and yield nearly identical results. The next figure shows the calibration curve of Gaussian naive Bayes on the same data, with both kinds of calibration and also without calibration.

One can see that Gaussian naive Bayes performs very badly but does so in an other way than linear SVC: While linear SVC exhibited a sigmoid calibration curve, Gaussian naive Bayes' calibration curve has a transposed-sigmoid shape. This is typical for an over-confident classifier. In this case, the classifier's overconfidence is caused by the redundant features which violate the naive Bayes assumption of feature-independence.

Calibration of the probabilities of Gaussian naive Bayes with isotonic regression can fix this issue as can be seen from the nearly diagonal calibration curve. Sigmoid calibration also improves the brier score slightly, albeit not as strongly as the non-parametric isotonic calibration. This is an intrinsic limitation of sigmoid calibration, whose parametric form

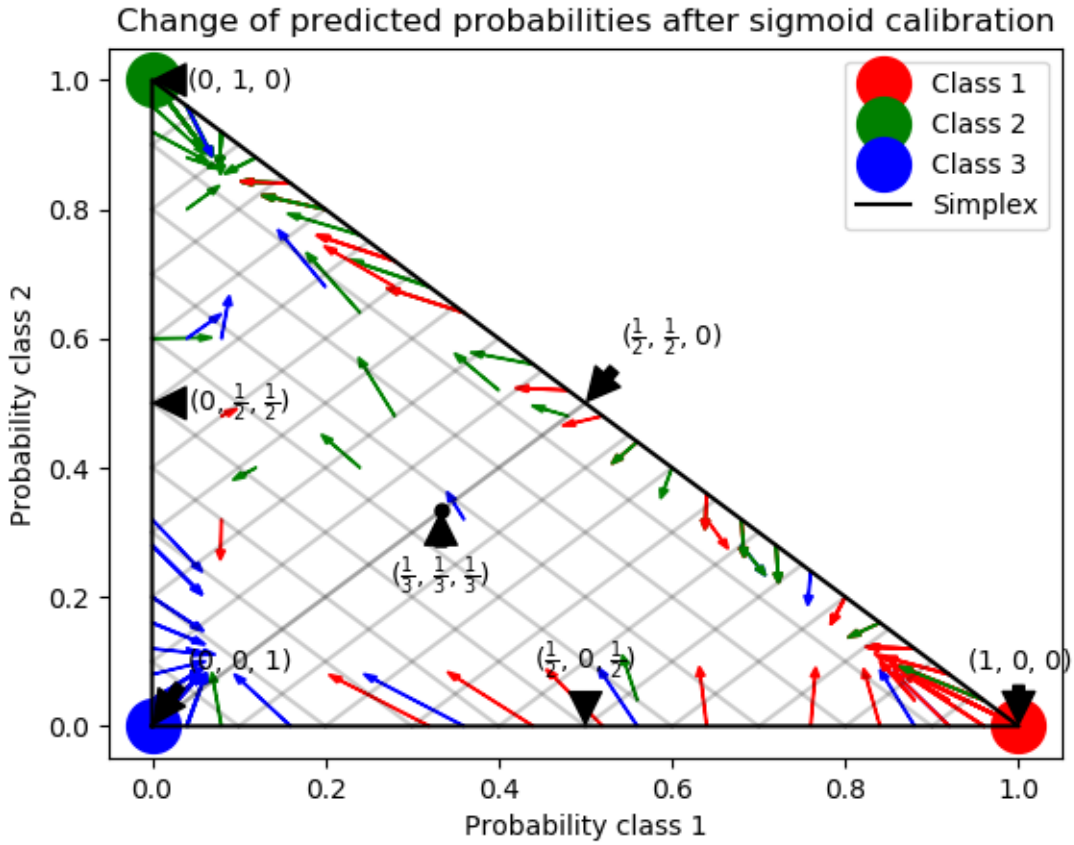
assumes a sigmoid rather than a transposed-sigmoid curve. The non-parametric isotonic calibration model, however, makes no such strong assumptions and can deal with either shape, provided that there is sufficient calibration data. In general, sigmoid calibration is preferable in cases where the calibration curve is sigmoid and where there is limited calibration data, while isotonic calibration is preferable for non-sigmoid calibration curves and in situations where large amounts of data are available for calibration.

`CalibratedClassifierCV` can also deal with classification tasks that involve more than two classes if the base estimator can do so. In this case, the classifier is calibrated first for each class separately in an one-vs-rest fashion. When predicting probabilities for unseen data, the calibrated probabilities for each class are predicted separately. As those probabilities do not necessarily sum to one, a postprocessing is performed to normalize them.

The next image illustrates how sigmoid calibration changes predicted probabilities for a 3-class classification problem. Illustrated is the standard 2-simplex, where the three corners correspond to the three classes. Arrows point from the probability vectors predicted by an uncalibrated classifier to the probability vectors predicted by the same classifier after sigmoid calibration on a hold-out validation set. Colors indicate the true class of an instance (red: class 1, green: class 2, blue: class 3).



The base classifier is a random forest classifier with 25 base estimators (trees). If this classifier is trained on all 800 training datapoints, it is overly confident in its predictions and thus incurs a large log-loss. Calibrating an identical classifier, which was trained on 600 datapoints, with method='sigmoid' on the remaining 200 datapoints reduces the confidence of the predictions, i.e., moves the probability vectors from the edges of the simplex towards the center:

This calibration results in a lower log-loss. Note that an alternative would have been to increase the number of base estimators which would have resulted in a similar decrease in log-loss.

4.1.17 Neural network models (supervised)

Warning: This implementation is not intended for large-scale applications. In particular, scikit-learn offers no GPU support. For much faster, GPU-based implementations, as well as frameworks offering much more flexibility to build deep learning architectures, see *Related Projects*.

Multi-layer Perceptron

Multi-layer Perceptron (MLP) is a supervised learning algorithm that learns a function $f(\cdot) : R^m \rightarrow R^o$ by training on a dataset, where m is the number of dimensions for input and o is the number of dimensions for output. Given a set of features $X = x_1, x_2, ..., x_m$ and a target y, it can learn a non-linear function approximator for either classification or regression. It is different from logistic regression, in that between the input and the output layer, there can be one or more non-linear layers, called hidden layers. Figure 1 shows a one hidden layer MLP with scalar output.

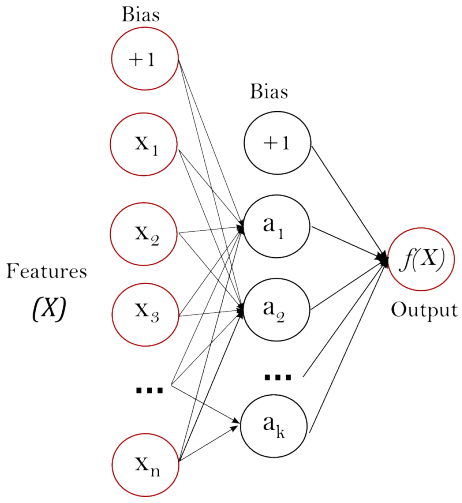

Fig. 2: **Figure 1 : One hidden layer MLP.**

The leftmost layer, known as the input layer, consists of a set of neurons $\{x_i | x_1, x_2, ..., x_m\}$ representing the input features. Each neuron in the hidden layer transforms the values from the previous layer with a weighted linear summation $w_1x_1 + w_2x_2 + ... + w_mx_m$, followed by a non-linear activation function $g(\cdot) : R \rightarrow R$ - like the hyperbolic tan function. The output layer receives the values from the last hidden layer and transforms them into output values.

The module contains the public attributes `coefs_` and `intercepts_`. `coefs_` is a list of weight matrices, where weight matrix at index i represents the weights between layer i and layer $i+1$. `intercepts_` is a list of bias vectors, where the vector at index i represents the bias values added to layer $i + 1$.

The advantages of Multi-layer Perceptron are:

- Capability to learn non-linear models.
- Capability to learn models in real-time (on-line learning) using `partial_fit`.

The disadvantages of Multi-layer Perceptron (MLP) include:

- MLP with hidden layers have a non-convex loss function where there exists more than one local minimum. Therefore different random weight initializations can lead to different validation accuracy.
- MLP requires tuning a number of hyperparameters such as the number of hidden neurons, layers, and iterations.
- MLP is sensitive to feature scaling.

Please see *Tips on Practical Use* section that addresses some of these disadvantages.

Classification

Class *MLPClassifier* implements a multi-layer perceptron (MLP) algorithm that trains using Backpropagation.

MLP trains on two arrays: array X of size (n_samples, n_features), which holds the training samples represented as floating point feature vectors; and array y of size (n_samples,), which holds the target values (class labels) for the training samples:

```
>>> from sklearn.neural_network import MLPClassifier
>>> X = [[0., 0.], [1., 1.]]
>>> y = [0, 1]
>>> clf = MLPClassifier(solver='lbfgs', alpha=1e-5,
...                     hidden_layer_sizes=(5, 2), random_state=1)
...
>>> clf.fit(X, y)
MLPClassifier(alpha=1e-05, hidden_layer_sizes=(5, 2), random_state=1,
              solver='lbfgs')
```

After fitting (training), the model can predict labels for new samples:

```
>>> clf.predict([[2., 2.], [-1., -2.]])
array([1, 0])
```

MLP can fit a non-linear model to the training data. `clf.coefs_` contains the weight matrices that constitute the model parameters:

```
>>> [coef.shape for coef in clf.coefs_]
[(2, 5), (5, 2), (2, 1)]
```

Currently, *MLPClassifier* supports only the Cross-Entropy loss function, which allows probability estimates by running the `predict_proba` method.

MLP trains using Backpropagation. More precisely, it trains using some form of gradient descent and the gradients are calculated using Backpropagation. For classification, it minimizes the Cross-Entropy loss function, giving a vector of probability estimates $P(y|x)$ per sample x:

```
>>> clf.predict_proba([[2., 2.], [1., 2.]])
array([[1.967...e-04, 9.998...-01],
       [1.967...e-04, 9.998...-01]])
```

MLPClassifier supports multi-class classification by applying Softmax as the output function.

Further, the model supports *multi-label classification* in which a sample can belong to more than one class. For each class, the raw output passes through the logistic function. Values larger or equal to `0.5` are rounded to `1`, otherwise to `0`. For a predicted output of a sample, the indices where the value is `1` represents the assigned classes of that sample:

```
>>> X = [[0., 0.], [1., 1.]]
>>> y = [[0, 1], [1, 1]]
>>> clf = MLPClassifier(solver='lbfgs', alpha=1e-5,
...                     hidden_layer_sizes=(15,), random_state=1)
...
>>> clf.fit(X, y)
MLPClassifier(alpha=1e-05, hidden_layer_sizes=(15,), random_state=1,
              solver='lbfgs')
>>> clf.predict([[1., 2.]])
array([[1, 1]])
>>> clf.predict([[0., 0.]])
array([[0, 1]])
```

See the examples below and the docstring of *`MLPClassifier.fit`* for further information.

Examples:

- *Compare Stochastic learning strategies for MLPClassifier*
- *Visualization of MLP weights on MNIST*

Regression

Class *`MLPRegressor`* implements a multi-layer perceptron (MLP) that trains using backpropagation with no activation function in the output layer, which can also be seen as using the identity function as activation function. Therefore, it uses the square error as the loss function, and the output is a set of continuous values.

`MLPRegressor` also supports multi-output regression, in which a sample can have more than one target.

Regularization

Both *`MLPRegressor`* and *`MLPClassifier`* use parameter `alpha` for regularization (L2 regularization) term which helps in avoiding overfitting by penalizing weights with large magnitudes. Following plot displays varying decision function with value of alpha.

See the examples below for further information.

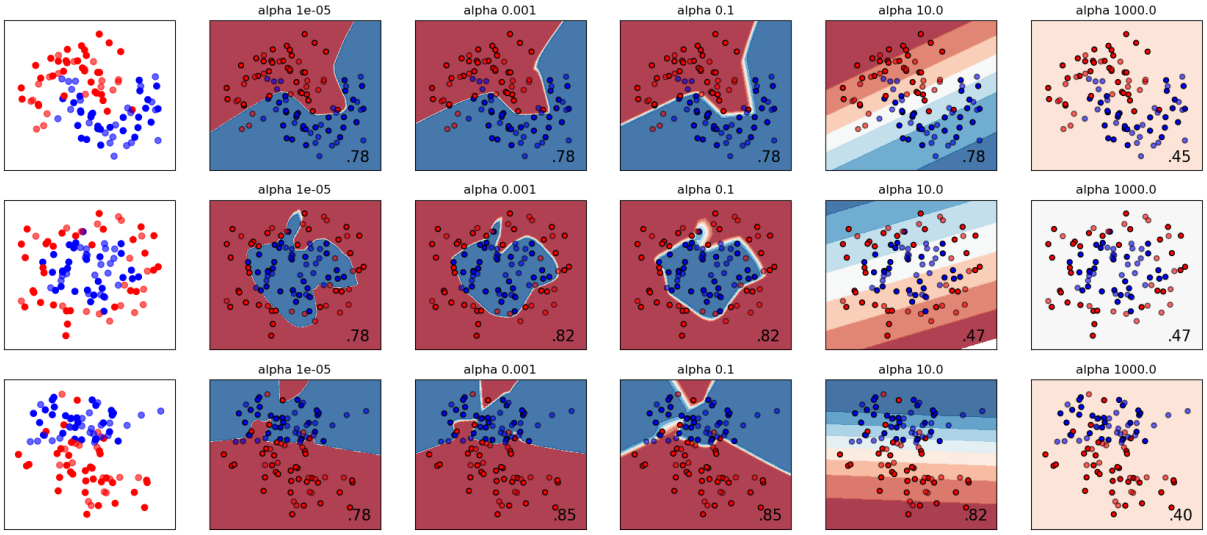
Examples:

- *Varying regularization in Multi-layer Perceptron*

Algorithms

MLP trains using Stochastic Gradient Descent, Adam, or L-BFGS. Stochastic Gradient Descent (SGD) updates parameters using the gradient of the loss function with respect to a parameter that needs adaptation, i.e.

$$w \leftarrow w - \eta(\alpha\frac{\partial R(w)}{\partial w} + \frac{\partial Loss}{\partial w})$$



where η is the learning rate which controls the step-size in the parameter space search. $Loss$ is the loss function used for the network.

More details can be found in the documentation of SGD

Adam is similar to SGD in a sense that it is a stochastic optimizer, but it can automatically adjust the amount to update parameters based on adaptive estimates of lower-order moments.

With SGD or Adam, training supports online and mini-batch learning.

L-BFGS is a solver that approximates the Hessian matrix which represents the second-order partial derivative of a function. Further it approximates the inverse of the Hessian matrix to perform parameter updates. The implementation uses the Scipy version of L-BFGS.

If the selected solver is 'L-BFGS', training does not support online nor mini-batch learning.

Complexity

Suppose there are n training samples, m features, k hidden layers, each containing h neurons - for simplicity, and o output neurons. The time complexity of backpropagation is $O(n \cdot m \cdot h^k \cdot o \cdot i)$, where i is the number of iterations. Since backpropagation has a high time complexity, it is advisable to start with smaller number of hidden neurons and few hidden layers for training.

Mathematical formulation

Given a set of training examples $(x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)$ where $x_i \in \mathbf{R}^n$ and $y_i \in \{0, 1\}$, a one hidden layer one hidden neuron MLP learns the function $f(x) = W_2 g(W_1^T x + b_1) + b_2$ where $W_1 \in \mathbf{R}^m$ and $W_2, b_1, b_2 \in \mathbf{R}$ are model parameters. W_1, W_2 represent the weights of the input layer and hidden layer, respectively; and b_1, b_2 represent the bias added to the hidden layer and the output layer, respectively. $g(\cdot) : R \rightarrow R$ is the activation function, set by default as the hyperbolic tan. It is given as,

$$g(z) = \frac{e^z - e^{-z}}{e^z + e^{-z}}$$

For binary classification, $f(x)$ passes through the logistic function $g(z) = 1/(1+e^{-z})$ to obtain output values between zero and one. A threshold, set to 0.5, would assign samples of outputs larger or equal 0.5 to the positive class, and the rest to the negative class.

If there are more than two classes, $f(x)$ itself would be a vector of size (n_classes,). Instead of passing through logistic function, it passes through the softmax function, which is written as,

$$\text{softmax}(z)_i = \frac{\exp(z_i)}{\sum_{l=1}^{k} \exp(z_l)}$$

where z_i represents the i th element of the input to softmax, which corresponds to class i, and K is the number of classes. The result is a vector containing the probabilities that sample x belong to each class. The output is the class with the highest probability.

In regression, the output remains as $f(x)$; therefore, output activation function is just the identity function.

MLP uses different loss functions depending on the problem type. The loss function for classification is Cross-Entropy, which in binary case is given as,

$$Loss(\hat{y}, y, W) = -y \ln \hat{y} - (1-y) \ln (1-\hat{y}) + \alpha ||W||_2^2$$

where $\alpha ||W||_2^2$ is an L2-regularization term (aka penalty) that penalizes complex models; and $\alpha > 0$ is a non-negative hyperparameter that controls the magnitude of the penalty.

For regression, MLP uses the Square Error loss function; written as,

$$Loss(\hat{y}, y, W) = \frac{1}{2} ||\hat{y} - y||_2^2 + \frac{\alpha}{2} ||W||_2^2$$

Starting from initial random weights, multi-layer perceptron (MLP) minimizes the loss function by repeatedly updating these weights. After computing the loss, a backward pass propagates it from the output layer to the previous layers, providing each weight parameter with an update value meant to decrease the loss.

In gradient descent, the gradient $\nabla Loss_W$ of the loss with respect to the weights is computed and deducted from W. More formally, this is expressed as,

$$W^{i+1} = W^i - \epsilon \nabla Loss_W^i$$

where i is the iteration step, and ϵ is the learning rate with a value larger than 0.

The algorithm stops when it reaches a preset maximum number of iterations; or when the improvement in loss is below a certain, small number.

Tips on Practical Use

- Multi-layer Perceptron is sensitive to feature scaling, so it is highly recommended to scale your data. For example, scale each attribute on the input vector X to [0, 1] or [-1, +1], or standardize it to have mean 0 and variance 1. Note that you must apply the *same* scaling to the test set for meaningful results. You can use `StandardScaler` for standardization.

```
>>> from sklearn.preprocessing import StandardScaler  # doctest: +SKIP
>>> scaler = StandardScaler()  # doctest: +SKIP
>>> # Don't cheat - fit only on training data
>>> scaler.fit(X_train)  # doctest: +SKIP
>>> X_train = scaler.transform(X_train)  # doctest: +SKIP
>>> # apply same transformation to test data
>>> X_test = scaler.transform(X_test)  # doctest: +SKIP
```

  An alternative and recommended approach is to use `StandardScaler` in a `Pipeline`

- Finding a reasonable regularization parameter α is best done using `GridSearchCV`, usually in the range `10.0 ** -np.arange(1, 7)`.
- Empirically, we observed that `L-BFGS` converges faster and with better solutions on small datasets. For relatively large datasets, however, `Adam` is very robust. It usually converges quickly and gives pretty good performance. `SGD` with momentum or nesterov's momentum, on the other hand, can perform better than those two algorithms if learning rate is correctly tuned.

More control with warm_start

If you want more control over stopping criteria or learning rate in SGD, or want to do additional monitoring, using `warm_start=True` and `max_iter=1` and iterating yourself can be helpful:

```
>>> X = [[0., 0.], [1., 1.]]
>>> y = [0, 1]
>>> clf = MLPClassifier(hidden_layer_sizes=(15,), random_state=1, max_iter=1, warm_
↪start=True)
>>> for i in range(10):
...     clf.fit(X, y)
...     # additional monitoring / inspection
MLPClassifier(...
```

4.2 Unsupervised learning

4.2.1 Gaussian mixture models

`sklearn.mixture` is a package which enables one to learn Gaussian Mixture Models (diagonal, spherical, tied and full covariance matrices supported), sample them, and estimate them from data. Facilities to help determine the appropriate number of components are also provided.

A Gaussian mixture model is a probabilistic model that assumes all the data points are generated from a mixture of a finite number of Gaussian distributions with unknown parameters. One can think of mixture models as generalizing k-means clustering to incorporate information about the covariance structure of the data as well as the centers of the latent Gaussians.

Scikit-learn implements different classes to estimate Gaussian mixture models, that correspond to different estimation strategies, detailed below.

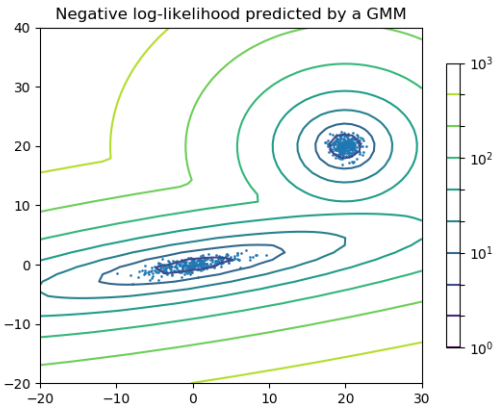

Fig. 3: **Two-component Gaussian mixture model:** *data points, and equi-probability surfaces of the model.*

Gaussian Mixture

The `GaussianMixture` object implements the *expectation-maximization* (EM) algorithm for fitting mixture-of-Gaussian models. It can also draw confidence ellipsoids for multivariate models, and compute the Bayesian Information Criterion to assess the number of clusters in the data. A `GaussianMixture.fit` method is provided that learns a Gaussian Mixture Model from train data. Given test data, it can assign to each sample the Gaussian it mostly probably belong to using the `GaussianMixture.predict` method.

The `GaussianMixture` comes with different options to constrain the covariance of the difference classes estimated: spherical, diagonal, tied or full covariance.

Examples:

- See *GMM covariances* for an example of using the Gaussian mixture as clustering on the iris dataset.
- See *Density Estimation for a Gaussian mixture* for an example on plotting the density estimation.

Pros and cons of class `GaussianMixture`

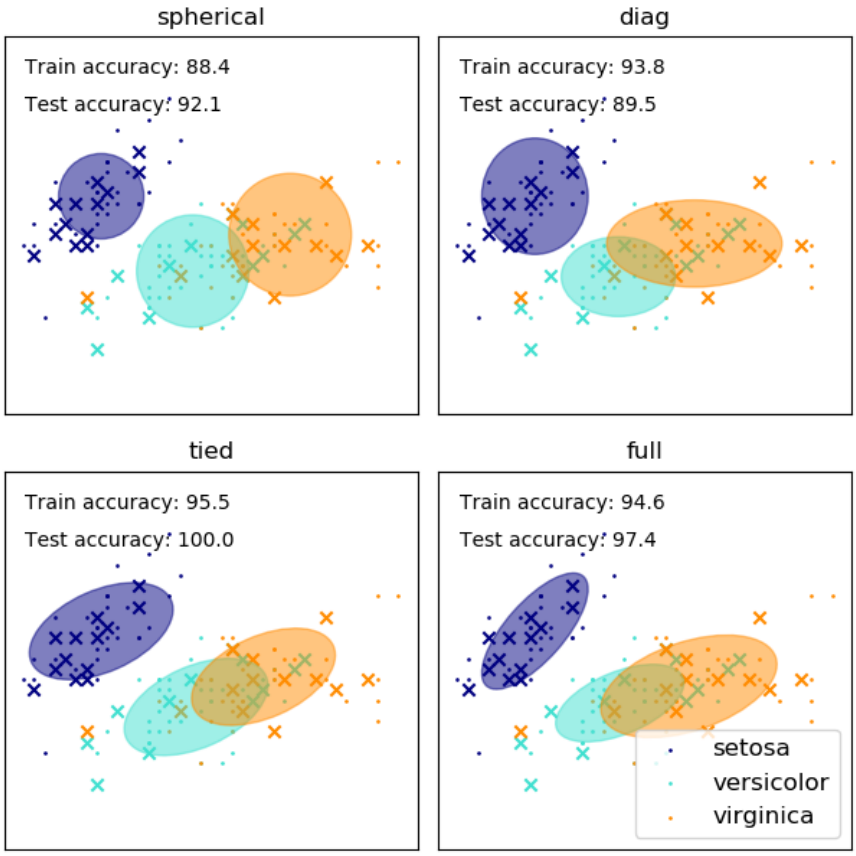
Pros

Speed It is the fastest algorithm for learning mixture models

Agnostic As this algorithm maximizes only the likelihood, it will not bias the means towards zero, or bias the cluster sizes to have specific structures that might or might not apply.

Cons

Singularities When one has insufficiently many points per mixture, estimating the covariance matrices becomes difficult, and the algorithm is known to diverge and find solutions with infinite likelihood unless one regularizes the covariances artificially.



Number of components This algorithm will always use all the components it has access to, needing held-out data or information theoretical criteria to decide how many components to use in the absence of external cues.

Selecting the number of components in a classical Gaussian Mixture Model

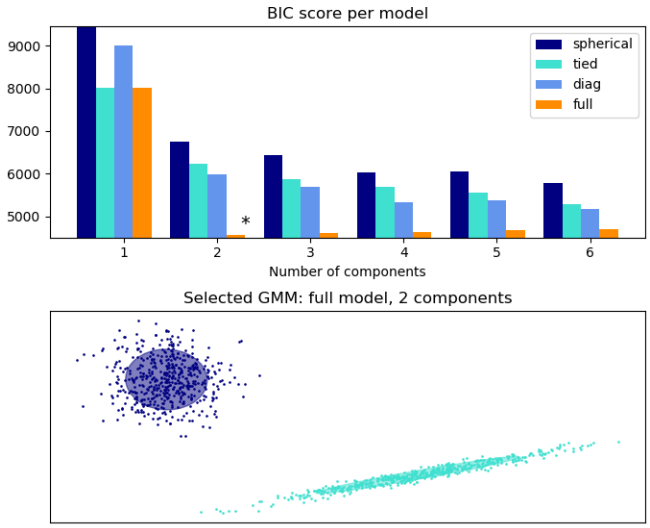
The BIC criterion can be used to select the number of components in a Gaussian Mixture in an efficient way. In theory, it recovers the true number of components only in the asymptotic regime (i.e. if much data is available and assuming that the data was actually generated i.i.d. from a mixture of Gaussian distribution). Note that using a *Variational Bayesian Gaussian mixture* avoids the specification of the number of components for a Gaussian mixture model.

Examples:

- See *Gaussian Mixture Model Selection* for an example of model selection performed with classical Gaussian mixture.

Estimation algorithm Expectation-maximization

The main difficulty in learning Gaussian mixture models from unlabeled data is that it is one usually doesn't know which points came from which latent component (if one has access to this information it gets very easy to fit a separate Gaussian distribution to each set of points). Expectation-maximization is a well-founded statistical algorithm to get around this problem by an iterative process. First one assumes random components (randomly centered on data points,



learned from k-means, or even just normally distributed around the origin) and computes for each point a probability of being generated by each component of the model. Then, one tweaks the parameters to maximize the likelihood of the data given those assignments. Repeating this process is guaranteed to always converge to a local optimum.

Variational Bayesian Gaussian Mixture

The *BayesianGaussianMixture* object implements a variant of the Gaussian mixture model with variational inference algorithms. The API is similar as the one defined by *GaussianMixture*.

Estimation algorithm: variational inference

Variational inference is an extension of expectation-maximization that maximizes a lower bound on model evidence (including priors) instead of data likelihood. The principle behind variational methods is the same as expectation-maximization (that is both are iterative algorithms that alternate between finding the probabilities for each point to be generated by each mixture and fitting the mixture to these assigned points), but variational methods add regularization by integrating information from prior distributions. This avoids the singularities often found in expectation-maximization solutions but introduces some subtle biases to the model. Inference is often notably slower, but not usually as much so as to render usage unpractical.

Due to its Bayesian nature, the variational algorithm needs more hyper- parameters than expectation-maximization, the most important of these being the concentration parameter `weight_concentration_prior`. Specifying a low value for the concentration prior will make the model put most of the weight on few components set the remaining components weights very close to zero. High values of the concentration prior will allow a larger number of components to be active in the mixture.

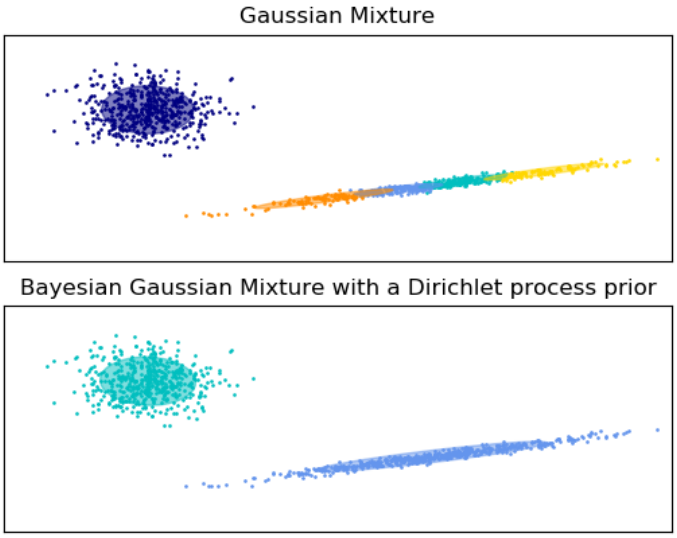
The parameters implementation of the *BayesianGaussianMixture* class proposes two types of prior for the weights distribution: a finite mixture model with Dirichlet distribution and an infinite mixture model with the Dirichlet Process. In practice Dirichlet Process inference algorithm is approximated and uses a truncated distribution with a fixed maximum number of components (called the Stick-breaking representation). The number of components actually used almost always depends on the data.

The next figure compares the results obtained for the different type of the weight concentration prior (parameter `weight_concentration_prior_type`) for different values of `weight_concentration_prior`. Here, we can see the value of the `weight_concentration_prior` parameter has a strong impact on the effective

number of active components obtained. We can also notice that large values for the concentration weight prior lead to more uniform weights when the type of prior is 'dirichlet_distribution' while this is not necessarily the case for the 'dirichlet_process' type (used by default).

The examples below compare Gaussian mixture models with a fixed number of components, to the variational Gaussian mixture models with a Dirichlet process prior. Here, a classical Gaussian mixture is fitted with 5 components on a dataset composed of 2 clusters. We can see that the variational Gaussian mixture with a Dirichlet process prior is able to limit itself to only 2 components whereas the Gaussian mixture fits the data with a fixed number of components that has to be set a priori by the user. In this case the user has selected `n_components=5` which does not match the

true generative distribution of this toy dataset. Note that with very little observations, the variational Gaussian mixture models with a Dirichlet process prior can take a conservative stand, and fit only one component.



On the following figure we are fitting a dataset not well-depicted by a Gaussian mixture. Adjusting the `weight_concentration_prior`, parameter of the *`BayesianGaussianMixture`* controls the number of components used to fit this data. We also present on the last two plots a random sampling generated from the two resulting mixtures.

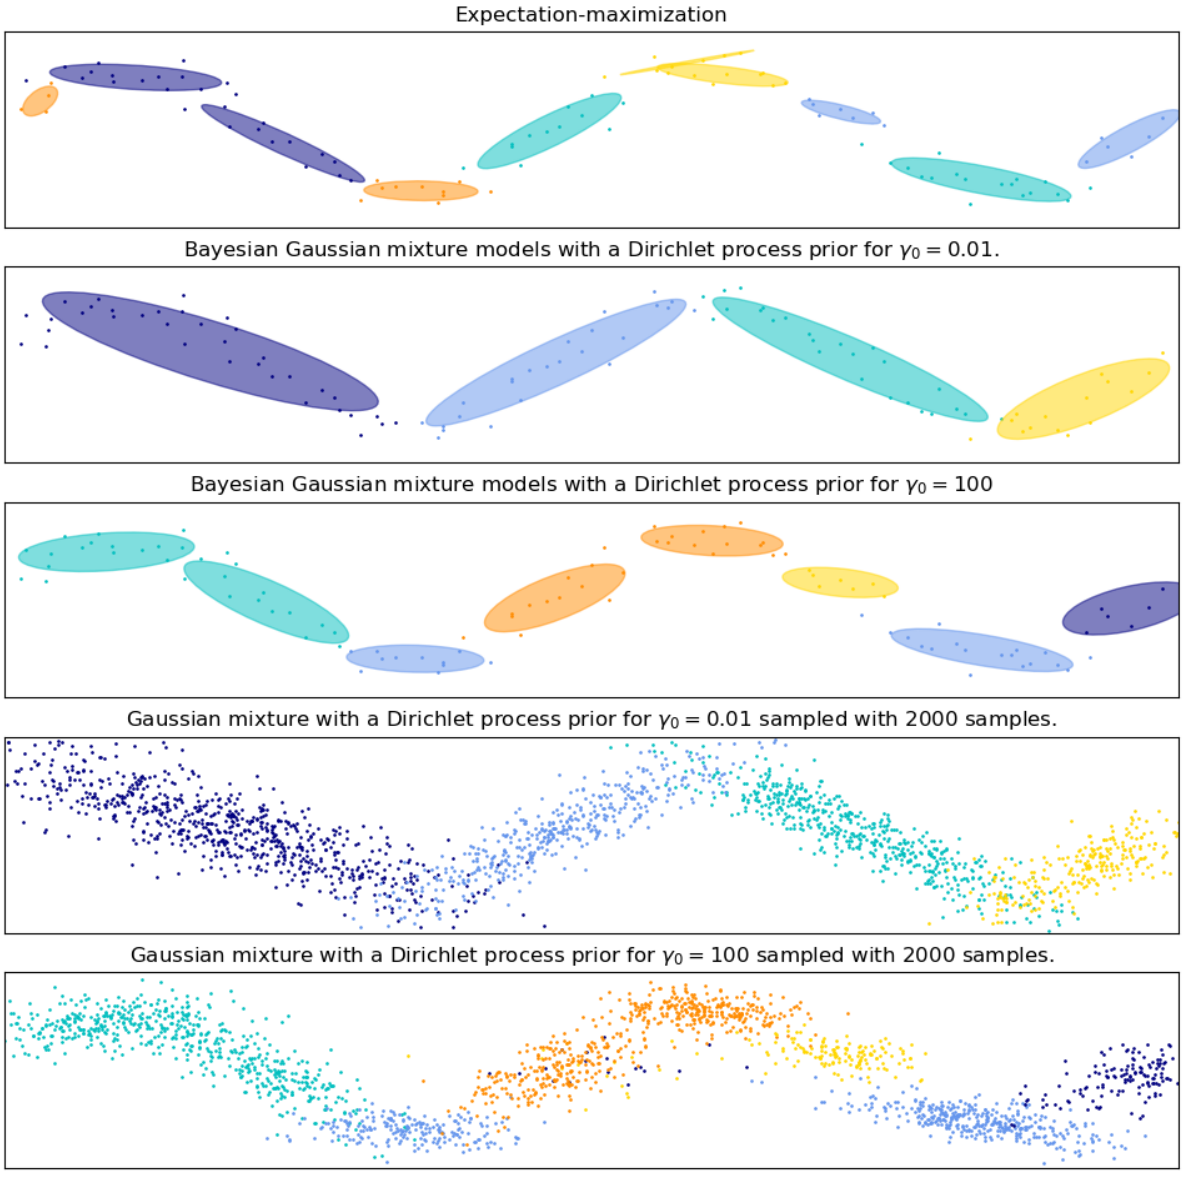
Examples:

- See *Gaussian Mixture Model Ellipsoids* for an example on plotting the confidence ellipsoids for both *`GaussianMixture`* and *`BayesianGaussianMixture`*.
- *Gaussian Mixture Model Sine Curve* shows using *`GaussianMixture`* and *`BayesianGaussianMixture`* to fit a sine wave.
- See *Concentration Prior Type Analysis of Variation Bayesian Gaussian Mixture* for an example plotting the confidence ellipsoids for the *`BayesianGaussianMixture`* with different `weight_concentration_prior_type` for different values of the parameter `weight_concentration_prior`.

Pros and cons of variational inference with `BayesianGaussianMixture`

Pros

Automatic selection when `weight_concentration_prior` is small enough and `n_components` is larger than what is found necessary by the model, the Variational Bayesian mixture model has a natural tendency to set some mixture weights values close to zero. This makes it possible to let the model choose a suitable number of effective components automatically. Only an upper bound of this number needs to be provided. Note however that the "ideal" number of active components is very application specific and is typically ill-defined in a data exploration setting.



Expectation-maximization
Bayesian Gaussian mixture models with a Dirichlet process prior for $\gamma_0 = 0.01$.
Bayesian Gaussian mixture models with a Dirichlet process prior for $\gamma_0 = 100$
Gaussian mixture with a Dirichlet process prior for $\gamma_0 = 0.01$ sampled with 2000 samples.
Gaussian mixture with a Dirichlet process prior for $\gamma_0 = 100$ sampled with 2000 samples.

Less sensitivity to the number of parameters unlike finite models, which will almost always use all components as much as they can, and hence will produce wildly different solutions for different numbers of components, the variational inference with a Dirichlet process prior (`weight_concentration_prior_type='dirichlet_process'`) won't change much with changes to the parameters, leading to more stability and less tuning.

Regularization due to the incorporation of prior information, variational solutions have less pathological special cases than expectation-maximization solutions.

Cons

Speed the extra parametrization necessary for variational inference make inference slower, although not by much.

Hyperparameters this algorithm needs an extra hyperparameter that might need experimental tuning via cross-validation.

Bias there are many implicit biases in the inference algorithms (and also in the Dirichlet process if used), and whenever there is a mismatch between these biases and the data it might be possible to fit better models using a finite mixture.

The Dirichlet Process

Here we describe variational inference algorithms on Dirichlet process mixture. The Dirichlet process is a prior probability distribution on *clusterings with an infinite, unbounded, number of partitions*. Variational techniques let us incorporate this prior structure on Gaussian mixture models at almost no penalty in inference time, comparing with a finite Gaussian mixture model.

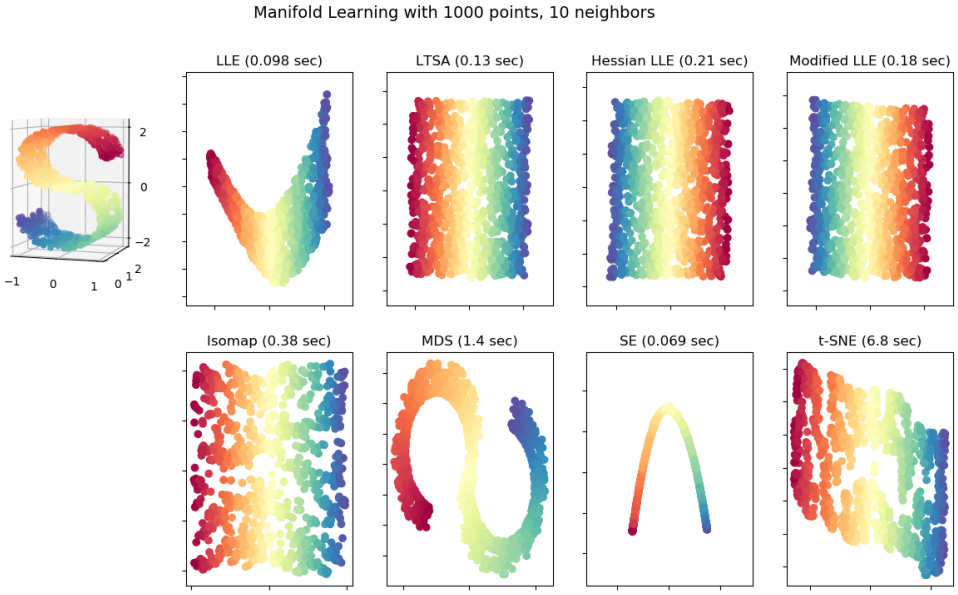
An important question is how can the Dirichlet process use an infinite, unbounded number of clusters and still be consistent. While a full explanation doesn't fit this manual, one can think of its stick breaking process analogy to help understanding it. The stick breaking process is a generative story for the Dirichlet process. We start with a unit-length stick and in each step we break off a portion of the remaining stick. Each time, we associate the length of the piece of the stick to the proportion of points that falls into a group of the mixture. At the end, to represent the infinite mixture, we associate the last remaining piece of the stick to the proportion of points that don't fall into all the other groups. The length of each piece is a random variable with probability proportional to the concentration parameter. Smaller value of the concentration will divide the unit-length into larger pieces of the stick (defining more concentrated distribution). Larger concentration values will create smaller pieces of the stick (increasing the number of components with non zero weights).

Variational inference techniques for the Dirichlet process still work with a finite approximation to this infinite mixture model, but instead of having to specify a priori how many components one wants to use, one just specifies the concentration parameter and an upper bound on the number of mixture components (this upper bound, assuming it is higher than the "true" number of components, affects only algorithmic complexity, not the actual number of components used).

4.2.2 Manifold learning

Look for the bare necessities
The simple bare necessities
Forget about your worries and your strife
I mean the bare necessities
Old Mother Nature's recipes
That bring the bare necessities of life

– Baloo's song [The Jungle Book]

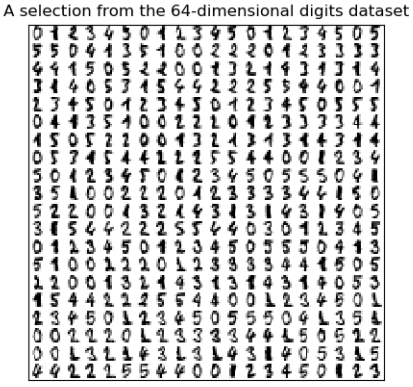


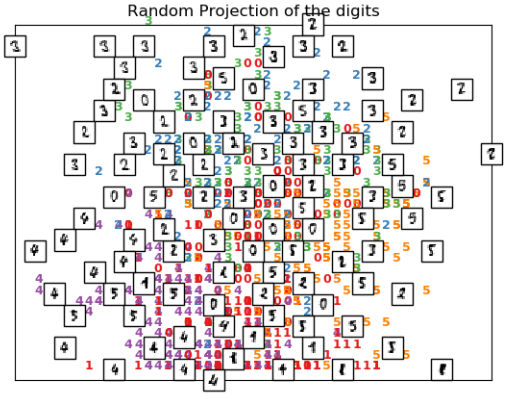
Manifold learning is an approach to non-linear dimensionality reduction. Algorithms for this task are based on the idea that the dimensionality of many data sets is only artificially high.

Introduction

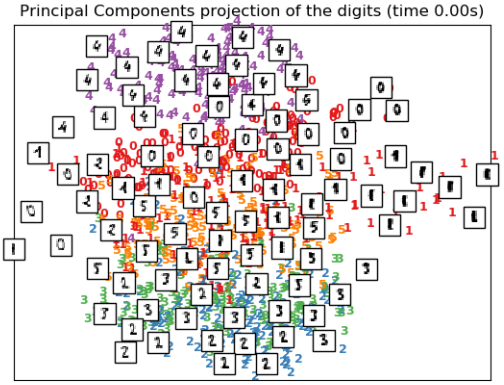
High-dimensional datasets can be very difficult to visualize. While data in two or three dimensions can be plotted to show the inherent structure of the data, equivalent high-dimensional plots are much less intuitive. To aid visualization of the structure of a dataset, the dimension must be reduced in some way.

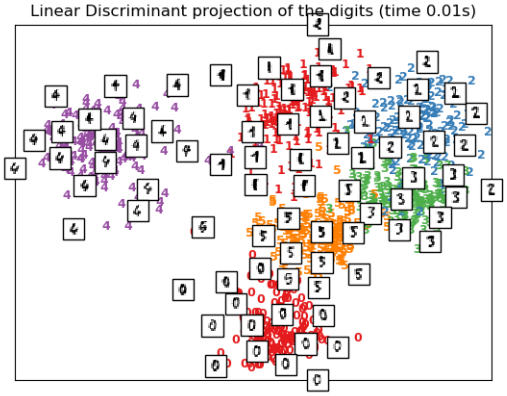
The simplest way to accomplish this dimensionality reduction is by taking a random projection of the data. Though this allows some degree of visualization of the data structure, the randomness of the choice leaves much to be desired. In a random projection, it is likely that the more interesting structure within the data will be lost.





To address this concern, a number of supervised and unsupervised linear dimensionality reduction frameworks have been designed, such as Principal Component Analysis (PCA), Independent Component Analysis, Linear Discriminant Analysis, and others. These algorithms define specific rubrics to choose an "interesting" linear projection of the data. These methods can be powerful, but often miss important non-linear structure in the data.





Manifold Learning can be thought of as an attempt to generalize linear frameworks like PCA to be sensitive to non-linear structure in data. Though supervised variants exist, the typical manifold learning problem is unsupervised: it learns the high-dimensional structure of the data from the data itself, without the use of predetermined classifications.

Examples:

- See *Manifold learning on handwritten digits: Locally Linear Embedding, Isomap…* for an example of dimensionality reduction on handwritten digits.
- See *Comparison of Manifold Learning methods* for an example of dimensionality reduction on a toy "S-curve" dataset.

The manifold learning implementations available in scikit-learn are summarized below

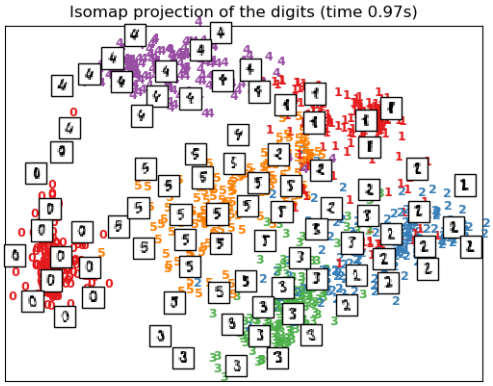
Isomap

One of the earliest approaches to manifold learning is the Isomap algorithm, short for Isometric Mapping. Isomap can be viewed as an extension of Multi-dimensional Scaling (MDS) or Kernel PCA. Isomap seeks a lower-dimensional embedding which maintains geodesic distances between all points. Isomap can be performed with the object `Isomap`.

Complexity

The Isomap algorithm comprises three stages:

1. **Nearest neighbor search.** Isomap uses `sklearn.neighbors.BallTree` for efficient neighbor search. The cost is approximately $O[D \log(k) N \log(N)]$, for k nearest neighbors of N points in D dimensions.
2. **Shortest-path graph search.** The most efficient known algorithms for this are *Dijkstra's Algorithm*, which is approximately $O[N^2(k + \log(N))]$, or the *Floyd-Warshall algorithm*, which is $O[N^3]$. The algorithm can be selected by the user with the `path_method` keyword of `Isomap`. If unspecified, the code attempts to choose the best algorithm for the input data.
3. **Partial eigenvalue decomposition.** The embedding is encoded in the eigenvectors corresponding to the d largest eigenvalues of the $N \times N$ isomap kernel. For a dense solver, the cost is approximately $O[dN^2]$. This



cost can often be improved using the `ARPACK` solver. The eigensolver can be specified by the user with the `path_method` keyword of `Isomap`. If unspecified, the code attempts to choose the best algorithm for the input data.

The overall complexity of Isomap is $O[D \log(k) N \log(N)] + O[N^2(k + \log(N))] + O[dN^2]$.

- N : number of training data points
- D : input dimension
- k : number of nearest neighbors
- d : output dimension

Locally Linear Embedding

Locally linear embedding (LLE) seeks a lower-dimensional projection of the data which preserves distances within local neighborhoods. It can be thought of as a series of local Principal Component Analyses which are globally compared to find the best non-linear embedding.

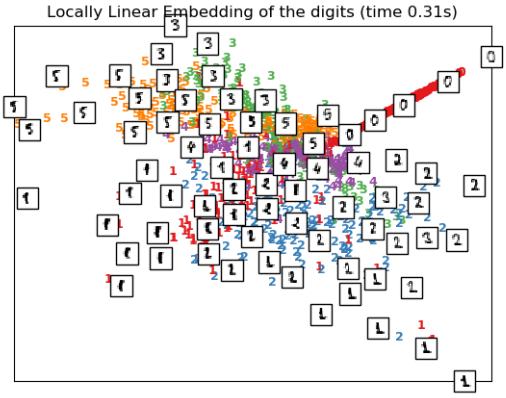
Locally linear embedding can be performed with function *`locally_linear_embedding`* or its object-oriented counterpart *`LocallyLinearEmbedding`*.

Complexity

The standard LLE algorithm comprises three stages:

1. **Nearest Neighbors Search**. See discussion under Isomap above.
2. **Weight Matrix Construction**. $O[DNk^3]$. The construction of the LLE weight matrix involves the solution of a $k \times k$ linear equation for each of the N local neighborhoods
3. **Partial Eigenvalue Decomposition**. See discussion under Isomap above.

The overall complexity of standard LLE is $O[D \log(k) N \log(N)] + O[DNk^3] + O[dN^2]$.



- N : number of training data points
- D : input dimension
- k : number of nearest neighbors
- d : output dimension

References:

- "Nonlinear dimensionality reduction by locally linear embedding" Roweis, S. & Saul, L. Science 290:2323 (2000)

Modified Locally Linear Embedding

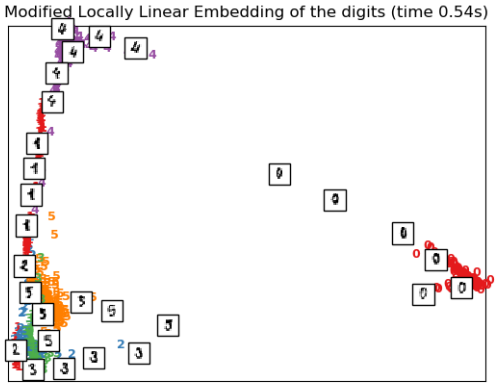
One well-known issue with LLE is the regularization problem. When the number of neighbors is greater than the number of input dimensions, the matrix defining each local neighborhood is rank-deficient. To address this, standard LLE applies an arbitrary regularization parameter r, which is chosen relative to the trace of the local weight matrix. Though it can be shown formally that as $r \to 0$, the solution converges to the desired embedding, there is no guarantee that the optimal solution will be found for $r > 0$. This problem manifests itself in embeddings which distort the underlying geometry of the manifold.

One method to address the regularization problem is to use multiple weight vectors in each neighborhood. This is the essence of *modified locally linear embedding* (MLLE). MLLE can be performed with function `locally_linear_embedding` or its object-oriented counterpart `LocallyLinearEmbedding`, with the keyword `method = 'modified'`. It requires `n_neighbors > n_components`.

Complexity

The MLLE algorithm comprises three stages:

1. **Nearest Neighbors Search**. Same as standard LLE
2. **Weight Matrix Construction**. Approximately $O[DNk^3]+O[N(k-D)k^2]$. The first term is exactly equivalent to that of standard LLE. The second term has to do with constructing the weight matrix from multiple weights. In practice, the added cost of constructing the MLLE weight matrix is relatively small compared to the cost of stages 1 and 3.



3. **Partial Eigenvalue Decomposition**. Same as standard LLE

The overall complexity of MLLE is $O[D\log(k)N\log(N)] + O[DNk^3] + O[N(k-D)k^2] + O[dN^2]$.

- N : number of training data points
- D : input dimension
- k : number of nearest neighbors
- d : output dimension

- "MLLE: Modified Locally Linear Embedding Using Multiple Weights" Zhang, Z. & Wang, J.

Hessian Eigenmapping

Hessian Eigenmapping (also known as Hessian-based LLE: HLLE) is another method of solving the regularization problem of LLE. It revolves around a hessian-based quadratic form at each neighborhood which is used to recover the locally linear structure. Though other implementations note its poor scaling with data size, `sklearn` implements some algorithmic improvements which make its cost comparable to that of other LLE variants for small output dimension. HLLE can be performed with function *`locally_linear_embedding`* or its object-oriented counterpart *`LocallyLinearEmbedding`*, with the keyword `method = 'hessian'`. It requires `n_neighbors > n_components * (n_components + 3) / 2`.

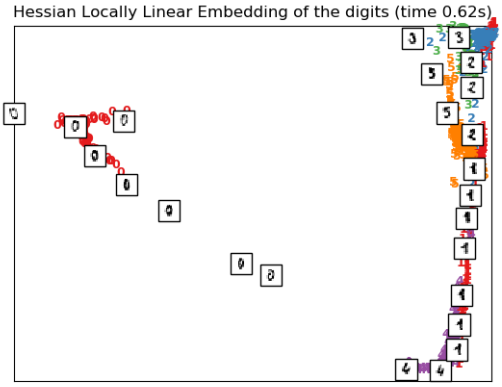
Complexity

The HLLE algorithm comprises three stages:

1. **Nearest Neighbors Search**. Same as standard LLE
2. **Weight Matrix Construction**. Approximately $O[DNk^3] + O[Nd^6]$. The first term reflects a similar cost to that of standard LLE. The second term comes from a QR decomposition of the local hessian estimator.
3. **Partial Eigenvalue Decomposition**. Same as standard LLE

The overall complexity of standard HLLE is $O[D\log(k)N\log(N)] + O[DNk^3] + O[Nd^6] + O[dN^2]$.

- N : number of training data points



- D : input dimension
- k : number of nearest neighbors
- d : output dimension

- "Hessian Eigenmaps: Locally linear embedding techniques for high-dimensional data" Donoho, D. & Grimes, C. Proc Natl Acad Sci USA. 100:5591 (2003)

Spectral Embedding

Spectral Embedding is an approach to calculating a non-linear embedding. Scikit-learn implements Laplacian Eigenmaps, which finds a low dimensional representation of the data using a spectral decomposition of the graph Laplacian. The graph generated can be considered as a discrete approximation of the low dimensional manifold in the high dimensional space. Minimization of a cost function based on the graph ensures that points close to each other on the manifold are mapped close to each other in the low dimensional space, preserving local distances. Spectral embedding can be performed with the function `spectral_embedding` or its object-oriented counterpart `SpectralEmbedding`.

Complexity

The Spectral Embedding (Laplacian Eigenmaps) algorithm comprises three stages:

1. **Weighted Graph Construction**. Transform the raw input data into graph representation using affinity (adjacency) matrix representation.
2. **Graph Laplacian Construction**. unnormalized Graph Laplacian is constructed as $L = D - A$ for and normalized one as $L = D^{-\frac{1}{2}}(D - A)D^{-\frac{1}{2}}$.
3. **Partial Eigenvalue Decomposition**. Eigenvalue decomposition is done on graph Laplacian

The overall complexity of spectral embedding is $O[D \log(k) N \log(N)] + O[DNk^3] + O[dN^2]$.

- N : number of training data points
- D : input dimension
- k : number of nearest neighbors

- d : output dimension

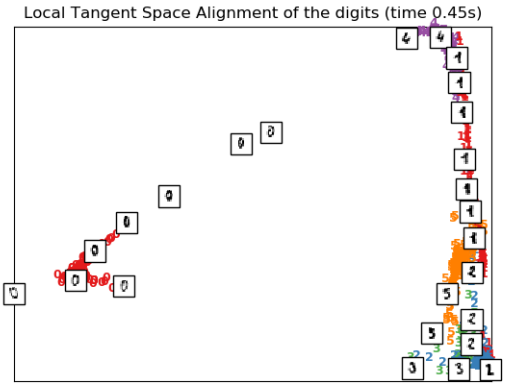
Local Tangent Space Alignment

Though not technically a variant of LLE, Local tangent space alignment (LTSA) is algorithmically similar enough to LLE that it can be put in this category. Rather than focusing on preserving neighborhood distances as in LLE, LTSA seeks to characterize the local geometry at each neighborhood via its tangent space, and performs a global optimization to align these local tangent spaces to learn the embedding. LTSA can be performed with function *locally_linear_embedding* or its object-oriented counterpart *LocallyLinearEmbedding*, with the keyword `method = 'ltsa'`.



Complexity

The LTSA algorithm comprises three stages:

1. **Nearest Neighbors Search**. Same as standard LLE
2. **Weight Matrix Construction**. Approximately $O[DNk^3] + O[k^2d]$. The first term reflects a similar cost to that of standard LLE.
3. **Partial Eigenvalue Decomposition**. Same as standard LLE

The overall complexity of standard LTSA is $O[D\log(k)N\log(N)] + O[DNk^3] + O[k^2d] + O[dN^2]$.

- N : number of training data points
- D : input dimension
- k : number of nearest neighbors
- d : output dimension

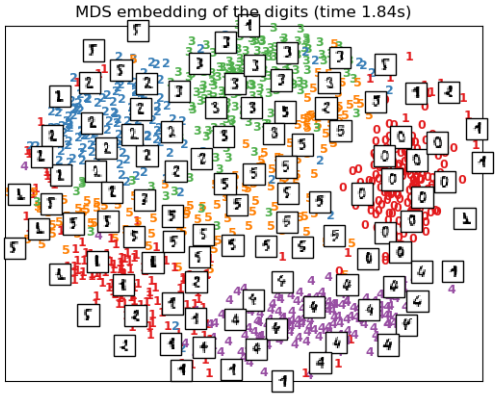
Multi-dimensional Scaling (MDS)

Multidimensional scaling (*MDS*) seeks a low-dimensional representation of the data in which the distances respect well the distances in the original high-dimensional space.

In general, *MDS* is a technique used for analyzing similarity or dissimilarity data. It attempts to model similarity or dissimilarity data as distances in a geometric spaces. The data can be ratings of similarity between objects, interaction frequencies of molecules, or trade indices between countries.

There exists two types of MDS algorithm: metric and non metric. In the scikit-learn, the class *MDS* implements both. In Metric MDS, the input similarity matrix arises from a metric (and thus respects the triangular inequality), the distances between output two points are then set to be as close as possible to the similarity or dissimilarity data. In the non-metric version, the algorithms will try to preserve the order of the distances, and hence seek for a monotonic relationship between the distances in the embedded space and the similarities/dissimilarities.



Let S be the similarity matrix, and X the coordinates of the n input points. Disparities $\hat{d}_{ij}$ are transformation of the similarities chosen in some optimal ways. The objective, called the stress, is then defined by $\sum_{i<j} d_{ij}(X) - \hat{d}_{ij}(X)$

Metric MDS

The simplest metric *MDS* model, called *absolute MDS*, disparities are defined by $\hat{d}_{ij} = S_{ij}$. With absolute MDS, the value S_{ij} should then correspond exactly to the distance between point i and j in the embedding point.

Most commonly, disparities are set to $\hat{d}_{ij} = bS_{ij}$.

Nonmetric MDS

Non metric *MDS* focuses on the ordination of the data. If $S_{ij} < S_{jk}$, then the embedding should enforce $d_{ij} < d_{jk}$. A simple algorithm to enforce that is to use a monotonic regression of d_{ij} on S_{ij}, yielding disparities $\hat{d}_{ij}$ in the same order as S_{ij}.

A trivial solution to this problem is to set all the points on the origin. In order to avoid that, the disparities $\hat{d}_{ij}$ are normalized.

t-distributed Stochastic Neighbor Embedding (t-SNE)

t-SNE (*TSNE*) converts affinities of data points to probabilities. The affinities in the original space are represented by Gaussian joint probabilities and the affinities in the embedded space are represented by Student's t-distributions. This allows t-SNE to be particularly sensitive to local structure and has a few other advantages over existing techniques:

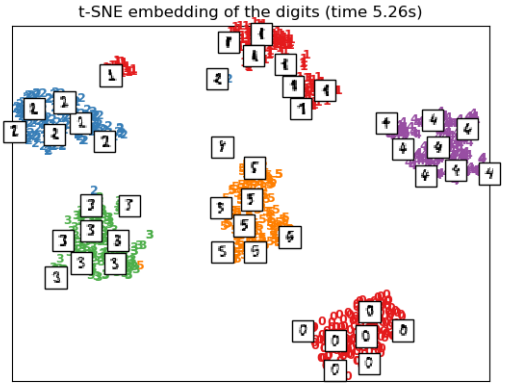
- Revealing the structure at many scales on a single map
- Revealing data that lie in multiple, different, manifolds or clusters
- Reducing the tendency to crowd points together at the center

While Isomap, LLE and variants are best suited to unfold a single continuous low dimensional manifold, t-SNE will focus on the local structure of the data and will tend to extract clustered local groups of samples as highlighted on the S-curve example. This ability to group samples based on the local structure might be beneficial to visually disentangle a dataset that comprises several manifolds at once as is the case in the digits dataset.

The Kullback-Leibler (KL) divergence of the joint probabilities in the original space and the embedded space will be minimized by gradient descent. Note that the KL divergence is not convex, i.e. multiple restarts with different initializations will end up in local minima of the KL divergence. Hence, it is sometimes useful to try different seeds and select the embedding with the lowest KL divergence.

The disadvantages to using t-SNE are roughly:

- t-SNE is computationally expensive, and can take several hours on million-sample datasets where PCA will finish in seconds or minutes
- The Barnes-Hut t-SNE method is limited to two or three dimensional embeddings.
- The algorithm is stochastic and multiple restarts with different seeds can yield different embeddings. However, it is perfectly legitimate to pick the embedding with the least error.
- Global structure is not explicitly preserved. This problem is mitigated by initializing points with PCA (using `init='pca'`).



Optimizing t-SNE

The main purpose of t-SNE is visualization of high-dimensional data. Hence, it works best when the data will be embedded on two or three dimensions.

Optimizing the KL divergence can be a little bit tricky sometimes. There are five parameters that control the optimization of t-SNE and therefore possibly the quality of the resulting embedding:

- perplexity
- early exaggeration factor
- learning rate
- maximum number of iterations
- angle (not used in the exact method)

The perplexity is defined as $k = 2^{(S)}$ where S is the Shannon entropy of the conditional probability distribution. The perplexity of a k-sided die is k, so that k is effectively the number of nearest neighbors t-SNE considers when generating the conditional probabilities. Larger perplexities lead to more nearest neighbors and less sensitive to small structure. Conversely a lower perplexity considers a smaller number of neighbors, and thus ignores more global information in favour of the local neighborhood. As dataset sizes get larger more points will be required to get a reasonable sample of the local neighborhood, and hence larger perplexities may be required. Similarly noisier datasets will require larger perplexity values to encompass enough local neighbors to see beyond the background noise.

The maximum number of iterations is usually high enough and does not need any tuning. The optimization consists of two phases: the early exaggeration phase and the final optimization. During early exaggeration the joint probabilities in the original space will be artificially increased by multiplication with a given factor. Larger factors result in larger gaps between natural clusters in the data. If the factor is too high, the KL divergence could increase during this phase. Usually it does not have to be tuned. A critical parameter is the learning rate. If it is too low gradient descent will get stuck in a bad local minimum. If it is too high the KL divergence will increase during optimization. More tips can be

found in Laurens van der Maaten's FAQ (see references). The last parameter, angle, is a tradeoff between performance and accuracy. Larger angles imply that we can approximate larger regions by a single point, leading to better speed but less accurate results.

"How to Use t-SNE Effectively" provides a good discussion of the effects of the various parameters, as well as interactive plots to explore the effects of different parameters.

Barnes-Hut t-SNE

The Barnes-Hut t-SNE that has been implemented here is usually much slower than other manifold learning algorithms. The optimization is quite difficult and the computation of the gradient is $O[dNlog(N)]$, where d is the number of output dimensions and N is the number of samples. The Barnes-Hut method improves on the exact method where t-SNE complexity is $O[dN^2]$, but has several other notable differences:

- The Barnes-Hut implementation only works when the target dimensionality is 3 or less. The 2D case is typical when building visualizations.
- Barnes-Hut only works with dense input data. Sparse data matrices can only be embedded with the exact method or can be approximated by a dense low rank projection for instance using *sklearn.decomposition.TruncatedSVD*
- Barnes-Hut is an approximation of the exact method. The approximation is parameterized with the angle parameter, therefore the angle parameter is unused when method="exact"
- Barnes-Hut is significantly more scalable. Barnes-Hut can be used to embed hundred of thousands of data points while the exact method can handle thousands of samples before becoming computationally intractable

For visualization purpose (which is the main use case of t-SNE), using the Barnes-Hut method is strongly recommended. The exact t-SNE method is useful for checking the theoretically properties of the embedding possibly in higher dimensional space but limit to small datasets due to computational constraints.

Also note that the digits labels roughly match the natural grouping found by t-SNE while the linear 2D projection of the PCA model yields a representation where label regions largely overlap. This is a strong clue that this data can be well separated by non linear methods that focus on the local structure (e.g. an SVM with a Gaussian RBF kernel). However, failing to visualize well separated homogeneously labeled groups with t-SNE in 2D does not necessarily imply that the data cannot be correctly classified by a supervised model. It might be the case that 2 dimensions are not low enough to accurately represents the internal structure of the data.

Tips on practical use

- Make sure the same scale is used over all features. Because manifold learning methods are based on a nearest-neighbor search, the algorithm may perform poorly otherwise. See *StandardScaler* for convenient ways of scaling heterogeneous data.

- The reconstruction error computed by each routine can be used to choose the optimal output dimension. For a d-dimensional manifold embedded in a D-dimensional parameter space, the reconstruction error will decrease as `n_components` is increased until `n_components == d`.
- Note that noisy data can "short-circuit" the manifold, in essence acting as a bridge between parts of the manifold that would otherwise be well-separated. Manifold learning on noisy and/or incomplete data is an active area of research.
- Certain input configurations can lead to singular weight matrices, for example when more than two points in the dataset are identical, or when the data is split into disjointed groups. In this case, `solver='arpack'` will fail to find the null space. The easiest way to address this is to use `solver='dense'` which will work on a singular matrix, though it may be very slow depending on the number of input points. Alternatively, one can attempt to understand the source of the singularity: if it is due to disjoint sets, increasing `n_neighbors` may help. If it is due to identical points in the dataset, removing these points may help.

See also:

Totally Random Trees Embedding can also be useful to derive non-linear representations of feature space, also it does not perform dimensionality reduction.

4.2.3 Clustering

Clustering of unlabeled data can be performed with the module *sklearn.cluster*.

Each clustering algorithm comes in two variants: a class, that implements the `fit` method to learn the clusters on train data, and a function, that, given train data, returns an array of integer labels corresponding to the different clusters. For the class, the labels over the training data can be found in the `labels_` attribute.

Input data

One important thing to note is that the algorithms implemented in this module can take different kinds of matrix as input. All the methods accept standard data matrices of shape `[n_samples, n_features]`. These can be obtained from the classes in the *sklearn.feature_extraction* module. For *AffinityPropagation*, *SpectralClustering* and *DBSCAN* one can also input similarity matrices of shape `[n_samples, n_samples]`. These can be obtained from the functions in the *sklearn.metrics.pairwise* module.

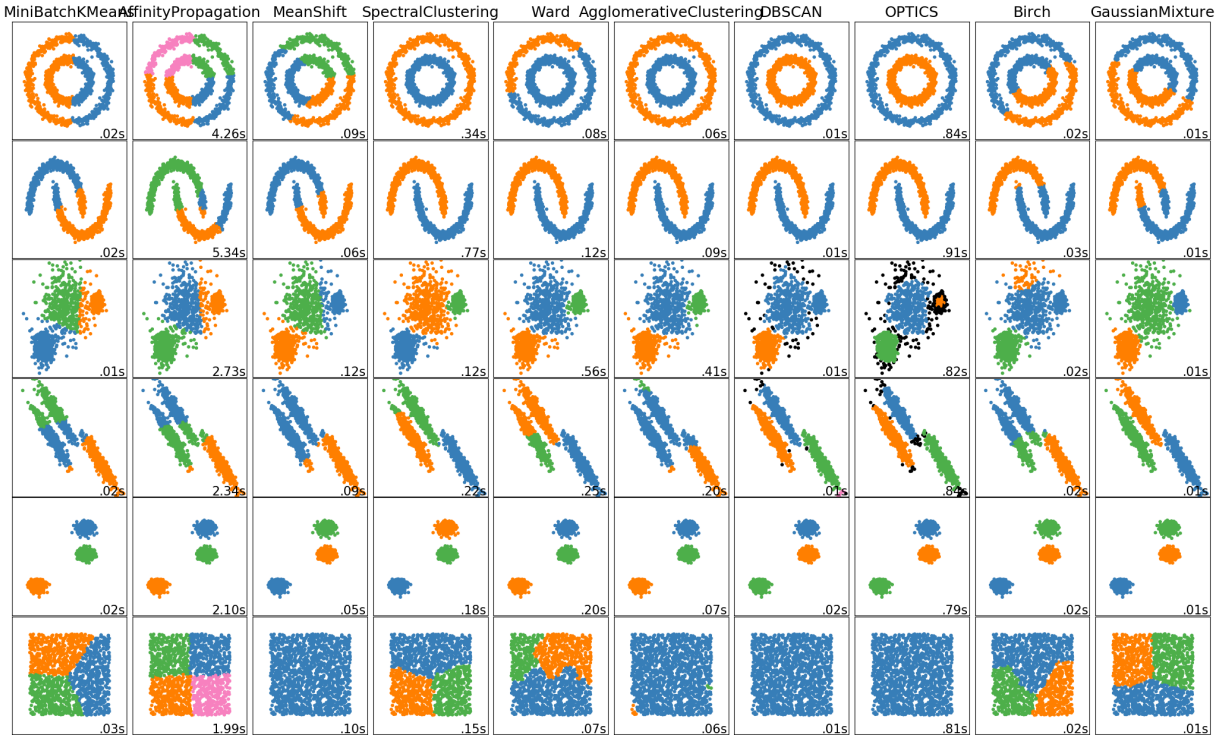

Fig. 4: A comparison of the clustering algorithms in scikit-learn

Overview of clustering methods

Method name	Parameters	Scalability	Usecase	Geometry (metric used)
K-Means	number of clusters	Very large `n_samples`, medium `n_clusters` with *MiniBatch code*	General-purpose, even cluster size, flat geometry, not too many clusters	Distances between points
Affinity propagation	damping, sample preference	Not scalable with n_samples	Many clusters, uneven cluster size, non-flat geometry	Graph distance (e.g. nearest-neighbor graph)
Mean-shift	bandwidth	Not scalable with `n_samples`	Many clusters, uneven cluster size, non-flat geometry	Distances between points
Spectral clustering	number of clusters	Medium `n_samples`, small `n_clusters`	Few clusters, even cluster size, non-flat geometry	Graph distance (e.g. nearest-neighbor graph)
Ward hierarchical clustering	number of clusters or distance threshold	Large `n_samples` and `n_clusters`	Many clusters, possibly connectivity constraints	Distances between points
Agglomerative clustering	number of clusters or distance threshold, linkage type, distance	Large `n_samples` and `n_clusters`	Many clusters, possibly connectivity constraints, non Euclidean distances	Any pairwise distance
DBSCAN	neighborhood size	Very large `n_samples`, medium `n_clusters`	Non-flat geometry, uneven cluster sizes	Distances between nearest points
OPTICS	minimum cluster membership	Very large `n_samples`, large `n_clusters`	Non-flat geometry, uneven cluster sizes, variable cluster density	Distances between points
Gaussian mix	many	Not scalable	Flat geometry, good for den	Mahalanobis dis

Non-flat geometry clustering is useful when the clusters have a specific shape, i.e. a non-flat manifold, and the standard euclidean distance is not the right metric. This case arises in the two top rows of the figure above.

Gaussian mixture models, useful for clustering, are described in *another chapter of the documentation* dedicated to mixture models. KMeans can be seen as a special case of Gaussian mixture model with equal covariance per component.

K-means

The `KMeans` algorithm clusters data by trying to separate samples in n groups of equal variance, minimizing a criterion known as the *inertia* or within-cluster sum-of-squares (see below). This algorithm requires the number of clusters to be specified. It scales well to large number of samples and has been used across a large range of application areas in many different fields.

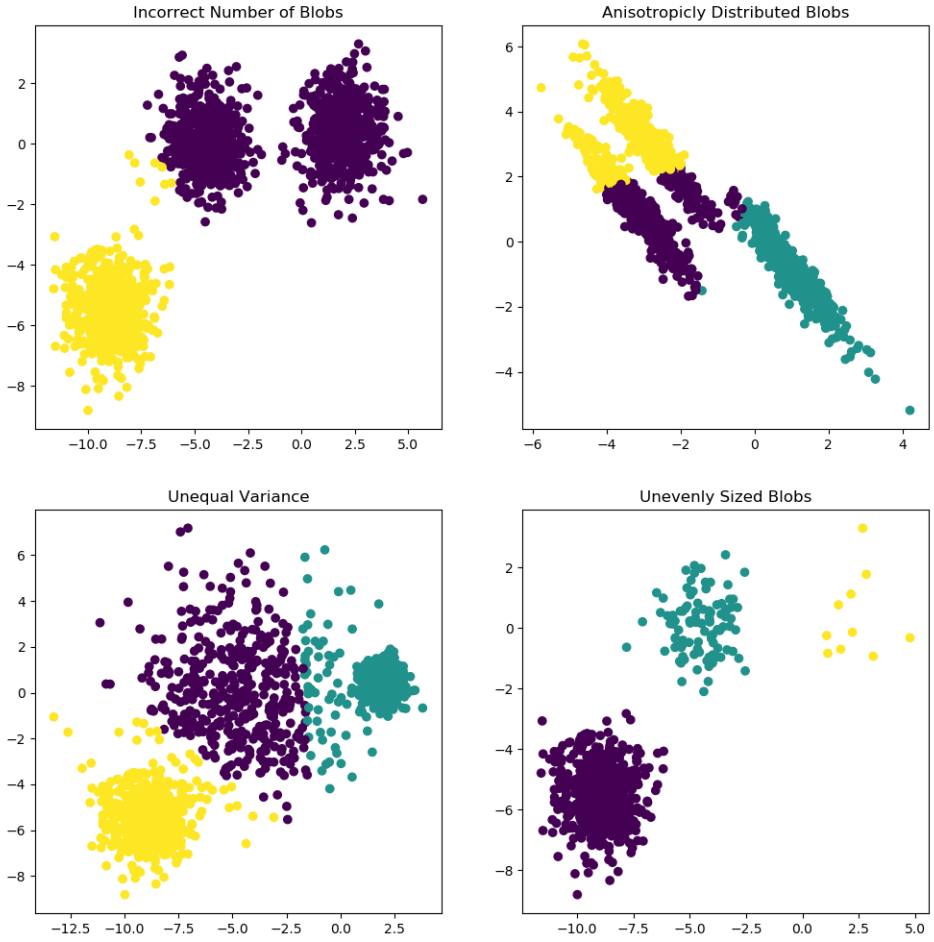
The k-means algorithm divides a set of N samples X into K disjoint clusters C, each described by the mean μ_j of the samples in the cluster. The means are commonly called the cluster "centroids"; note that they are not, in general, points from X, although they live in the same space.

The K-means algorithm aims to choose centroids that minimise the **inertia**, or **within-cluster sum-of-squares criterion**:

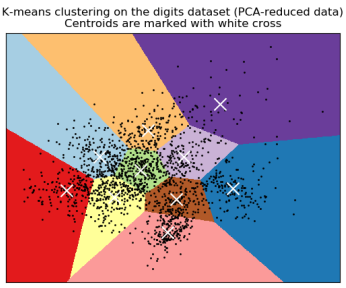
$$\sum_{i=0}^{n} \min_{\mu_j \in C} (||x_i - \mu_j||^2)$$

Inertia can be recognized as a measure of how internally coherent clusters are. It suffers from various drawbacks:

- Inertia makes the assumption that clusters are convex and isotropic, which is not always the case. It responds poorly to elongated clusters, or manifolds with irregular shapes.
- Inertia is not a normalized metric: we just know that lower values are better and zero is optimal. But in very high-dimensional spaces, Euclidean distances tend to become inflated (this is an instance of the so-called "curse of dimensionality"). Running a dimensionality reduction algorithm such as *Principal component analysis (PCA)* prior to k-means clustering can alleviate this problem and speed up the computations.



K-means is often referred to as Lloyd's algorithm. In basic terms, the algorithm has three steps. The first step chooses the initial centroids, with the most basic method being to choose k samples from the dataset X. After initialization, K-means consists of looping between the two other steps. The first step assigns each sample to its nearest centroid. The second step creates new centroids by taking the mean value of all of the samples assigned to each previous centroid. The difference between the old and the new centroids are computed and the algorithm repeats these last two steps until this value is less than a threshold. In other words, it repeats until the centroids do not move significantly.



K-means is equivalent to the expectation-maximization algorithm with a small, all-equal, diagonal covariance matrix.

The algorithm can also be understood through the concept of Voronoi diagrams. First the Voronoi diagram of the points is calculated using the current centroids. Each segment in the Voronoi diagram becomes a separate cluster. Secondly, the centroids are updated to the mean of each segment. The algorithm then repeats this until a stopping criterion is fulfilled. Usually, the algorithm stops when the relative decrease in the objective function between iterations is less than the given tolerance value. This is not the case in this implementation: iteration stops when centroids move less than the tolerance.

Given enough time, K-means will always converge, however this may be to a local minimum. This is highly dependent on the initialization of the centroids. As a result, the computation is often done several times, with different initializations of the centroids. One method to help address this issue is the k-means++ initialization scheme, which has been implemented in scikit-learn (use the `init='k-means++'` parameter). This initializes the centroids to be (generally) distant from each other, leading to provably better results than random initialization, as shown in the reference.

The algorithm supports sample weights, which can be given by a parameter `sample_weight`. This allows to assign more weight to some samples when computing cluster centers and values of inertia. For example, assigning a weight of 2 to a sample is equivalent to adding a duplicate of that sample to the dataset X.

A parameter can be given to allow K-means to be run in parallel, called `n_jobs`. Giving this parameter a positive value uses that many processors (default: 1). A value of -1 uses all available processors, with -2 using one less, and so on. Parallelization generally speeds up computation at the cost of memory (in this case, multiple copies of centroids need to be stored, one for each job).

Warning: The parallel version of K-Means is broken on OS X when `numpy` uses the `Accelerate` Framework. This is expected behavior: `Accelerate` can be called after a fork but you need to execv the subprocess with the Python binary (which multiprocessing does not do under posix).

K-means can be used for vector quantization. This is achieved using the transform method of a trained model of *KMeans*.

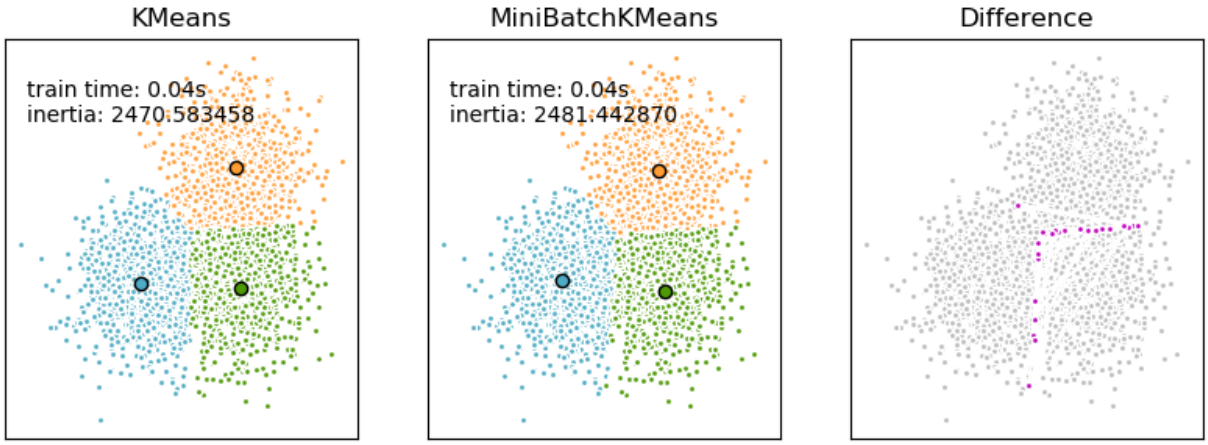
Mini Batch K-Means

The *MiniBatchKMeans* is a variant of the *KMeans* algorithm which uses mini-batches to reduce the computation time, while still attempting to optimise the same objective function. Mini-batches are subsets of the input data, randomly sampled in each training iteration. These mini-batches drastically reduce the amount of computation required

to converge to a local solution. In contrast to other algorithms that reduce the convergence time of k-means, mini-batch k-means produces results that are generally only slightly worse than the standard algorithm.

The algorithm iterates between two major steps, similar to vanilla k-means. In the first step, b samples are drawn randomly from the dataset, to form a mini-batch. These are then assigned to the nearest centroid. In the second step, the centroids are updated. In contrast to k-means, this is done on a per-sample basis. For each sample in the mini-batch, the assigned centroid is updated by taking the streaming average of the sample and all previous samples assigned to that centroid. This has the effect of decreasing the rate of change for a centroid over time. These steps are performed until convergence or a predetermined number of iterations is reached.

`MiniBatchKMeans` converges faster than `KMeans`, but the quality of the results is reduced. In practice this difference in quality can be quite small, as shown in the example and cited reference.



Examples:

- *Comparison of the K-Means and MiniBatchKMeans clustering algorithms*: Comparison of KMeans and MiniBatchKMeans
- *Clustering text documents using k-means*: Document clustering using sparse MiniBatchKMeans
- *Online learning of a dictionary of parts of faces*

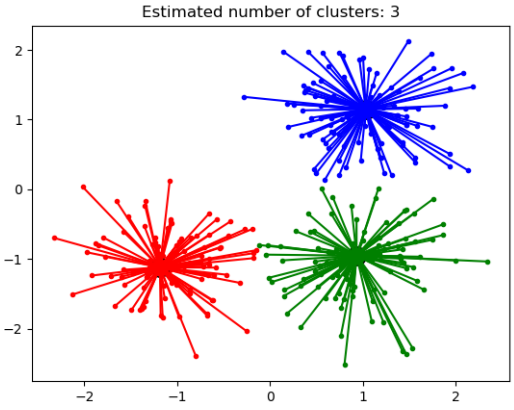
Affinity Propagation

`AffinityPropagation` creates clusters by sending messages between pairs of samples until convergence. A dataset is then described using a small number of exemplars, which are identified as those most representative of other samples. The messages sent between pairs represent the suitability for one sample to be the exemplar of the other, which is updated in response to the values from other pairs. This updating happens iteratively until convergence, at which point the final exemplars are chosen, and hence the final clustering is given.

Affinity Propagation can be interesting as it chooses the number of clusters based on the data provided. For this purpose, the two important parameters are the *preference*, which controls how many exemplars are used, and the *damping*



factor which damps the responsibility and availability messages to avoid numerical oscillations when updating these messages.

The main drawback of Affinity Propagation is its complexity. The algorithm has a time complexity of the order $O(N^2T)$, where N is the number of samples and T is the number of iterations until convergence. Further, the memory complexity is of the order $O(N^2)$ if a dense similarity matrix is used, but reducible if a sparse similarity matrix is used. This makes Affinity Propagation most appropriate for small to medium sized datasets.

Examples:

- *Demo of affinity propagation clustering algorithm*: Affinity Propagation on a synthetic 2D datasets with 3 classes.
- *Visualizing the stock market structure* Affinity Propagation on Financial time series to find groups of companies

Algorithm description: The messages sent between points belong to one of two categories. The first is the responsibility $r(i, k)$, which is the accumulated evidence that sample k should be the exemplar for sample i. The second is the availability $a(i, k)$ which is the accumulated evidence that sample i should choose sample k to be its exemplar, and considers the values for all other samples that k should be an exemplar. In this way, exemplars are chosen by samples if they are (1) similar enough to many samples and (2) chosen by many samples to be representative of themselves.

More formally, the responsibility of a sample k to be the exemplar of sample i is given by:

$$r(i, k) \leftarrow s(i, k) - max[a(i, k') + s(i, k')\forall k' \neq k]$$

Where $s(i, k)$ is the similarity between samples i and k. The availability of sample k to be the exemplar of sample i is given by:

$$a(i, k) \leftarrow min[0, r(k, k) + \sum_{i' \ s.t. \ i' \notin \{i,k\}} r(i', k)]$$

To begin with, all values for r and a are set to zero, and the calculation of each iterates until convergence. As discussed above, in order to avoid numerical oscillations when updating the messages, the damping factor λ is introduced to iteration process:

$$r_{t+1}(i, k) = \lambda \cdot r_t(i, k) + (1 - \lambda) \cdot r_{t+1}(i, k)$$

$$a_{t+1}(i, k) = \lambda \cdot a_t(i, k) + (1 - \lambda) \cdot a_{t+1}(i, k)$$

where t indicates the iteration times.

Mean Shift

`MeanShift` clustering aims to discover *blobs* in a smooth density of samples. It is a centroid based algorithm, which works by updating candidates for centroids to be the mean of the points within a given region. These candidates are then filtered in a post-processing stage to eliminate near-duplicates to form the final set of centroids.

Given a candidate centroid x_i for iteration t, the candidate is updated according to the following equation:

$$x_i^{t+1} = m(x_i^t)$$

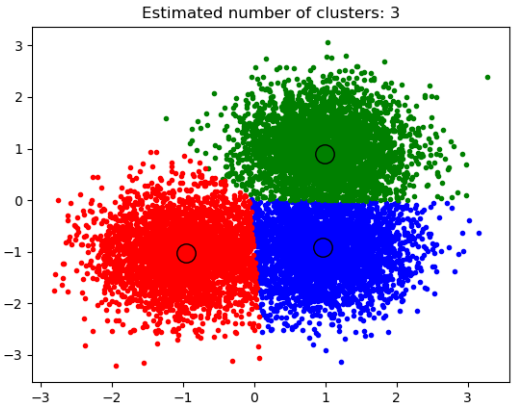
Where $N(x_i)$ is the neighborhood of samples within a given distance around x_i and m is the *mean shift* vector that is computed for each centroid that points towards a region of the maximum increase in the density of points. This is computed using the following equation, effectively updating a centroid to be the mean of the samples within its neighborhood:

$$m(x_i) = \frac{\sum_{x_j \in N(x_i)} K(x_j - x_i) x_j}{\sum_{x_j \in N(x_i)} K(x_j - x_i)}$$

The algorithm automatically sets the number of clusters, instead of relying on a parameter `bandwidth`, which dictates the size of the region to search through. This parameter can be set manually, but can be estimated using the provided `estimate_bandwidth` function, which is called if the bandwidth is not set.

The algorithm is not highly scalable, as it requires multiple nearest neighbor searches during the execution of the algorithm. The algorithm is guaranteed to converge, however the algorithm will stop iterating when the change in centroids is small.

Labelling a new sample is performed by finding the nearest centroid for a given sample.



Examples:

- *A demo of the mean-shift clustering algorithm*: Mean Shift clustering on a synthetic 2D datasets with 3 classes.

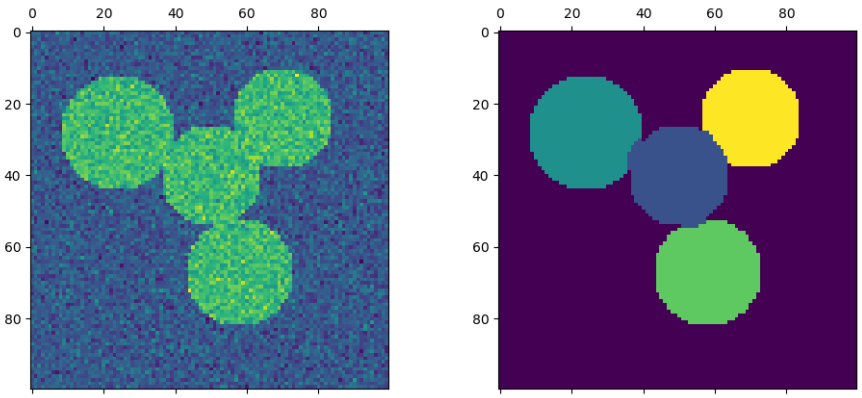
Spectral clustering

SpectralClustering performs a low-dimension embedding of the affinity matrix between samples, followed by clustering, e.g., by KMeans, of the components of the eigenvectors in the low dimensional space. It is especially computationally efficient if the affinity matrix is sparse and the `amg` solver is used for the eigenvalue problem (Note, the `amg` solver requires that the pyamg module is installed.)

The present version of SpectralClustering requires the number of clusters to be specified in advance. It works well for a small number of clusters, but is not advised for many clusters.

For two clusters, SpectralClustering solves a convex relaxation of the normalised cuts problem on the similarity graph: cutting the graph in two so that the weight of the edges cut is small compared to the weights of the edges inside each cluster. This criteria is especially interesting when working on images, where graph vertices are pixels, and weights of the edges of the similarity graph are computed using a function of a gradient of the image.



Warning: Transforming distance to well-behaved similarities

Note that if the values of your similarity matrix are not well distributed, e.g. with negative values or with a distance matrix rather than a similarity, the spectral problem will be singular and the problem not solvable. In which case it is advised to apply a transformation to the entries of the matrix. For instance, in the case of a signed distance matrix, is common to apply a heat kernel:

```
similarity = np.exp(-beta * distance / distance.std())
```

See the examples for such an application.

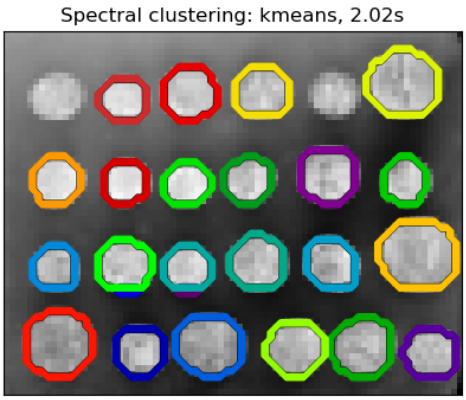
Examples:

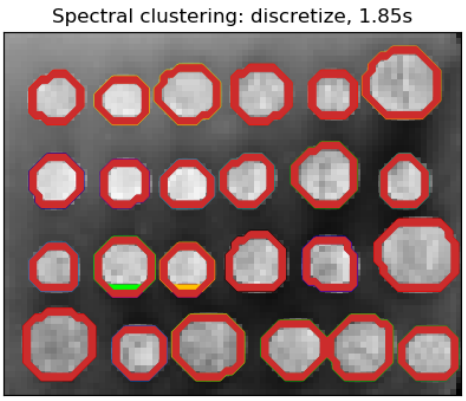
- *Spectral clustering for image segmentation*: Segmenting objects from a noisy background using spectral clustering.
- *Segmenting the picture of greek coins in regions*: Spectral clustering to split the image of coins in regions.

Different label assignment strategies

Different label assignment strategies can be used, corresponding to the `assign_labels` parameter of *SpectralClustering*. `"kmeans"` strategy can match finer details, but can be unstable. In particular, unless

you control the `random_state`, it may not be reproducible from run-to-run, as it depends on random initialization. The alternative `"discretize"` strategy is 100% reproducible, but tends to create parcels of fairly even and geometrical shape.

`assign_labels="kmeans"`	`assign_labels="discretize"`
	




Spectral Clustering Graphs

Spectral Clustering can also be used to partition graphs via their spectral embeddings. In this case, the affinity matrix is the adjacency matrix of the graph, and SpectralClustering is initialized with `affinity='precomputed'`:

```
>>> from sklearn.cluster import SpectralClustering
>>> sc = SpectralClustering(3, affinity='precomputed', n_init=100,
...                         assign_labels='discretize')
>>> sc.fit_predict(adjacency_matrix)
```

Hierarchical clustering

Hierarchical clustering is a general family of clustering algorithms that build nested clusters by merging or splitting them successively. This hierarchy of clusters is represented as a tree (or dendrogram). The root of the tree is the unique

cluster that gathers all the samples, the leaves being the clusters with only one sample. See the Wikipedia page for more details.

The *AgglomerativeClustering* object performs a hierarchical clustering using a bottom up approach: each observation starts in its own cluster, and clusters are successively merged together. The linkage criteria determines the metric used for the merge strategy:

- **Ward** minimizes the sum of squared differences within all clusters. It is a variance-minimizing approach and in this sense is similar to the k-means objective function but tackled with an agglomerative hierarchical approach.
- **Maximum** or **complete linkage** minimizes the maximum distance between observations of pairs of clusters.
- **Average linkage** minimizes the average of the distances between all observations of pairs of clusters.
- **Single linkage** minimizes the distance between the closest observations of pairs of clusters.

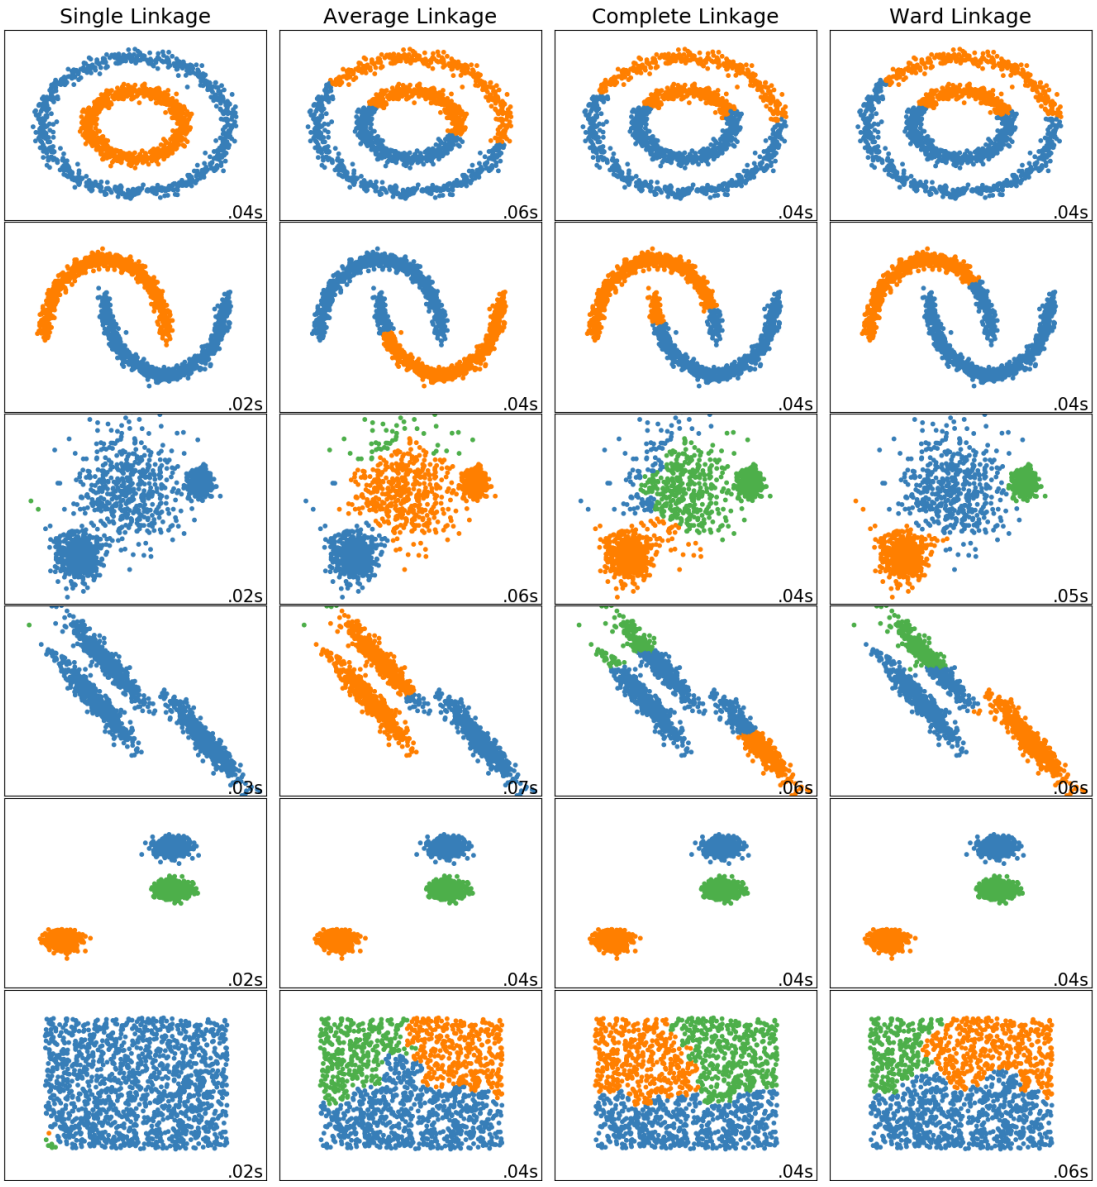
AgglomerativeClustering can also scale to large number of samples when it is used jointly with a connectivity matrix, but is computationally expensive when no connectivity constraints are added between samples: it considers at each step all the possible merges.

FeatureAgglomeration

The *FeatureAgglomeration* uses agglomerative clustering to group together features that look very similar, thus decreasing the number of features. It is a dimensionality reduction tool, see *Unsupervised dimensionality reduction*.

Different linkage type: Ward, complete, average, and single linkage

AgglomerativeClustering supports Ward, single, average, and complete linkage strategies.



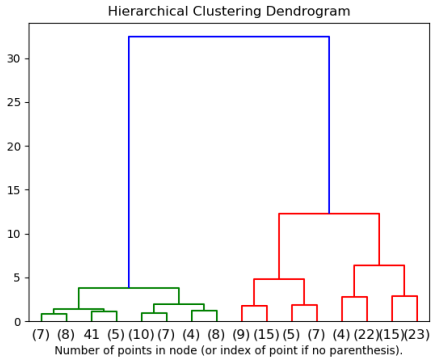
Agglomerative cluster has a "rich get richer" behavior that leads to uneven cluster sizes. In this regard, single linkage is the worst strategy, and Ward gives the most regular sizes. However, the affinity (or distance used in clustering) cannot be varied with Ward, thus for non Euclidean metrics, average linkage is a good alternative. Single linkage, while not robust to noisy data, can be computed very efficiently and can therefore be useful to provide hierarchical clustering of larger datasets. Single linkage can also perform well on non-globular data.

Examples:

- *Various Agglomerative Clustering on a 2D embedding of digits*: exploration of the different linkage strategies in a real dataset.

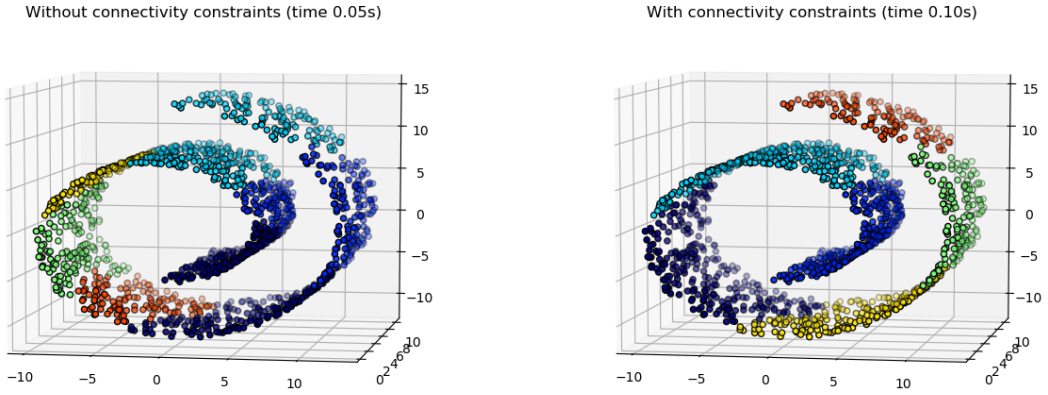
Visualization of cluster hierarchy

It's possible to visualize the tree representing the hierarchical merging of clusters as a dendrogram. Visual inspection can often be useful for understanding the structure of the data, though more so in the case of small sample sizes.



Adding connectivity constraints

An interesting aspect of *AgglomerativeClustering* is that connectivity constraints can be added to this algorithm (only adjacent clusters can be merged together), through a connectivity matrix that defines for each sample the neighboring samples following a given structure of the data. For instance, in the swiss-roll example below, the connectivity constraints forbid the merging of points that are not adjacent on the swiss roll, and thus avoid forming clusters that extend across overlapping folds of the roll.



These constraint are useful to impose a certain local structure, but they also make the algorithm faster, especially when the number of the samples is high.

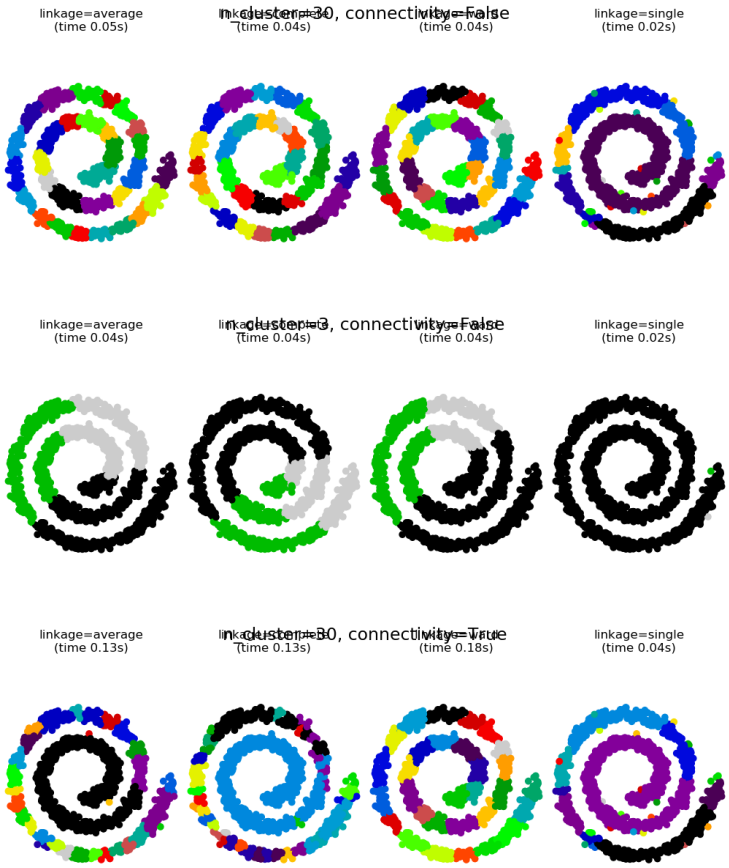
The connectivity constraints are imposed via an connectivity matrix: a scipy sparse matrix that has elements only at the intersection of a row and a column with indices of the dataset that should be connected. This matrix can be constructed from a-priori information: for instance, you may wish to cluster web pages by only merging pages with a link pointing from one to another. It can also be learned from the data, for instance using *sklearn.neighbors.kneighbors_graph* to restrict merging to nearest neighbors as in *this example*, or using *sklearn.feature_extraction.image.grid_to_graph* to enable only merging of neighboring pixels on an image, as in the *coin* example.

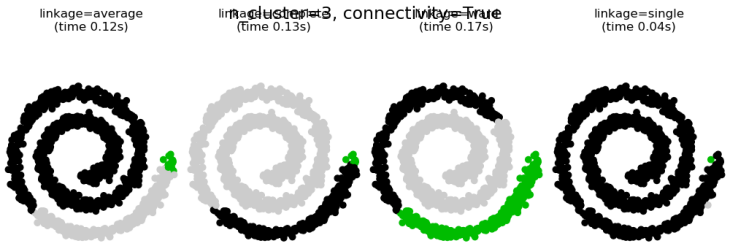
Examples:

- *A demo of structured Ward hierarchical clustering on an image of coins*: Ward clustering to split the image of coins in regions.
- *Hierarchical clustering: structured vs unstructured ward*: Example of Ward algorithm on a swiss-roll, comparison of structured approaches versus unstructured approaches.
- *Feature agglomeration vs. univariate selection*: Example of dimensionality reduction with feature agglomeration based on Ward hierarchical clustering.
- *Agglomerative clustering with and without structure*

Warning: Connectivity constraints with single, average and complete linkage

Connectivity constraints and single, complete or average linkage can enhance the 'rich getting richer' aspect of agglomerative clustering, particularly so if they are built with `sklearn.neighbors.kneighbors_graph`. In the limit of a small number of clusters, they tend to give a few macroscopically occupied clusters and almost empty ones. (see the discussion in *Agglomerative clustering with and without structure*). Single linkage is the most brittle linkage option with regard to this issue.



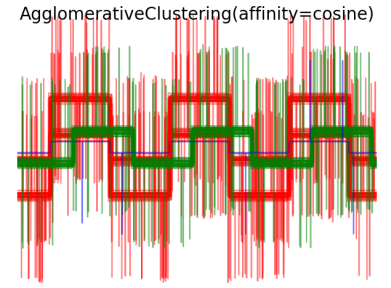


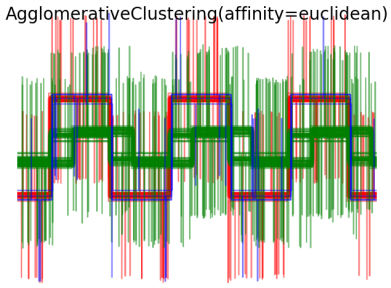
Varying the metric

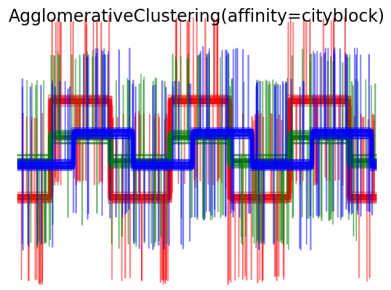
Single, average and complete linkage can be used with a variety of distances (or affinities), in particular Euclidean distance (*l2*), Manhattan distance (or Cityblock, or *l1*), cosine distance, or any precomputed affinity matrix.

- *l1* distance is often good for sparse features, or sparse noise: i.e. many of the features are zero, as in text mining using occurrences of rare words.
- *cosine* distance is interesting because it is invariant to global scalings of the signal.

The guidelines for choosing a metric is to use one that maximizes the distance between samples in different classes, and minimizes that within each class.







Examples:

- *Agglomerative clustering with different metrics*

DBSCAN

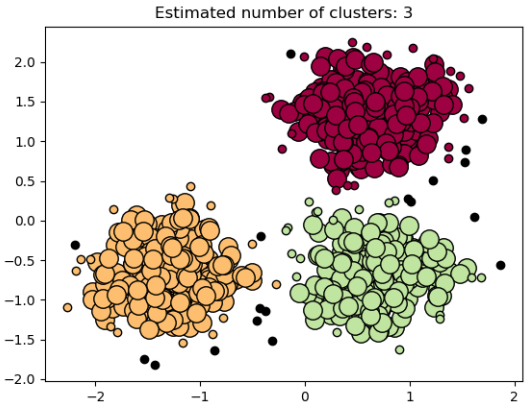
The `DBSCAN` algorithm views clusters as areas of high density separated by areas of low density. Due to this rather generic view, clusters found by DBSCAN can be any shape, as opposed to k-means which assumes that clusters are convex shaped. The central component to the DBSCAN is the concept of *core samples*, which are samples that are in areas of high density. A cluster is therefore a set of core samples, each close to each other (measured by some distance measure) and a set of non-core samples that are close to a core sample (but are not themselves core samples). There are two parameters to the algorithm, `min_samples` and `eps`, which define formally what we mean when we say *dense*. Higher `min_samples` or lower `eps` indicate higher density necessary to form a cluster.

More formally, we define a core sample as being a sample in the dataset such that there exist `min_samples` other samples within a distance of `eps`, which are defined as *neighbors* of the core sample. This tells us that the core sample is in a dense area of the vector space. A cluster is a set of core samples that can be built by recursively taking a core sample, finding all of its neighbors that are core samples, finding all of *their* neighbors that are core samples, and so on. A cluster also has a set of non-core samples, which are samples that are neighbors of a core sample in the cluster but are not themselves core samples. Intuitively, these samples are on the fringes of a cluster.

Any core sample is part of a cluster, by definition. Any sample that is not a core sample, and is at least `eps` in distance from any core sample, is considered an outlier by the algorithm.

While the parameter `min_samples` primarily controls how tolerant the algorithm is towards noise (on noisy and large data sets it may be desirable to increase this parameter), the parameter `eps` is *crucial to choose appropriately* for the data set and distance function and usually cannot be left at the default value. It controls the local neighborhood of the points. When chosen too small, most data will not be clustered at all (and labeled as `-1` for "noise"). When chosen too large, it causes close clusters to be merged into one cluster, and eventually the entire data set to be returned as a single cluster. Some heuristics for choosing this parameter have been discussed in the literature, for example based on a knee in the nearest neighbor distances plot (as discussed in the references below).

In the figure below, the color indicates cluster membership, with large circles indicating core samples found by the algorithm. Smaller circles are non-core samples that are still part of a cluster. Moreover, the outliers are indicated by black points below.



Examples:

- *Demo of DBSCAN clustering algorithm*

Implementation

The DBSCAN algorithm is deterministic, always generating the same clusters when given the same data in the same order. However, the results can differ when data is provided in a different order. First, even though the core samples will always be assigned to the same clusters, the labels of those clusters will depend on the order in which those samples are encountered in the data. Second and more importantly, the clusters to which non-core samples are assigned can differ depending on the data order. This would happen when a non-core sample has a distance lower than `eps` to two core samples in different clusters. By the triangular inequality, those two core samples must be more distant than `eps` from each other, or they would be in the same cluster. The non-core sample is assigned to whichever cluster is generated first in a pass through the data, and so the results will depend on the data ordering.

The current implementation uses ball trees and kd-trees to determine the neighborhood of points, which avoids calculating the full distance matrix (as was done in scikit-learn versions before 0.14). The possibility to use custom metrics is retained; for details, see `NearestNeighbors`.

Memory consumption for large sample sizes

This implementation is by default not memory efficient because it constructs a full pairwise similarity matrix in the case where kd-trees or ball-trees cannot be used (e.g., with sparse matrices). This matrix will consume n^2 floats. A couple of mechanisms for getting around this are:

- Use *OPTICS* clustering in conjunction with the `extract_dbscan` method. OPTICS clustering also calculates the full pairwise matrix, but only keeps one row in memory at a time (memory complexity n).
- A sparse radius neighborhood graph (where missing entries are presumed to be out of eps) can be precomputed in a memory-efficient way and dbscan can be run over this with `metric='precomputed'`. See *`sklearn.neighbors.NearestNeighbors.radius_neighbors_graph`*.
- The dataset can be compressed, either by removing exact duplicates if these occur in your data, or by using BIRCH. Then you only have a relatively small number of representatives for a large number of points. You can then provide a `sample_weight` when fitting DBSCAN.

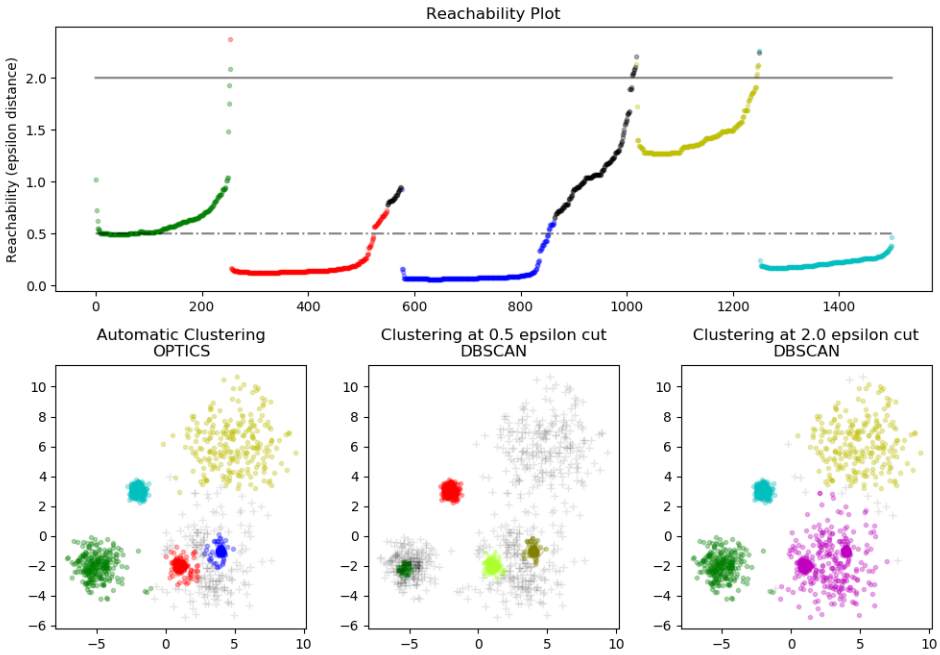
OPTICS

The *`OPTICS`* algorithm shares many similarities with the *`DBSCAN`* algorithm, and can be considered a generalization of DBSCAN that relaxes the `eps` requirement from a single value to a value range. The key difference between DBSCAN and OPTICS is that the OPTICS algorithm builds a *reachability* graph, which assigns each sample both

a `reachability_` distance, and a spot within the cluster `ordering_` attribute; these two attributes are assigned when the model is fitted, and are used to determine cluster membership. If OPTICS is run with the default value of *inf* set for `max_eps`, then DBSCAN style cluster extraction can be performed repeatedly in linear time for any given `eps` value using the `cluster_optics_dbscan` method. Setting `max_eps` to a lower value will result in shorter run times, and can be thought of as the maximum neighborhood radius from each point to find other potential reachable points.



The *reachability* distances generated by OPTICS allow for variable density extraction of clusters within a single data set. As shown in the above plot, combining *reachability* distances and data set `ordering_` produces a *reachability plot*, where point density is represented on the Y-axis, and points are ordered such that nearby points are adjacent. 'Cutting' the reachability plot at a single value produces DBSCAN like results; all points above the 'cut' are classified as noise, and each time that there is a break when reading from left to right signifies a new cluster. The default cluster extraction with OPTICS looks at the steep slopes within the graph to find clusters, and the user can define what counts as a steep slope using the parameter `xi`. There are also other possibilities for analysis on the graph itself, such as generating hierarchical representations of the data through reachability-plot dendrograms, and the hierarchy of clusters detected by the algorithm can be accessed through the `cluster_hierarchy_` parameter. The plot above has been color-coded so that cluster colors in planar space match the linear segment clusters of the reachability plot. Note that the blue and red clusters are adjacent in the reachability plot, and can be hierarchically represented as children of a larger parent cluster.

Examples:

- *Demo of OPTICS clustering algorithm*

Comparison with DBSCAN

The results from OPTICS `cluster_optics_dbscan` method and DBSCAN are very similar, but not always identical; specifically, labeling of periphery and noise points. This is in part because the first samples of each dense area processed by OPTICS have a large reachability value while being close to other points in their area, and will thus sometimes be marked as noise rather than periphery. This affects adjacent points when they are considered as

candidates for being marked as either periphery or noise.

Note that for any single value of `eps`, DBSCAN will tend to have a shorter run time than OPTICS; however, for repeated runs at varying `eps` values, a single run of OPTICS may require less cumulative runtime than DBSCAN. It is also important to note that OPTICS' output is close to DBSCAN's only if `eps` and `max_eps` are close.

Computational Complexity

Spatial indexing trees are used to avoid calculating the full distance matrix, and allow for efficient memory usage on large sets of samples. Different distance metrics can be supplied via the `metric` keyword.

For large datasets, similar (but not identical) results can be obtained via HDBSCAN. The HDBSCAN implementation is multithreaded, and has better algorithmic runtime complexity than OPTICS, at the cost of worse memory scaling. For extremely large datasets that exhaust system memory using HDBSCAN, OPTICS will maintain *n* (as opposed to *n*^2) memory scaling; however, tuning of the `max_eps` parameter will likely need to be used to give a solution in a reasonable amount of wall time.

Birch

The *Birch* builds a tree called the Clustering Feature Tree (CFT) for the given data. The data is essentially lossy compressed to a set of Clustering Feature nodes (CF Nodes). The CF Nodes have a number of subclusters called Clustering Feature subclusters (CF Subclusters) and these CF Subclusters located in the non-terminal CF Nodes can have CF Nodes as children.

The CF Subclusters hold the necessary information for clustering which prevents the need to hold the entire input data in memory. This information includes:

- Number of samples in a subcluster.
- Linear Sum - A n-dimensional vector holding the sum of all samples
- Squared Sum - Sum of the squared L2 norm of all samples.
- Centroids - To avoid recalculation linear sum / n_samples.
- Squared norm of the centroids.

The Birch algorithm has two parameters, the threshold and the branching factor. The branching factor limits the number of subclusters in a node and the threshold limits the distance between the entering sample and the existing subclusters.

This algorithm can be viewed as an instance or data reduction method, since it reduces the input data to a set of subclusters which are obtained directly from the leaves of the CFT. This reduced data can be further processed by feeding it into a global clusterer. This global clusterer can be set by `n_clusters`. If `n_clusters` is set to None, the subclusters from the leaves are directly read off, otherwise a global clustering step labels these subclusters into global clusters (labels) and the samples are mapped to the global label of the nearest subcluster.

Algorithm description:

- A new sample is inserted into the root of the CF Tree which is a CF Node. It is then merged with the subcluster of the root, that has the smallest radius after merging, constrained by the threshold and branching factor conditions. If the subcluster has any child node, then this is done repeatedly till it reaches a leaf. After finding the nearest subcluster in the leaf, the properties of this subcluster and the parent subclusters are recursively updated.
- If the radius of the subcluster obtained by merging the new sample and the nearest subcluster is greater than the square of the threshold and if the number of subclusters is greater than the branching factor, then a space is temporarily allocated to this new sample. The two farthest subclusters are taken and the subclusters are divided into two groups on the basis of the distance between these subclusters.
- If this split node has a parent subcluster and there is room for a new subcluster, then the parent is split into two. If there is no room, then this node is again split into two and the process is continued recursively, till it reaches the root.

Birch or MiniBatchKMeans?

- Birch does not scale very well to high dimensional data. As a rule of thumb if `n_features` is greater than twenty, it is generally better to use MiniBatchKMeans.
- If the number of instances of data needs to be reduced, or if one wants a large number of subclusters either as a preprocessing step or otherwise, Birch is more useful than MiniBatchKMeans.

How to use partial_fit?

To avoid the computation of global clustering, for every call of `partial_fit` the user is advised

1. To set `n_clusters=None` initially
2. Train all data by multiple calls to partial_fit.
3. Set `n_clusters` to a required value using `brc.set_params(n_clusters=n_clusters)`.
4. Call `partial_fit` finally with no arguments, i.e. `brc.partial_fit()` which performs the global clustering.

Clustering performance evaluation

Evaluating the performance of a clustering algorithm is not as trivial as counting the number of errors or the precision and recall of a supervised classification algorithm. In particular any evaluation metric should not take the absolute values of the cluster labels into account but rather if this clustering define separations of the data similar to some ground truth set of classes or satisfying some assumption such that members belong to the same class are more similar than members of different classes according to some similarity metric.

Adjusted Rand index

Given the knowledge of the ground truth class assignments `labels_true` and our clustering algorithm assignments of the same samples `labels_pred`, the **adjusted Rand index** is a function that measures the **similarity** of the two assignments, ignoring permutations and **with chance normalization**:

```
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]

>>> metrics.adjusted_rand_score(labels_true, labels_pred)
0.24...
```

One can permute 0 and 1 in the predicted labels, rename 2 to 3, and get the same score:

```
>>> labels_pred = [1, 1, 0, 0, 3, 3]
>>> metrics.adjusted_rand_score(labels_true, labels_pred)
0.24...
```

Furthermore, *adjusted_rand_score* is **symmetric**: swapping the argument does not change the score. It can thus be used as a **consensus measure**:

```
>>> metrics.adjusted_rand_score(labels_pred, labels_true)
0.24...
```

Perfect labeling is scored 1.0:

```
>>> labels_pred = labels_true[:]
>>> metrics.adjusted_rand_score(labels_true, labels_pred)
1.0
```

Bad (e.g. independent labelings) have negative or close to 0.0 scores:

```
>>> labels_true = [0, 1, 2, 0, 3, 4, 5, 1]
>>> labels_pred = [1, 1, 0, 0, 2, 2, 2, 2]
>>> metrics.adjusted_rand_score(labels_true, labels_pred)
-0.12...
```

Advantages

- **Random (uniform) label assignments have a ARI score close to 0.0** for any value of `n_clusters` and `n_samples` (which is not the case for raw Rand index or the V-measure for instance).
- **Bounded range [-1, 1]**: negative values are bad (independent labelings), similar clusterings have a positive ARI, 1.0 is the perfect match score.

- **No assumption is made on the cluster structure**: can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with "folded" shapes.

Drawbacks

- Contrary to inertia, **ARI requires knowledge of the ground truth classes** while is almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

  However ARI can also be useful in a purely unsupervised setting as a building block for a Consensus Index that can be used for clustering model selection (TODO).

Examples:

- *Adjustment for chance in clustering performance evaluation*: Analysis of the impact of the dataset size on the value of clustering measures for random assignments.

Mathematical formulation

If C is a ground truth class assignment and K the clustering, let us define a and b as:

- a, the number of pairs of elements that are in the same set in C and in the same set in K
- b, the number of pairs of elements that are in different sets in C and in different sets in K

The raw (unadjusted) Rand index is then given by:

$$\text{RI} = \frac{a + b}{C_2^{n_{samples}}}$$

Where $C_2^{n_{samples}}$ is the total number of possible pairs in the dataset (without ordering).

However the RI score does not guarantee that random label assignments will get a value close to zero (esp. if the number of clusters is in the same order of magnitude as the number of samples).

To counter this effect we can discount the expected RI $E[\text{RI}]$ of random labelings by defining the adjusted Rand index as follows:

$$\text{ARI} = \frac{\text{RI} - E[\text{RI}]}{\max(\text{RI}) - E[\text{RI}]}$$

- Wikipedia entry for the adjusted Rand index

Mutual Information based scores

Given the knowledge of the ground truth class assignments `labels_true` and our clustering algorithm assignments of the same samples `labels_pred`, the **Mutual Information** is a function that measures the **agreement** of the two assignments, ignoring permutations. Two different normalized versions of this measure are available, **Normalized Mutual Information (NMI)** and **Adjusted Mutual Information (AMI)**. NMI is often used in the literature, while AMI was proposed more recently and is **normalized against chance**:

```
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]

>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
0.22504...
```

One can permute 0 and 1 in the predicted labels, rename 2 to 3 and get the same score:

```
>>> labels_pred = [1, 1, 0, 0, 3, 3]
>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
0.22504...
```

All, *mutual_info_score*, *adjusted_mutual_info_score* and *normalized_mutual_info_score* are symmetric: swapping the argument does not change the score. Thus they can be used as a **consensus measure**:

```
>>> metrics.adjusted_mutual_info_score(labels_pred, labels_true)
0.22504...
```

Perfect labeling is scored 1.0:

```
>>> labels_pred = labels_true[:]
>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
1.0

>>> metrics.normalized_mutual_info_score(labels_true, labels_pred)
1.0
```

This is not true for `mutual_info_score`, which is therefore harder to judge:

```
>>> metrics.mutual_info_score(labels_true, labels_pred)
0.69...
```

Bad (e.g. independent labelings) have non-positive scores:

```
>>> labels_true = [0, 1, 2, 0, 3, 4, 5, 1]
>>> labels_pred = [1, 1, 0, 0, 2, 2, 2, 2]
>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
-0.10526...
```

Advantages

- **Random (uniform) label assignments have a AMI score close to 0.0** for any value of `n_clusters` and `n_samples` (which is not the case for raw Mutual Information or the V-measure for instance).
- **Upper bound of 1**: Values close to zero indicate two label assignments that are largely independent, while values close to one indicate significant agreement. Further, an AMI of exactly 1 indicates that the two label assignments are equal (with or without permutation).

Drawbacks

- Contrary to inertia, **MI-based measures require the knowledge of the ground truth classes** while almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

However MI-based measures can also be useful in purely unsupervised setting as a building block for a Consensus Index that can be used for clustering model selection.

- NMI and MI are not adjusted against chance.

Examples:

- *Adjustment for chance in clustering performance evaluation*: Analysis of the impact of the dataset size on the value of clustering measures for random assignments. This example also includes the Adjusted Rand Index.

Mathematical formulation

Assume two label assignments (of the same N objects), U and V. Their entropy is the amount of uncertainty for a partition set, defined by:

$$H(U) = -\sum_{i=1}^{|U|} P(i) \log(P(i))$$

where $P(i) = |U_i|/N$ is the probability that an object picked at random from U falls into class U_i. Likewise for V:

$$H(V) = -\sum_{j=1}^{|V|} P'(j) \log(P'(j))$$

With $P'(j) = |V_j|/N$. The mutual information (MI) between U and V is calculated by:

$$\text{MI}(U, V) = \sum_{i=1}^{|U|} \sum_{j=1}^{|V|} P(i, j) \log \left(\frac{P(i,j)}{P(i)P'(j)} \right)$$

where $P(i, j) = |U_i \cap V_j|/N$ is the probability that an object picked at random falls into both classes U_i and V_j.

It also can be expressed in set cardinality formulation:

$$\text{MI}(U, V) = \sum_{i=1}^{|U|} \sum_{j=1}^{|V|} \frac{|U_i \cap V_j|}{N} \log \left(\frac{N|U_i \cap V_j|}{|U_i||V_j|} \right)$$

The normalized mutual information is defined as

$$\text{NMI}(U, V) = \frac{\text{MI}(U, V)}{\text{mean}(H(U), H(V))}$$

This value of the mutual information and also the normalized variant is not adjusted for chance and will tend to increase as the number of different labels (clusters) increases, regardless of the actual amount of "mutual information" between the label assignments.

The expected value for the mutual information can be calculated using the following equation [VEB2009]. In this equation, $a_i = |U_i|$ (the number of elements in U_i) and $b_j = |V_j|$ (the number of elements in V_j).

$$E[\text{MI}(U, V)] = \sum_{i=1}^{|U|} \sum_{j=1}^{|V|} \sum_{n_{ij}=(a_i+b_j-N)^+}^{\min(a_i, b_j)} \frac{n_{ij}}{N} \log \left(\frac{N.n_{ij}}{a_i b_j} \right) \frac{a_i! b_j! (N - a_i)! (N - b_j)!}{N! n_{ij}! (a_i - n_{ij})! (b_j - n_{ij})! (N - a_i - b_j + n_{ij})!}$$

Using the expected value, the adjusted mutual information can then be calculated using a similar form to that of the adjusted Rand index:

$$\text{AMI} = \frac{\text{MI} - E[\text{MI}]}{\text{mean}(H(U), H(V)) - E[\text{MI}]}$$

For normalized mutual information and adjusted mutual information, the normalizing value is typically some *generalized* mean of the entropies of each clustering. Various generalized means exist, and no firm rules exist for preferring one over the others. The decision is largely a field-by-field basis; for instance, in community detection, the arithmetic mean is most common. Each normalizing method provides "qualitatively similar behaviours" [YAT2016]. In our implementation, this is controlled by the `average_method` parameter.

Vinh et al. (2010) named variants of NMI and AMI by their averaging method [VEB2010]. Their 'sqrt' and 'sum' averages are the geometric and arithmetic means; we use these more broadly common names.

Homogeneity, completeness and V-measure

Given the knowledge of the ground truth class assignments of the samples, it is possible to define some intuitive metric using conditional entropy analysis.

In particular Rosenberg and Hirschberg (2007) define the following two desirable objectives for any cluster assignment:

- **homogeneity**: each cluster contains only members of a single class.
- **completeness**: all members of a given class are assigned to the same cluster.

We can turn those concept as scores *homogeneity_score* and *completeness_score*. Both are bounded below by 0.0 and above by 1.0 (higher is better):

```
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]

>>> metrics.homogeneity_score(labels_true, labels_pred)
0.66...

>>> metrics.completeness_score(labels_true, labels_pred)
0.42...
```

Their harmonic mean called **V-measure** is computed by *v_measure_score*:

```
>>> metrics.v_measure_score(labels_true, labels_pred)
0.51...
```

This function's formula is as follows:

$$v = \frac{(1 + \beta) \times \text{homogeneity} \times \text{completeness}}{(\beta \times \text{homogeneity} + \text{completeness})}$$

`beta` defaults to a value of 1.0, but for using a value less than 1 for beta:

```
>>> metrics.v_measure_score(labels_true, labels_pred, beta=0.6)
0.54...
```

more weight will be attributed to homogeneity, and using a value greater than 1:

```
>>> metrics.v_measure_score(labels_true, labels_pred, beta=1.8)
0.48...
```

more weight will be attributed to completeness.

The V-measure is actually equivalent to the mutual information (NMI) discussed above, with the aggregation function being the arithmetic mean [B2011].

Homogeneity, completeness and V-measure can be computed at once using *homogeneity_completeness_v_measure* as follows:

```
>>> metrics.homogeneity_completeness_v_measure(labels_true, labels_pred)
(0.66..., 0.42..., 0.51...)
```

The following clustering assignment is slightly better, since it is homogeneous but not complete:

```
>>> labels_pred = [0, 0, 0, 1, 2, 2]
>>> metrics.homogeneity_completeness_v_measure(labels_true, labels_pred)
(1.0, 0.68..., 0.81...)
```

Note: *v_measure_score* is **symmetric**: it can be used to evaluate the **agreement** of two independent assignments on the same dataset.

This is not the case for *completeness_score* and *homogeneity_score*: both are bound by the relationship:

```
homogeneity_score(a, b) == completeness_score(b, a)
```

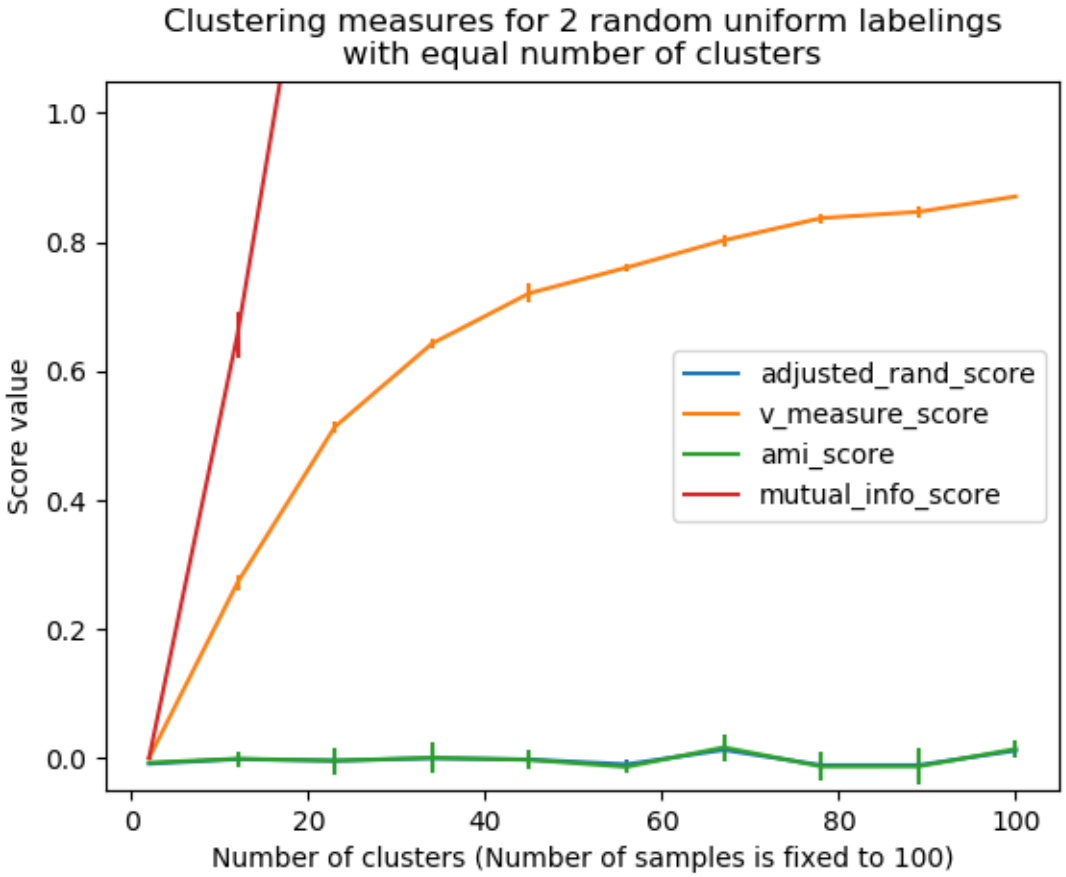
Advantages

- **Bounded scores**: 0.0 is as bad as it can be, 1.0 is a perfect score.
- Intuitive interpretation: clustering with bad V-measure can be **qualitatively analyzed in terms of homogeneity and completeness** to better feel what 'kind' of mistakes is done by the assignment.
- **No assumption is made on the cluster structure**: can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with "folded" shapes.

Drawbacks

- The previously introduced metrics are **not normalized with regards to random labeling**: this means that depending on the number of samples, clusters and ground truth classes, a completely random labeling will not always yield the same values for homogeneity, completeness and hence v-measure. In particular **random labeling won't yield zero scores especially when the number of clusters is large**.

  This problem can safely be ignored when the number of samples is more than a thousand and the number of clusters is less than 10. **For smaller sample sizes or larger number of clusters it is safer to use an adjusted index such as the Adjusted Rand Index (ARI)**.



Clustering measures for 2 random uniform labelings

60
80
100

- These metrics **require the knowledge of the ground truth classes** while almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

Examples:

- *Adjustment for chance in clustering performance evaluation*: Analysis of the impact of the dataset size on the value of clustering measures for random assignments.

Mathematical formulation

Homogeneity and completeness scores are formally given by:

$$h = 1 - \frac{H(C|K)}{H(C)}$$

$$c = 1 - \frac{H(K|C)}{H(K)}$$

where $H(C|K)$ is the **conditional entropy of the classes given the cluster assignments** and is given by:

$$H(C|K) = -\sum_{c=1}^{|C|}\sum_{k=1}^{|K|}\frac{n_{c,k}}{n}\cdot\log\left(\frac{n_{c,k}}{n_k}\right)$$

and $H(C)$ is the **entropy of the classes** and is given by:

$$H(C) = -\sum_{c=1}^{|C|}\frac{n_c}{n}\cdot\log\left(\frac{n_c}{n}\right)$$

with n the total number of samples, n_c and n_k the number of samples respectively belonging to class c and cluster k, and finally $n_{c,k}$ the number of samples from class c assigned to cluster k.

The **conditional entropy of clusters given class** $H(K|C)$ and the **entropy of clusters** $H(K)$ are defined in a symmetric manner.

Rosenberg and Hirschberg further define **V-measure** as the **harmonic mean of homogeneity and completeness**:

$$v = 2\cdot\frac{h\cdot c}{h+c}$$

Fowlkes-Mallows scores

The Fowlkes-Mallows index (`sklearn.metrics.fowlkes_mallows_score`) can be used when the ground truth class assignments of the samples is known. The Fowlkes-Mallows score FMI is defined as the geometric mean of the pairwise precision and recall:

$$\text{FMI} = \frac{\text{TP}}{\sqrt{(\text{TP}+\text{FP})(\text{TP}+\text{FN})}}$$

Where `TP` is the number of **True Positive** (i.e. the number of pair of points that belong to the same clusters in both the true labels and the predicted labels), `FP` is the number of **False Positive** (i.e. the number of pair of points that belong to the same clusters in the true labels and not in the predicted labels) and `FN` is the number of **False Negative** (i.e the number of pair of points that belongs in the same clusters in the predicted labels and not in the true labels).

The score ranges from 0 to 1. A high value indicates a good similarity between two clusters.

```
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]
```

```
>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
0.47140...
```

One can permute 0 and 1 in the predicted labels, rename 2 to 3 and get the same score:

```
>>> labels_pred = [1, 1, 0, 0, 3, 3]

>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
0.47140...
```

Perfect labeling is scored 1.0:

```
>>> labels_pred = labels_true[:]
>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
1.0
```

Bad (e.g. independent labelings) have zero scores:

```
>>> labels_true = [0, 1, 2, 0, 3, 4, 5, 1]
>>> labels_pred = [1, 1, 0, 0, 2, 2, 2, 2]
>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
0.0
```

Advantages

- **Random (uniform) label assignments have a FMI score close to 0.0** for any value of `n_clusters` and `n_samples` (which is not the case for raw Mutual Information or the V-measure for instance).
- **Upper-bounded at 1**: Values close to zero indicate two label assignments that are largely independent, while values close to one indicate significant agreement. Further, values of exactly 0 indicate **purely** independent label assignments and a FMI of exactly 1 indicates that the two label assignments are equal (with or without permutation).
- **No assumption is made on the cluster structure**: can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with "folded" shapes.

Drawbacks

- Contrary to inertia, **FMI-based measures require the knowledge of the ground truth classes** while almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

Silhouette Coefficient

If the ground truth labels are not known, evaluation must be performed using the model itself. The Silhouette Coefficient (*sklearn.metrics.silhouette_score*) is an example of such an evaluation, where a higher Silhouette Coefficient score relates to a model with better defined clusters. The Silhouette Coefficient is defined for each sample and is composed of two scores:

- **a**: The mean distance between a sample and all other points in the same class.
- **b**: The mean distance between a sample and all other points in the *next nearest cluster*.

The Silhouette Coefficient s for a single sample is then given as:

$$s = \frac{b - a}{max(a, b)}$$

The Silhouette Coefficient for a set of samples is given as the mean of the Silhouette Coefficient for each sample.

```
>>> from sklearn import metrics
>>> from sklearn.metrics import pairwise_distances
>>> from sklearn import datasets
>>> X, y = datasets.load_iris(return_X_y=True)
```

In normal usage, the Silhouette Coefficient is applied to the results of a cluster analysis.

```
>>> import numpy as np
>>> from sklearn.cluster import KMeans
>>> kmeans_model = KMeans(n_clusters=3, random_state=1).fit(X)
>>> labels = kmeans_model.labels_
>>> metrics.silhouette_score(X, labels, metric='euclidean')
0.55...
```

References

- Peter J. Rousseeuw (1987). "Silhouettes: a Graphical Aid to the Interpretation and Validation of Cluster Analysis". Computational and Applied Mathematics 20: 53–65. doi:10.1016/0377-0427(87)90125-7.

Advantages

- The score is bounded between -1 for incorrect clustering and +1 for highly dense clustering. Scores around zero indicate overlapping clusters.
- The score is higher when clusters are dense and well separated, which relates to a standard concept of a cluster.

Drawbacks

- The Silhouette Coefficient is generally higher for convex clusters than other concepts of clusters, such as density based clusters like those obtained through DBSCAN.

Examples:

- *Selecting the number of clusters with silhouette analysis on KMeans clustering* : In this example the silhouette analysis is used to choose an optimal value for n_clusters.

Calinski-Harabasz Index

If the ground truth labels are not known, the Calinski-Harabasz index (*sklearn.metrics.calinski_harabasz_score*) - also known as the Variance Ratio Criterion - can be used to evaluate the model, where a higher Calinski-Harabasz score relates to a model with better defined clusters.

The index is the ratio of the sum of between-clusters dispersion and of inter-cluster dispersion for all clusters (where dispersion is defined as the sum of distances squared):

```
>>> from sklearn import metrics
>>> from sklearn.metrics import pairwise_distances
>>> from sklearn import datasets
>>> X, y = datasets.load_iris(return_X_y=True)
```

In normal usage, the Calinski-Harabasz index is applied to the results of a cluster analysis:

```
>>> import numpy as np
>>> from sklearn.cluster import KMeans
>>> kmeans_model = KMeans(n_clusters=3, random_state=1).fit(X)
>>> labels = kmeans_model.labels_
>>> metrics.calinski_harabasz_score(X, labels)
561.62...
```

Advantages

- The score is higher when clusters are dense and well separated, which relates to a standard concept of a cluster.
- The score is fast to compute.

Drawbacks

- The Calinski-Harabasz index is generally higher for convex clusters than other concepts of clusters, such as density based clusters like those obtained through DBSCAN.

Mathematical formulation

For a set of data E of size n_E which has been clustered into k clusters, the Calinski-Harabasz score s is defined as the ratio of the between-clusters dispersion mean and the within-cluster dispersion:

$$s = \frac{\mathrm{tr}(B_k)}{\mathrm{tr}(W_k)} \times \frac{n_E - k}{k - 1}$$

where $\mathrm{tr}(B_k)$ is trace of the between group dispersion matrix and $\mathrm{tr}(W_k)$ is the trace of the within-cluster dispersion matrix defined by:

$$W_k = \sum_{q=1}^{k} \sum_{x \in C_q} (x - c_q)(x - c_q)^T$$

$$B_k = \sum_{q=1}^{k} n_q (c_q - c_E)(c_q - c_E)^T$$

with C_q the set of points in cluster q, c_q the center of cluster q, c_E the center of E, and n_q the number of points in cluster q.

References

- Caliński, T., & Harabasz, J. (1974). "A Dendrite Method for Cluster Analysis". Communications in Statistics-theory and Methods 3: 1-27. doi:10.1080/03610927408827101.

Davies-Bouldin Index

If the ground truth labels are not known, the Davies-Bouldin index (*sklearn.metrics.davies_bouldin_score*) can be used to evaluate the model, where a lower Davies-Bouldin index relates to a model with better separation between the clusters.

This index signifies the average 'similarity' between clusters, where the similarity is a measure that compares the distance between clusters with the size of the clusters themselves.

Zero is the lowest possible score. Values closer to zero indicate a better partition.

In normal usage, the Davies-Bouldin index is applied to the results of a cluster analysis as follows:

```
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> X = iris.data
>>> from sklearn.cluster import KMeans
>>> from sklearn.metrics import davies_bouldin_score
>>> kmeans = KMeans(n_clusters=3, random_state=1).fit(X)
>>> labels = kmeans.labels_
>>> davies_bouldin_score(X, labels)
0.6619...
```

Advantages

- The computation of Davies-Bouldin is simpler than that of Silhouette scores.
- The index is computed only quantities and features inherent to the dataset.

Drawbacks

- The Davies-Boulding index is generally higher for convex clusters than other concepts of clusters, such as density based clusters like those obtained from DBSCAN.
- The usage of centroid distance limits the distance metric to Euclidean space.

Mathematical formulation

The index is defined as the average similarity between each cluster C_i for $i = 1, ..., k$ and its most similar one C_j. In the context of this index, similarity is defined as a measure R_{ij} that trades off:

- s_i, the average distance between each point of cluster i and the centroid of that cluster – also know as cluster diameter.
- d_{ij}, the distance between cluster centroids i and j.

A simple choice to construct R_ij so that it is nonnegative and symmetric is:

$$R_{ij} = \frac{s_i + s_j}{d_{ij}}$$

Then the Davies-Bouldin index is defined as:

$$DB = \frac{1}{k} \sum_{i=1}^{k} \max_{i \neq j} R_{ij}$$

Contingency Matrix

Contingency matrix (`sklearn.metrics.cluster.contingency_matrix`) reports the intersection cardinality for every true/predicted cluster pair. The contingency matrix provides sufficient statistics for all clustering metrics where the samples are independent and identically distributed and one doesn't need to account for some instances not being clustered.

Here is an example:

```
>>> from sklearn.metrics.cluster import contingency_matrix
>>> x = ["a", "a", "a", "b", "b", "b"]
>>> y = [0, 0, 1, 1, 2, 2]
>>> contingency_matrix(x, y)
array([[2, 1, 0],
       [0, 1, 2]])
```

The first row of output array indicates that there are three samples whose true cluster is "a". Of them, two are in predicted cluster 0, one is in 1, and none is in 2. And the second row indicates that there are three samples whose true cluster is "b". Of them, none is in predicted cluster 0, one is in 1 and two are in 2.

A *confusion matrix* for classification is a square contingency matrix where the order of rows and columns correspond to a list of classes.

Advantages

- Allows to examine the spread of each true cluster across predicted clusters and vice versa.

- The contingency table calculated is typically utilized in the calculation of a similarity statistic (like the others listed in this document) between the two clusterings.

Drawbacks

- Contingency matrix is easy to interpret for a small number of clusters, but becomes very hard to interpret for a large number of clusters.
- It doesn't give a single metric to use as an objective for clustering optimisation.

References

- Wikipedia entry for contingency matrix

4.2.4 Biclustering

Biclustering can be performed with the module `sklearn.cluster.bicluster`. Biclustering algorithms simultaneously cluster rows and columns of a data matrix. These clusters of rows and columns are known as biclusters. Each determines a submatrix of the original data matrix with some desired properties.

For instance, given a matrix of shape `(10, 10)`, one possible bicluster with three rows and two columns induces a submatrix of shape `(3, 2)`:

```
>>> import numpy as np
>>> data = np.arange(100).reshape(10, 10)
>>> rows = np.array([0, 2, 3])[:, np.newaxis]
>>> columns = np.array([1, 2])
>>> data[rows, columns]
array([[ 1,  2],
       [21, 22],
       [31, 32]])
```

For visualization purposes, given a bicluster, the rows and columns of the data matrix may be rearranged to make the bicluster contiguous.

Algorithms differ in how they define biclusters. Some of the common types include:

- constant values, constant rows, or constant columns
- unusually high or low values
- submatrices with low variance
- correlated rows or columns

Algorithms also differ in how rows and columns may be assigned to biclusters, which leads to different bicluster structures. Block diagonal or checkerboard structures occur when rows and columns are divided into partitions.

If each row and each column belongs to exactly one bicluster, then rearranging the rows and columns of the data matrix reveals the biclusters on the diagonal. Here is an example of this structure where biclusters have higher average values than the other rows and columns:

In the checkerboard case, each row belongs to all column clusters, and each column belongs to all row clusters. Here is an example of this structure where the variance of the values within each bicluster is small:

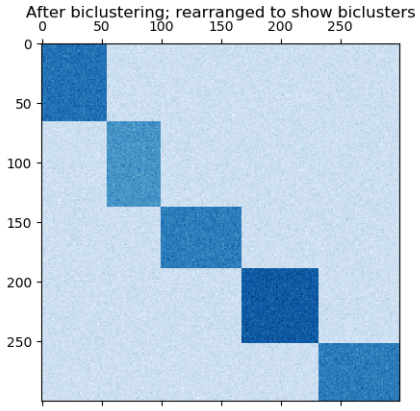

Fig. 5: An example of biclusters formed by partitioning rows and columns.

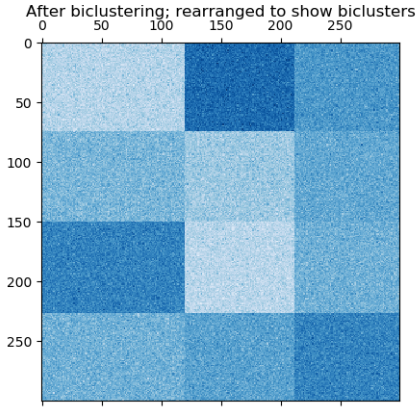

Fig. 6: An example of checkerboard biclusters.

After fitting a model, row and column cluster membership can be found in the `rows_` and `columns_` attributes. `rows_[i]` is a binary vector with nonzero entries corresponding to rows that belong to bicluster `i`. Similarly, `columns_[i]` indicates which columns belong to bicluster `i`.

Some models also have `row_labels_` and `column_labels_` attributes. These models partition the rows and columns, such as in the block diagonal and checkerboard bicluster structures.

Note: Biclustering has many other names in different fields including co-clustering, two-mode clustering, two-way clustering, block clustering, coupled two-way clustering, etc. The names of some algorithms, such as the Spectral Co-Clustering algorithm, reflect these alternate names.

Spectral Co-Clustering

The `SpectralCoclustering` algorithm finds biclusters with values higher than those in the corresponding other rows and columns. Each row and each column belongs to exactly one bicluster, so rearranging the rows and columns to make partitions contiguous reveals these high values along the diagonal:

Note: The algorithm treats the input data matrix as a bipartite graph: the rows and columns of the matrix correspond to the two sets of vertices, and each entry corresponds to an edge between a row and a column. The algorithm approximates the normalized cut of this graph to find heavy subgraphs.

Mathematical formulation

An approximate solution to the optimal normalized cut may be found via the generalized eigenvalue decomposition of the Laplacian of the graph. Usually this would mean working directly with the Laplacian matrix. If the original data matrix A has shape $m \times n$, the Laplacian matrix for the corresponding bipartite graph has shape $(m + n) \times (m + n)$. However, in this case it is possible to work directly with A, which is smaller and more efficient.

The input matrix A is preprocessed as follows:

$$A_n = R^{-1/2} A C^{-1/2}$$

Where R is the diagonal matrix with entry i equal to $\sum_j A_{ij}$ and C is the diagonal matrix with entry j equal to $\sum_i A_{ij}$.

The singular value decomposition, $A_n = U \Sigma V^\top$, provides the partitions of the rows and columns of A. A subset of the left singular vectors gives the row partitions, and a subset of the right singular vectors gives the column partitions.

The $\ell = \lceil \log_2 k \rceil$ singular vectors, starting from the second, provide the desired partitioning information. They are used to form the matrix Z:

$$Z = \begin{bmatrix} R^{-1/2} U \\ \\ C^{-1/2} V \end{bmatrix}$$

where the columns of U are $u_2, \ldots, u_{\ell+1}$, and similarly for V.

Then the rows of Z are clustered using *k-means*. The first `n_rows` labels provide the row partitioning, and the remaining `n_columns` labels provide the column partitioning.

Examples:

- *A demo of the Spectral Co-Clustering algorithm*: A simple example showing how to generate a data matrix with biclusters and apply this method to it.
- *Biclustering documents with the Spectral Co-clustering algorithm*: An example of finding biclusters in the twenty newsgroup dataset.

References:

- Dhillon, Inderjit S, 2001. Co-clustering documents and words using bipartite spectral graph partitioning.

Spectral Biclustering

The `SpectralBiclustering` algorithm assumes that the input data matrix has a hidden checkerboard structure. The rows and columns of a matrix with this structure may be partitioned so that the entries of any bicluster in the Cartesian product of row clusters and column clusters are approximately constant. For instance, if there are two row partitions and three column partitions, each row will belong to three biclusters, and each column will belong to two biclusters.

The algorithm partitions the rows and columns of a matrix so that a corresponding blockwise-constant checkerboard matrix provides a good approximation to the original matrix.

Mathematical formulation

The input matrix A is first normalized to make the checkerboard pattern more obvious. There are three possible methods:

1. *Independent row and column normalization*, as in Spectral Co-Clustering. This method makes the rows sum to a constant and the columns sum to a different constant.
2. **Bistochastization**: repeated row and column normalization until convergence. This method makes both rows and columns sum to the same constant.
3. **Log normalization**: the log of the data matrix is computed: $L = \log A$. Then the column mean $\overline{L_{i\cdot}}$, row mean $\overline{L_{\cdot j}}$, and overall mean $\overline{L_{\cdot\cdot}}$ of L are computed. The final matrix is computed according to the formula

$$K_{ij} = L_{ij} - \overline{L_{i\cdot}} - \overline{L_{\cdot j}} + \overline{L_{\cdot\cdot}}$$

After normalizing, the first few singular vectors are computed, just as in the Spectral Co-Clustering algorithm.

If log normalization was used, all the singular vectors are meaningful. However, if independent normalization or bistochastization were used, the first singular vectors, u_1 and v_1. are discarded. From now on, the "first" singular vectors refers to $u_2 \dots u_{p+1}$ and $v_2 \dots v_{p+1}$ except in the case of log normalization.

Given these singular vectors, they are ranked according to which can be best approximated by a piecewise-constant vector. The approximations for each vector are found using one-dimensional k-means and scored using the Euclidean distance. Some subset of the best left and right singular vector are selected. Next, the data is projected to this best subset of singular vectors and clustered.

For instance, if p singular vectors were calculated, the q best are found as described, where $q < p$. Let U be the matrix with columns the q best left singular vectors, and similarly V for the right. To partition the rows, the rows of A are projected to a q dimensional space: $A * V$. Treating the m rows of this $m \times q$ matrix as samples and clustering using k-means yields the row labels. Similarly, projecting the columns to $A^\top * U$ and clustering this $n \times q$ matrix yields the column labels.

Examples:

- *A demo of the Spectral Biclustering algorithm*: a simple example showing how to generate a checkerboard matrix and bicluster it.

Biclustering evaluation

There are two ways of evaluating a biclustering result: internal and external. Internal measures, such as cluster stability, rely only on the data and the result themselves. Currently there are no internal bicluster measures in scikit-learn. External measures refer to an external source of information, such as the true solution. When working with real data the true solution is usually unknown, but biclustering artificial data may be useful for evaluating algorithms precisely because the true solution is known.

To compare a set of found biclusters to the set of true biclusters, two similarity measures are needed: a similarity measure for individual biclusters, and a way to combine these individual similarities into an overall score.

To compare individual biclusters, several measures have been used. For now, only the Jaccard index is implemented:

$$J(A, B) = \frac{|A \cap B|}{|A| + |B| - |A \cap B|}$$

where A and B are biclusters, $|A \cap B|$ is the number of elements in their intersection. The Jaccard index achieves its minimum of 0 when the biclusters to not overlap at all and its maximum of 1 when they are identical.

Several methods have been developed to compare two sets of biclusters. For now, only `consensus_score` (Hochreiter et. al., 2010) is available:

1. Compute bicluster similarities for pairs of biclusters, one in each set, using the Jaccard index or a similar measure.
2. Assign biclusters from one set to another in a one-to-one fashion to maximize the sum of their similarities. This step is performed using the Hungarian algorithm.
3. The final sum of similarities is divided by the size of the larger set.

The minimum consensus score, 0, occurs when all pairs of biclusters are totally dissimilar. The maximum score, 1, occurs when both sets are identical.

4.2.5 Decomposing signals in components (matrix factorization problems)

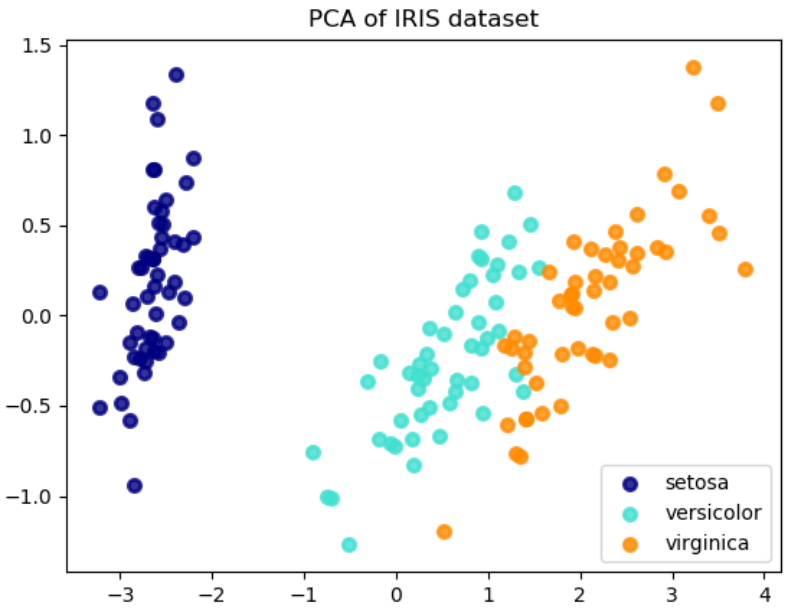
Principal component analysis (PCA)

Exact PCA and probabilistic interpretation

PCA is used to decompose a multivariate dataset in a set of successive orthogonal components that explain a maximum amount of the variance. In scikit-learn, `PCA` is implemented as a *transformer* object that learns n components in its `fit` method, and can be used on new data to project it on these components.

PCA centers but does not scale the input data for each feature before applying the SVD. The optional parameter `whiten=True` makes it possible to project the data onto the singular space while scaling each component to unit variance. This is often useful if the models down-stream make strong assumptions on the isotropy of the signal: this is for example the case for Support Vector Machines with the RBF kernel and the K-Means clustering algorithm.

Below is an example of the iris dataset, which is comprised of 4 features, projected on the 2 dimensions that explain most variance:



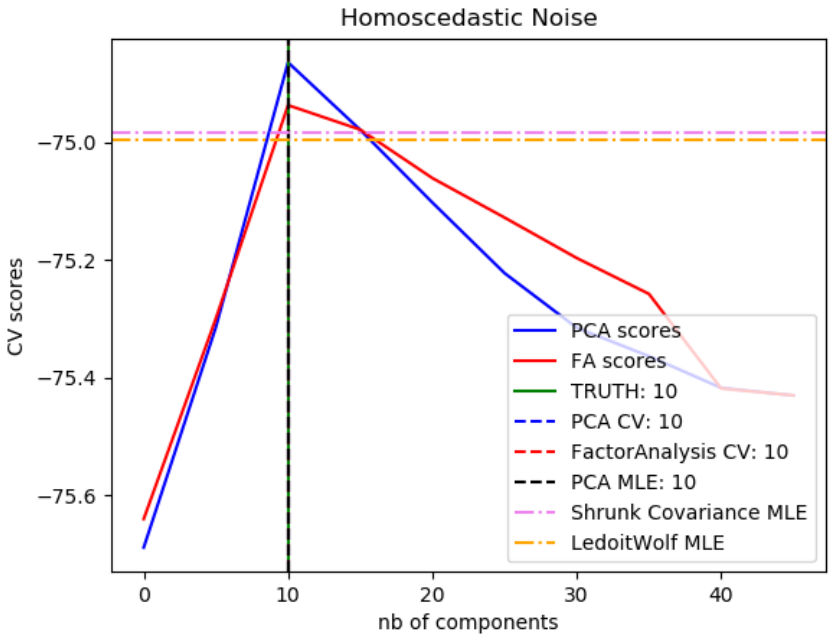
The `PCA` object also provides a probabilistic interpretation of the PCA that can give a likelihood of data based on the amount of variance it explains. As such it implements a *score* method that can be used in cross-validation:

Examples:

- *Comparison of LDA and PCA 2D projection of Iris dataset*
- *Model selection with Probabilistic PCA and Factor Analysis (FA)*

Incremental PCA

The `PCA` object is very useful, but has certain limitations for large datasets. The biggest limitation is that `PCA` only supports batch processing, which means all of the data to be processed must fit in main memory. The `IncrementalPCA` object uses a different form of processing and allows for partial computations which almost exactly match the results of `PCA` while processing the data in a minibatch fashion. `IncrementalPCA` makes it possible to implement out-of-core Principal Component Analysis either by:



- Using its `partial_fit` method on chunks of data fetched sequentially from the local hard drive or a network database.
- Calling its fit method on a sparse matrix or a memory mapped file using `numpy.memmap`.

IncrementalPCA only stores estimates of component and noise variances, in order update `explained_variance_ratio_` incrementally. This is why memory usage depends on the number of samples per batch, rather than the number of samples to be processed in the dataset.

As in *PCA*, *IncrementalPCA* centers but does not scale the input data for each feature before applying the SVD.

Examples:

- *Incremental PCA*

PCA using randomized SVD

It is often interesting to project data to a lower-dimensional space that preserves most of the variance, by dropping the singular vector of components associated with lower singular values.

For instance, if we work with 64x64 pixel gray-level pictures for face recognition, the dimensionality of the data is 4096 and it is slow to train an RBF support vector machine on such wide data. Furthermore we know that the intrinsic dimensionality of the data is much lower than 4096 since all pictures of human faces look somewhat alike. The samples lie on a manifold of much lower dimension (say around 200 for instance). The PCA algorithm can be used to linearly transform the data while both reducing the dimensionality and preserve most of the explained variance at the same time.

The class *PCA* used with the optional parameter `svd_solver='randomized'` is very useful in that case: since we are going to drop most of the singular vectors it is much more efficient to limit the computation to an approximated estimate of the singular vectors we will keep to actually perform the transform.

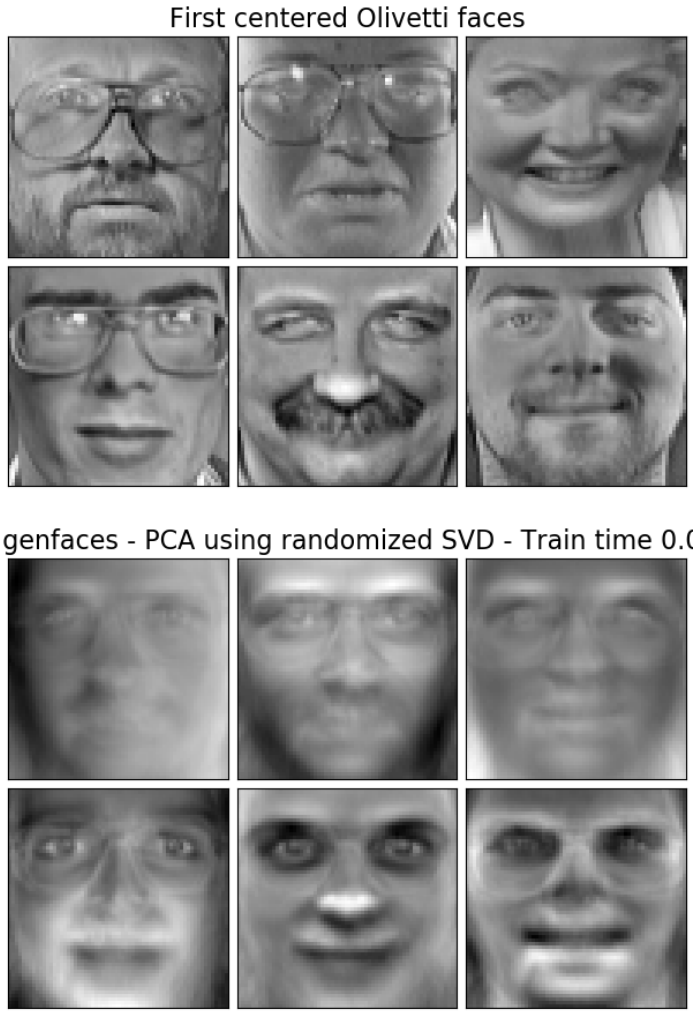
For instance, the following shows 16 sample portraits (centered around 0.0) from the Olivetti dataset. On the right hand side are the first 16 singular vectors reshaped as portraits. Since we only require the top 16 singular vectors of a dataset with size $n_{samples} = 400$ and $n_{features} = 64 \times 64 = 4096$, the computation time is less than 1s:



If we note $n_{\max} = \max(n_{\text{samples}}, n_{\text{features}})$ and $n_{\min} = \min(n_{\text{samples}}, n_{\text{features}})$, the time complexity of the randomized `PCA` is $O(n_{\max}^2 \cdot n_{\text{components}})$ instead of $O(n_{\max}^2 \cdot n_{\min})$ for the exact method implemented in `PCA`.

The memory footprint of randomized `PCA` is also proportional to $2 \cdot n_{\max} \cdot n_{\text{components}}$ instead of $n_{\max} \cdot n_{\min}$ for the exact method.

Note: the implementation of `inverse_transform` in `PCA` with `svd_solver='randomized'` is not the exact inverse transform of `transform` even when `whiten=False` (default).

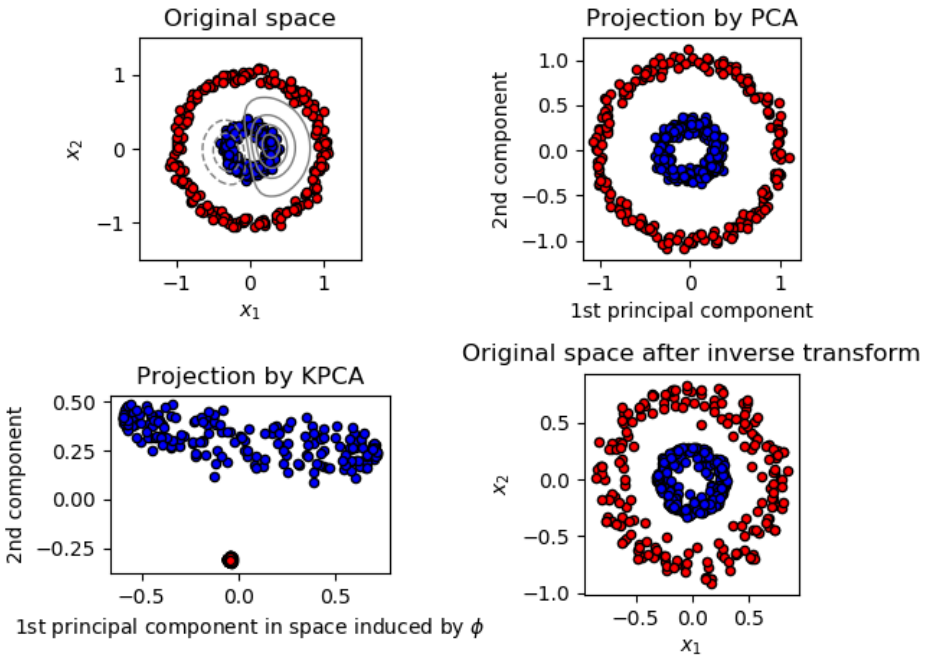
- "Finding structure with randomness: Stochastic algorithms for constructing approximate matrix decompositions" Halko, et al., 2009

Kernel PCA

`KernelPCA` is an extension of PCA which achieves non-linear dimensionality reduction through the use of kernels (see *Pairwise metrics, Affinities and Kernels*). It has many applications including denoising, compression and structured prediction (kernel dependency estimation). `KernelPCA` supports both `transform` and `inverse_transform`.



Examples:

- *Kernel PCA*

Sparse principal components analysis (SparsePCA and MiniBatchSparsePCA)

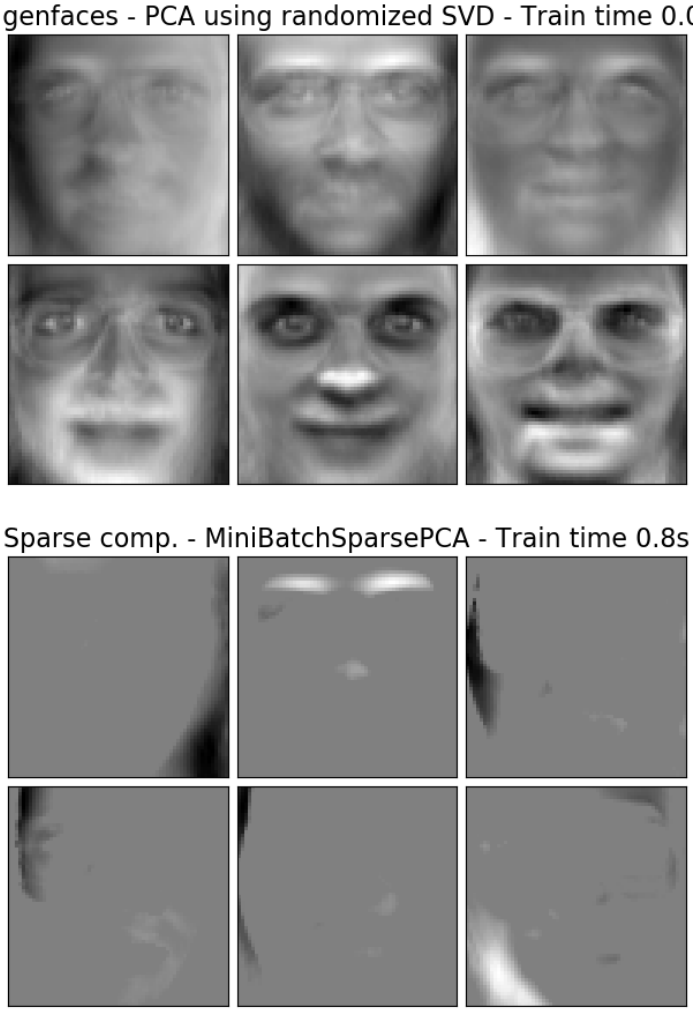
`SparsePCA` is a variant of PCA, with the goal of extracting the set of sparse components that best reconstruct the data.

Mini-batch sparse PCA (`MiniBatchSparsePCA`) is a variant of `SparsePCA` that is faster but less accurate. The increased speed is reached by iterating over small chunks of the set of features, for a given number of iterations.

Principal component analysis (`PCA`) has the disadvantage that the components extracted by this method have exclusively dense expressions, i.e. they have non-zero coefficients when expressed as linear combinations of the original variables. This can make interpretation difficult. In many cases, the real underlying components can be more naturally imagined as sparse vectors; for example in face recognition, components might naturally map to parts of faces.

Sparse principal components yields a more parsimonious, interpretable representation, clearly emphasizing which of the original features contribute to the differences between samples.

The following example illustrates 16 components extracted using sparse PCA from the Olivetti faces dataset. It can be seen how the regularization term induces many zeros. Furthermore, the natural structure of the data causes the non-zero coefficients to be vertically adjacent. The model does not enforce this mathematically: each component is a vector $h \in \mathbf{R}^{4096}$, and there is no notion of vertical adjacency except during the human-friendly visualization as 64x64 pixel images. The fact that the components shown below appear local is the effect of the inherent structure of the data, which makes such local patterns minimize reconstruction error. There exist sparsity-inducing norms that take into account adjacency and different kinds of structure; see [Jen09] for a review of such methods. For more details on how to use Sparse PCA, see the Examples section, below.



Note that there are many different formulations for the Sparse PCA problem. The one implemented here is based on [Mrl09] . The optimization problem solved is a PCA problem (dictionary learning) with an ℓ_1 penalty on the components:

$$(U^*, V^*) = \arg\min_{U,V} \frac{1}{2}||X - UV||_2^2 + \alpha||V||_1$$
$$\text{subject to } ||U_k||_2 = 1 \text{ for all } 0 \leq k < n_{components}$$

The sparsity-inducing ℓ_1 norm also prevents learning components from noise when few training samples are available. The degree of penalization (and thus sparsity) can be adjusted through the hyperparameter `alpha`. Small values lead

to a gently regularized factorization, while larger values shrink many coefficients to zero.

Note: While in the spirit of an online algorithm, the class `MiniBatchSparsePCA` does not implement `partial_fit` because the algorithm is online along the features direction, not the samples direction.

Examples:

- *Faces dataset decompositions*

Truncated singular value decomposition and latent semantic analysis

`TruncatedSVD` implements a variant of singular value decomposition (SVD) that only computes the k largest singular values, where k is a user-specified parameter.

When truncated SVD is applied to term-document matrices (as returned by `CountVectorizer` or `TfidfVectorizer`), this transformation is known as latent semantic analysis (LSA), because it transforms such matrices to a "semantic" space of low dimensionality. In particular, LSA is known to combat the effects of synonymy and polysemy (both of which roughly mean there are multiple meanings per word), which cause term-document matrices to be overly sparse and exhibit poor similarity under measures such as cosine similarity.

Note: LSA is also known as latent semantic indexing, LSI, though strictly that refers to its use in persistent indexes for information retrieval purposes.

Mathematically, truncated SVD applied to training samples X produces a low-rank approximation X:

$$X \approx X_k = U_k \Sigma_k V_k^\top$$

After this operation, $U_k \Sigma_k^\top$ is the transformed training set with k features (called `n_components` in the API).

To also transform a test set X, we multiply it with V_k:

$$X' = X V_k$$

Note: Most treatments of LSA in the natural language processing (NLP) and information retrieval (IR) literature swap the axes of the matrix X so that it has shape `n_features` × `n_samples`. We present LSA in a different way that matches the scikit-learn API better, but the singular values found are the same.

`TruncatedSVD` is very similar to `PCA`, but differs in that it works on sample matrices X directly instead of their covariance matrices. When the columnwise (per-feature) means of X are subtracted from the feature values, truncated SVD on the resulting matrix is equivalent to PCA. In practical terms, this means that the `TruncatedSVD` transformer accepts `scipy.sparse` matrices without the need to densify them, as densifying may fill up memory even for medium-sized document collections.

While the `TruncatedSVD` transformer works with any (sparse) feature matrix, using it on tf–idf matrices is recommended over raw frequency counts in an LSA/document processing setting. In particular, sublinear scaling and inverse

document frequency should be turned on (`sublinear_tf=True, use_idf=True`) to bring the feature values closer to a Gaussian distribution, compensating for LSA's erroneous assumptions about textual data.

Examples:

- *Clustering text documents using k-means*

Dictionary Learning

Sparse coding with a precomputed dictionary

The `SparseCoder` object is an estimator that can be used to transform signals into sparse linear combination of atoms from a fixed, precomputed dictionary such as a discrete wavelet basis. This object therefore does not implement a `fit` method. The transformation amounts to a sparse coding problem: finding a representation of the data as a linear combination of as few dictionary atoms as possible. All variations of dictionary learning implement the following transform methods, controllable via the `transform_method` initialization parameter:

- Orthogonal matching pursuit (*Orthogonal Matching Pursuit (OMP)*)
- Least-angle regression (*Least Angle Regression*)
- Lasso computed by least-angle regression
- Lasso using coordinate descent (*Lasso*)
- Thresholding

Thresholding is very fast but it does not yield accurate reconstructions. They have been shown useful in literature for classification tasks. For image reconstruction tasks, orthogonal matching pursuit yields the most accurate, unbiased reconstruction.

The dictionary learning objects offer, via the `split_code` parameter, the possibility to separate the positive and negative values in the results of sparse coding. This is useful when dictionary learning is used for extracting features that will be used for supervised learning, because it allows the learning algorithm to assign different weights to negative loadings of a particular atom, from to the corresponding positive loading.

The split code for a single sample has length `2 * n_components` and is constructed using the following rule: First, the regular code of length `n_components` is computed. Then, the first `n_components` entries of the `split_code` are filled with the positive part of the regular code vector. The second half of the split code is filled with the negative part of the code vector, only with a positive sign. Therefore, the split_code is non-negative.

Examples:

- *Sparse coding with a precomputed dictionary*

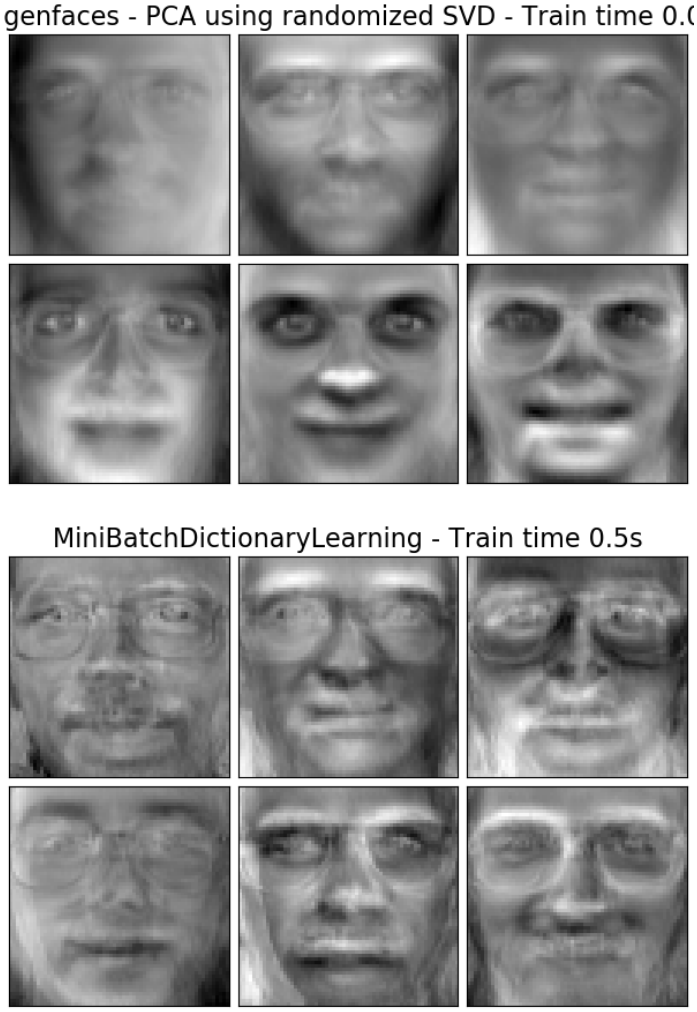
Generic dictionary learning

Dictionary learning (`DictionaryLearning`) is a matrix factorization problem that amounts to finding a (usually overcomplete) dictionary that will perform well at sparsely encoding the fitted data.

Representing data as sparse combinations of atoms from an overcomplete dictionary is suggested to be the way the mammalian primary visual cortex works. Consequently, dictionary learning applied on image patches has been shown to give good results in image processing tasks such as image completion, inpainting and denoising, as well as for supervised recognition tasks.

Dictionary learning is an optimization problem solved by alternatively updating the sparse code, as a solution to multiple Lasso problems, considering the dictionary fixed, and then updating the dictionary to best fit the sparse code.

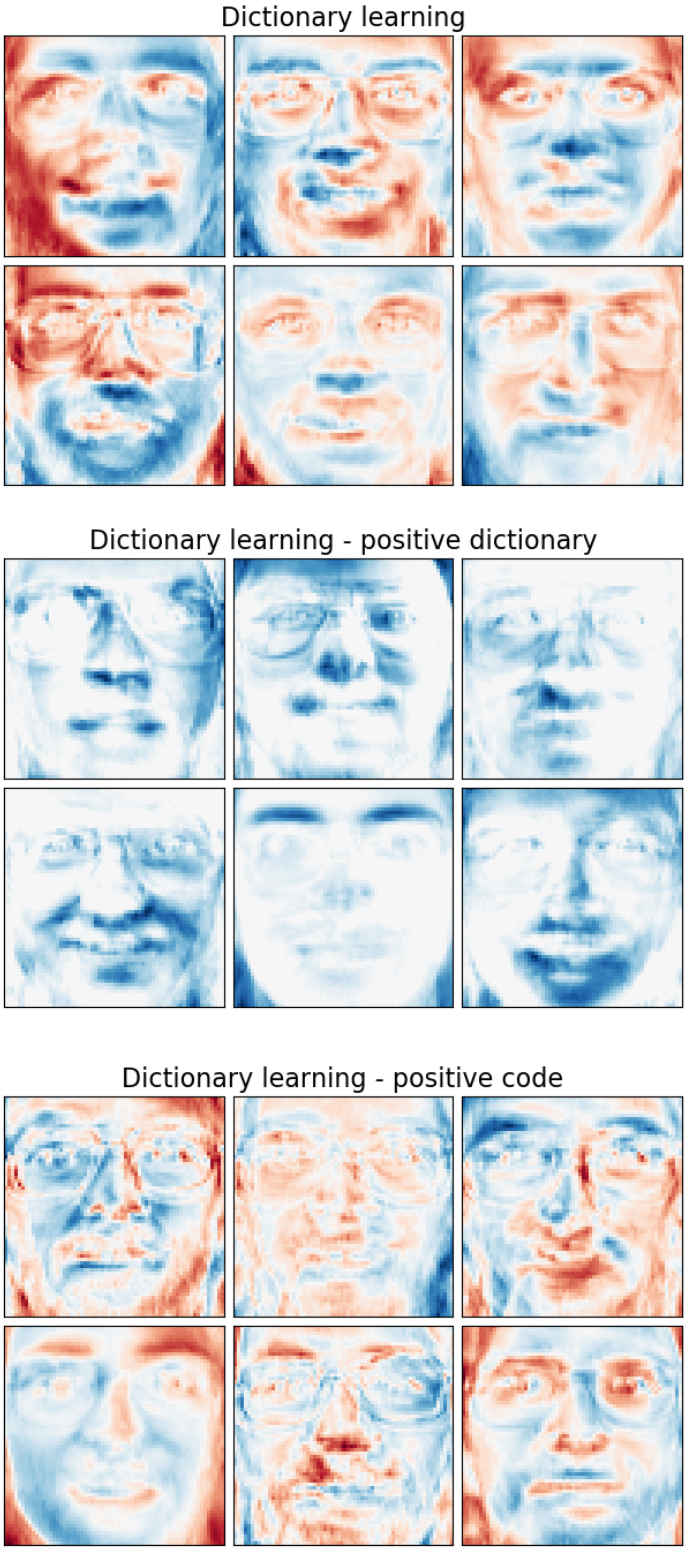
$$(U^*, V^*) = \arg\min_{U,V} \frac{1}{2}||X - UV||_2^2 + \alpha||U||_1$$
$$\text{subject to } ||V_k||_2 = 1 \text{ for all } 0 \leq k < n_{\text{atoms}}$$

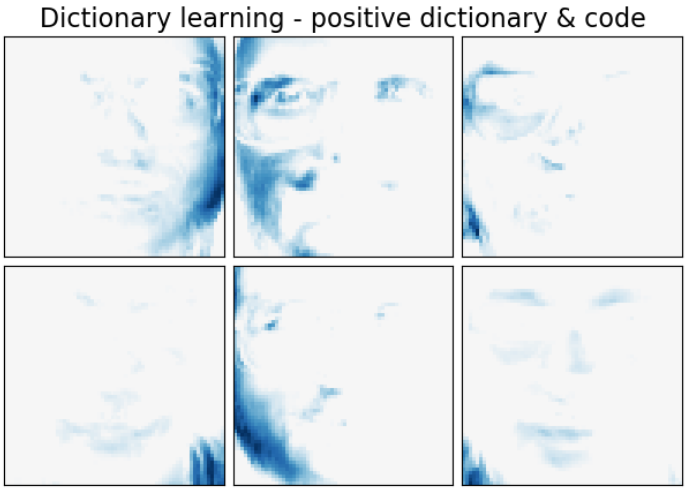


After using such a procedure to fit the dictionary, the transform is simply a sparse coding step that shares the same implementation with all dictionary learning objects (see *Sparse coding with a precomputed dictionary*).

It is also possible to constrain the dictionary and/or code to be positive to match constraints that may be present in the data. Below are the faces with different positivity constraints applied. Red indicates negative values, blue indicates

positive values, and white represents zeros.





The following image shows how a dictionary learned from 4x4 pixel image patches extracted from part of the image of a raccoon face looks like.

Examples:

- *Image denoising using dictionary learning*

References:

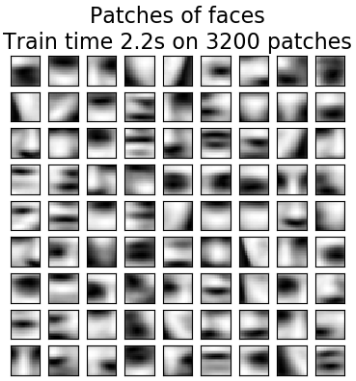
- "Online dictionary learning for sparse coding" J. Mairal, F. Bach, J. Ponce, G. Sapiro, 2009

Mini-batch dictionary learning

`MiniBatchDictionaryLearning` implements a faster, but less accurate version of the dictionary learning algorithm that is better suited for large datasets.

By default, `MiniBatchDictionaryLearning` divides the data into mini-batches and optimizes in an online manner by cycling over the mini-batches for the specified number of iterations. However, at the moment it does not implement a stopping condition.

The estimator also implements `partial_fit`, which updates the dictionary by iterating only once over a mini-batch. This can be used for online learning when the data is not readily available from the start, or for when the data does not fit into the memory.



Clustering for dictionary learning

Note that when using dictionary learning to extract a representation (e.g. for sparse coding) clustering can be a good proxy to learn the dictionary. For instance the `MiniBatchKMeans` estimator is computationally efficient and implements on-line learning with a `partial_fit` method.

Example: *Online learning of a dictionary of parts of faces*

Factor Analysis

In unsupervised learning we only have a dataset $X = \{x_1, x_2, \ldots, x_n\}$. How can this dataset be described mathematically? A very simple `continuous latent variable` model for X is

$$x_i = W h_i + \mu + \epsilon$$

The vector h_i is called "latent" because it is unobserved. ϵ is considered a noise term distributed according to a Gaussian with mean 0 and covariance Ψ (i.e. $\epsilon \sim \mathcal{N}(0, \Psi)$), μ is some arbitrary offset vector. Such a model is called "generative" as it describes how x_i is generated from h_i. If we use all the x_i's as columns to form a matrix $\mathbf{X}$ and all the h_i's as columns of a matrix $\mathbf{H}$ then we can write (with suitably defined $\mathbf{M}$ and $\mathbf{E}$):

$$\mathbf{X} = W\mathbf{H} + \mathbf{M} + \mathbf{E}$$

In other words, we *decomposed* matrix $\mathbf{X}$.

If h_i is given, the above equation automatically implies the following probabilistic interpretation:

$$p(x_i|h_i) = \mathcal{N}(W h_i + \mu, \Psi)$$

For a complete probabilistic model we also need a prior distribution for the latent variable h. The most straightforward assumption (based on the nice properties of the Gaussian distribution) is $h \sim \mathcal{N}(0, \mathbf{I})$. This yields a Gaussian as the marginal distribution of x:

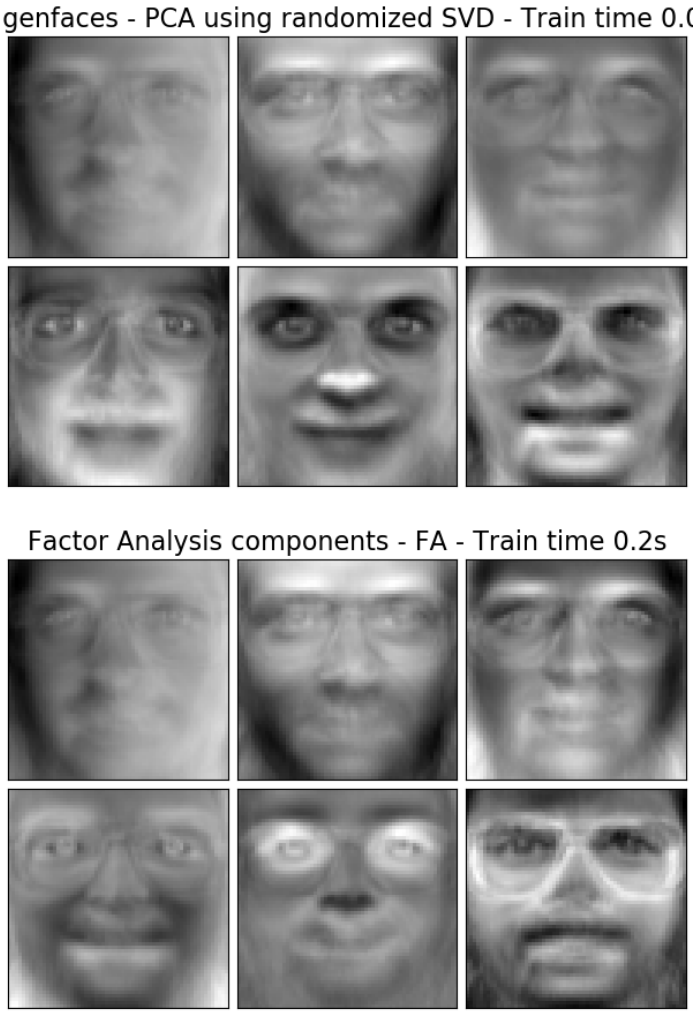
$$p(x) = \mathcal{N}(\mu, W W^T + \Psi)$$

Now, without any further assumptions the idea of having a latent variable h would be superfluous – x can be completely modelled with a mean and a covariance. We need to impose some more specific structure on one of these two parameters. A simple additional assumption regards the structure of the error covariance Ψ:

- $\Psi = \sigma^2\mathbf{I}$: This assumption leads to the probabilistic model of `PCA`.
- $\Psi = \mathrm{diag}(\psi_1, \psi_2, \ldots, \psi_n)$: This model is called `FactorAnalysis`, a classical statistical model. The matrix W is sometimes called the "factor loading matrix".

Both models essentially estimate a Gaussian with a low-rank covariance matrix. Because both models are probabilistic they can be integrated in more complex models, e.g. Mixture of Factor Analysers. One gets very different models (e.g. `FastICA`) if non-Gaussian priors on the latent variables are assumed.

Factor analysis *can* produce similar components (the columns of its loading matrix) to `PCA`. However, one can not make any general statements about these components (e.g. whether they are orthogonal):



The main advantage for Factor Analysis over `PCA` is that it can model the variance in every direction of the input space independently (heteroscedastic noise):

This allows better model selection than probabilistic PCA in the presence of heteroscedastic noise:

Examples:

- *Model selection with Probabilistic PCA and Factor Analysis (FA)*

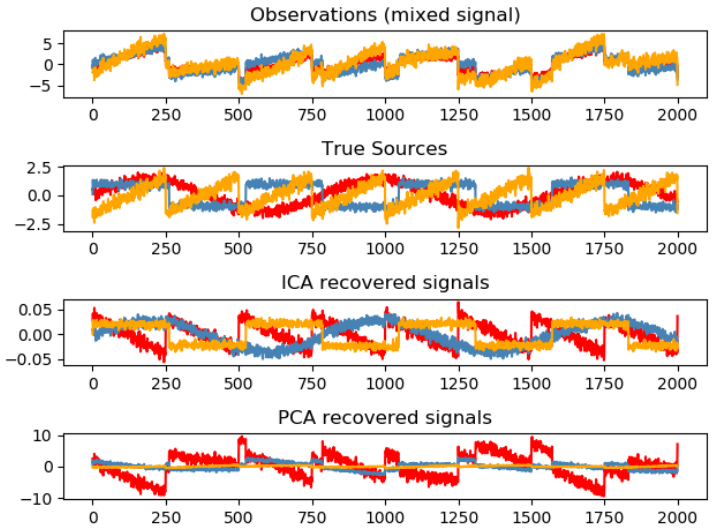
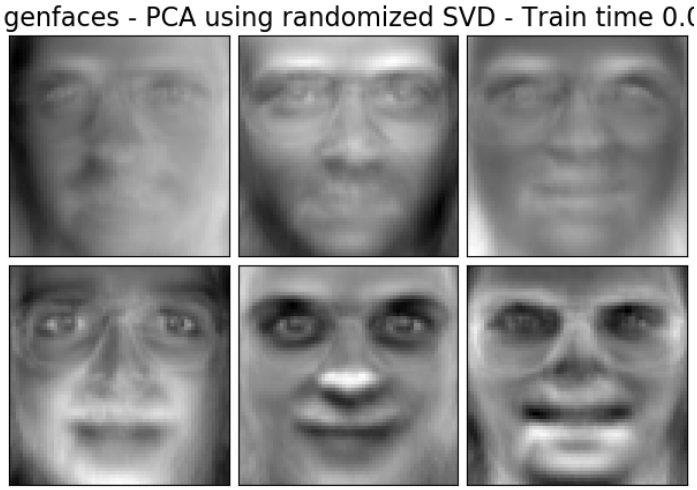
Independent component analysis (ICA)

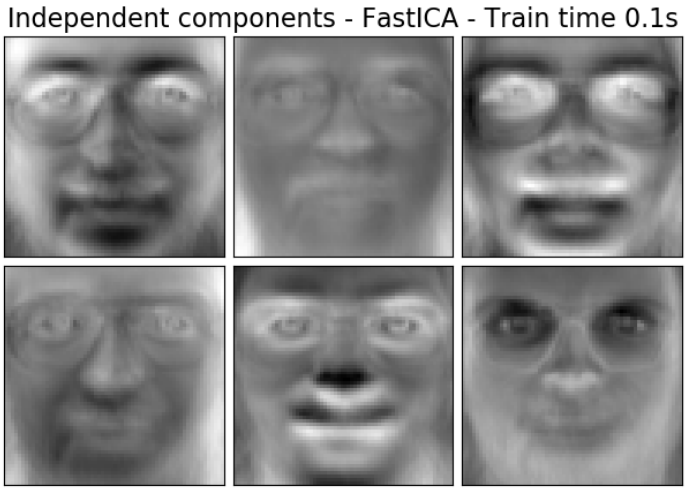
Independent component analysis separates a multivariate signal into additive subcomponents that are maximally independent. It is implemented in scikit-learn using the *Fast ICA* algorithm. Typically, ICA is not used for reducing dimensionality but for separating superimposed signals. Since the ICA model does not include a noise term, for the model to be correct, whitening must be applied. This can be done internally using the whiten argument or manually using one of the PCA variants.

It is classically used to separate mixed signals (a problem known as *blind source separation*), as in the example below:



ICA can also be used as yet another non linear decomposition that finds components with some sparsity:





Examples:

- *Blind source separation using FastICA*
- *FastICA on 2D point clouds*
- *Faces dataset decompositions*

Non-negative matrix factorization (NMF or NNMF)

NMF with the Frobenius norm

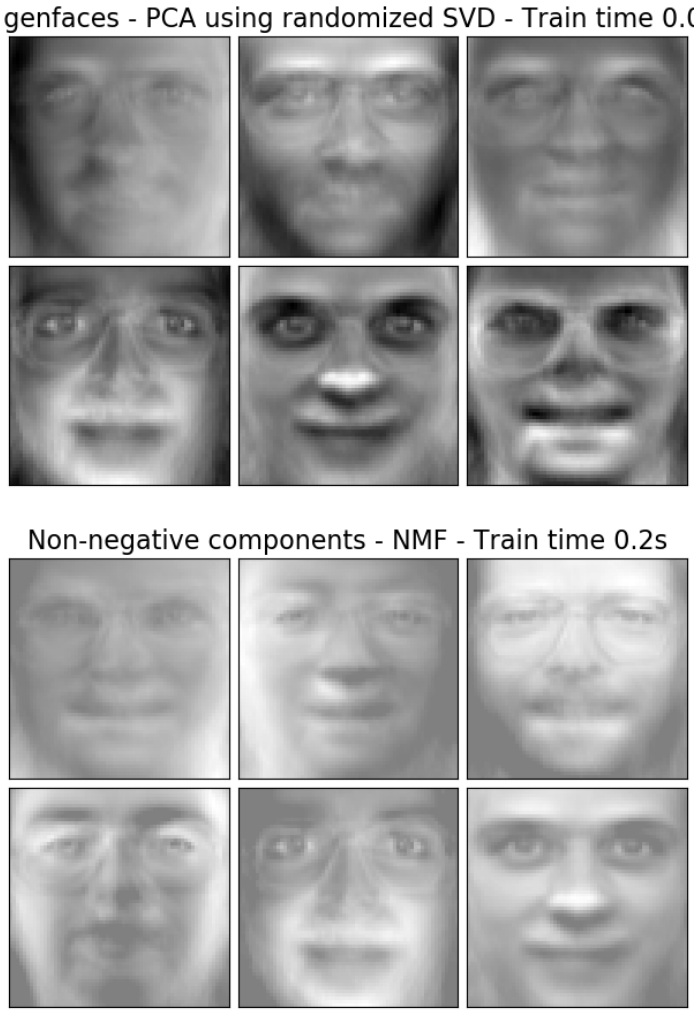
NMF[1] is an alternative approach to decomposition that assumes that the data and the components are non-negative. *NMF* can be plugged in instead of *PCA* or its variants, in the cases where the data matrix does not contain negative values. It finds a decomposition of samples X into two matrices W and H of non-negative elements, by optimizing the distance d between X and the matrix product WH. The most widely used distance function is the squared Frobenius norm, which is an obvious extension of the Euclidean norm to matrices:

$$d_{\mathrm{Fro}}(X, Y) = \frac{1}{2}||X - Y||_{\mathrm{Fro}}^2 = \frac{1}{2}\sum_{i,j}(X_{ij} - Y_{ij})^2$$

Unlike *PCA*, the representation of a vector is obtained in an additive fashion, by superimposing the components, without subtracting. Such additive models are efficient for representing images and text.

It has been observed in [Hoyer, 2004][2] that, when carefully constrained, *NMF* can produce a parts-based representation of the dataset, resulting in interpretable models. The following example displays 16 sparse components found by *NMF* from the images in the Olivetti faces dataset, in comparison with the PCA eigenfaces.

[1] "Learning the parts of objects by non-negative matrix factorization" D. Lee, S. Seung, 1999
[2] "Non-negative Matrix Factorization with Sparseness Constraints" P. Hoyer, 2004



The `init` attribute determines the initialization method applied, which has a great impact on the performance of the method. *NMF* implements the method Nonnegative Double Singular Value Decomposition. NNDSVD[4] is based on two SVD processes, one approximating the data matrix, the other approximating positive sections of the resulting partial SVD factors utilizing an algebraic property of unit rank matrices. The basic NNDSVD algorithm is better fit for sparse factorization. Its variants NNDSVDa (in which all zeros are set equal to the mean of all elements of the data), and NNDSVDar (in which the zeros are set to random perturbations less than the mean of the data divided by 100) are recommended in the dense case.

Note that the Multiplicative Update ('mu') solver cannot update zeros present in the initialization, so it leads to poorer results when used jointly with the basic NNDSVD algorithm which introduces a lot of zeros; in this case, NNDSVDa or NNDSVDar should be preferred.

NMF can also be initialized with correctly scaled random non-negative matrices by setting `init="random"`. An integer seed or a `RandomState` can also be passed to `random_state` to control reproducibility.

In *NMF*, L1 and L2 priors can be added to the loss function in order to regularize the model. The L2 prior uses the Frobenius norm, while the L1 prior uses an elementwise L1 norm. As in `ElasticNet`, we control the combination of L1 and L2 with the `l1_ratio` (ρ) parameter, and the intensity of the regularization with the `alpha` (α) parameter. Then the priors terms are:

$$\alpha\rho||W||_1 + \alpha\rho||H||_1 + \frac{\alpha(1-\rho)}{2}||W||_{\text{Fro}}^2 + \frac{\alpha(1-\rho)}{2}||H||_{\text{Fro}}^2$$

[4] "SVD based initialization: A head start for nonnegative matrix factorization" C. Boutsidis, E. Gallopoulos, 2008

and the regularized objective function is:

$$d_{\text{Fro}}(X, WH) + \alpha\rho||W||_1 + \alpha\rho||H||_1 + \frac{\alpha(1-\rho)}{2}||W||^2_{\text{Fro}} + \frac{\alpha(1-\rho)}{2}||H||^2_{\text{Fro}}$$

NMF regularizes both W and H. The public function *non_negative_factorization* allows a finer control through the `regularization` attribute, and may regularize only W, only H, or both.

NMF with a beta-divergence

As described previously, the most widely used distance function is the squared Frobenius norm, which is an obvious extension of the Euclidean norm to matrices:

$$d_{\text{Fro}}(X, Y) = \frac{1}{2}||X - Y||^2_{Fro} = \frac{1}{2}\sum_{i,j}(X_{ij} - Y_{ij})^2$$

Other distance functions can be used in NMF as, for example, the (generalized) Kullback-Leibler (KL) divergence, also referred as I-divergence:

$$d_{KL}(X, Y) = \sum_{i,j}(X_{ij}\log(\frac{X_{ij}}{Y_{ij}}) - X_{ij} + Y_{ij})$$

Or, the Itakura-Saito (IS) divergence:

$$d_{IS}(X, Y) = \sum_{i,j}(\frac{X_{ij}}{Y_{ij}} - \log(\frac{X_{ij}}{Y_{ij}}) - 1)$$

These three distances are special cases of the beta-divergence family, with $\beta = 2, 1, 0$ respectively[6]. The beta-divergence are defined by :

$$d_{\beta}(X, Y) = \sum_{i,j}\frac{1}{\beta(\beta-1)}(X_{ij}^{\beta} + (\beta-1)Y_{ij}^{\beta} - \beta X_{ij}Y_{ij}^{\beta-1})$$

Note that this definition is not valid if $\beta \in (0; 1)$, yet it can be continuously extended to the definitions of d_{KL} and d_{IS} respectively.

NMF implements two solvers, using Coordinate Descent ('cd')[5], and Multiplicative Update ('mu')[6]. The 'mu' solver can optimize every beta-divergence, including of course the Frobenius norm ($\beta = 2$), the (generalized) Kullback-Leibler divergence ($\beta = 1$) and the Itakura-Saito divergence ($\beta = 0$). Note that for $\beta \in (1; 2)$, the 'mu' solver is significantly faster than for other values of β. Note also that with a negative (or 0, i.e. 'itakura-saito') β, the input matrix cannot contain zero values.

The 'cd' solver can only optimize the Frobenius norm. Due to the underlying non-convexity of NMF, the different solvers may converge to different minima, even when optimizing the same distance function.

NMF is best used with the `fit_transform` method, which returns the matrix W. The matrix H is stored into the fitted model in the `components_` attribute; the method `transform` will decompose a new matrix X_new based on these stored components:

```
>>> import numpy as np
>>> X = np.array([[1, 1], [2, 1], [3, 1.2], [4, 1], [5, 0.8], [6, 1]])
>>> from sklearn.decomposition import NMF
```

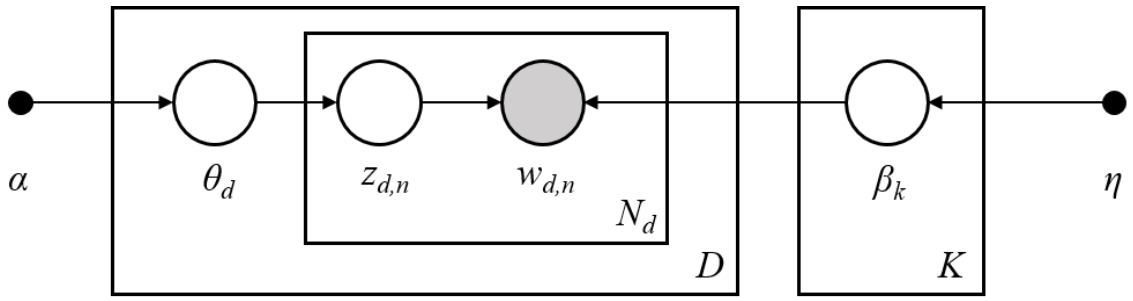
Latent Dirichlet Allocation (LDA)

Latent Dirichlet Allocation is a generative probabilistic model for collections of discrete dataset such as text corpora. It is also a topic model that is used for discovering abstract topics from a collection of documents.

The graphical model of LDA is a three-level generative model:



Note on notations presented in the graphical model above, which can be found in Hoffman et al. (2013):

- The corpus is a collection of D documents.
- A document is a sequence of N words.
- There are K topics in the corpus.
- The boxes represent repeated sampling.

In the graphical model, each node is a random variable and has a role in the generative process. A shaded node indicates an observed variable and an unshaded node indicates a hidden (latent) variable. In this case, words in the corpus are the only data that we observe. The latent variables determine the random mixture of topics in the corpus and the distribution of words in the documents. The goal of LDA is to use the observed words to infer the hidden topic structure.

When modeling text corpora, the model assumes the following generative process for a corpus with D documents and K topics, with K corresponding to `n_components` in the API:

1. For each topic $k \in K$, draw $\beta_k \sim \text{Dirichlet}(\eta)$. This provides a distribution over the words, i.e. the probability of a word appearing in topic k. η corresponds to `topic_word_prior`.
2. For each document $d \in D$, draw the topic proportions $\theta_d \sim \text{Dirichlet}(\alpha)$. α corresponds to `doc_topic_prior`.
3. For each word i in document d:

a. Draw the topic assignment $z_{di} \sim \text{Multinomial}(\theta_d)$

b. Draw the observed word $w_{ij} \sim \text{Multinomial}(\beta_{z_{di}})$

For parameter estimation, the posterior distribution is:

$$p(z, \theta, \beta | w, \alpha, \eta) = \frac{p(z, \theta, \beta | \alpha, \eta)}{p(w | \alpha, \eta)}$$

Since the posterior is intractable, variational Bayesian method uses a simpler distribution $q(z, \theta, \beta | \lambda, \phi, \gamma)$ to approximate it, and those variational parameters λ, ϕ, γ are optimized to maximize the Evidence Lower Bound (ELBO):

$$\log\ P(w | \alpha, \eta) \geq L(w, \phi, \gamma, \lambda) \stackrel{\triangle}{=} E_q[\log\ p(w, z, \theta, \beta | \alpha, \eta)] - E_q[\log\ q(z, \theta, \beta)]$$

Maximizing ELBO is equivalent to minimizing the Kullback-Leibler(KL) divergence between $q(z, \theta, \beta)$ and the true posterior $p(z, \theta, \beta | w, \alpha, \eta)$.

`LatentDirichletAllocation` implements the online variational Bayes algorithm and supports both online and batch update methods. While the batch method updates variational variables after each full pass through the data, the online method updates variational variables from mini-batch data points.

Note: Although the online method is guaranteed to converge to a local optimum point, the quality of the optimum point and the speed of convergence may depend on mini-batch size and attributes related to learning rate setting.

When *LatentDirichletAllocation* is applied on a "document-term" matrix, the matrix will be decomposed into a "topic-term" matrix and a "document-topic" matrix. While "topic-term" matrix is stored as `components_` in the model, "document-topic" matrix can be calculated from `transform` method.

LatentDirichletAllocation also implements `partial_fit` method. This is used when data can be fetched sequentially.

4.2.6 Covariance estimation

Many statistical problems require the estimation of a population's covariance matrix, which can be seen as an estimation of data set scatter plot shape. Most of the time, such an estimation has to be done on a sample whose properties (size, structure, homogeneity) have a large influence on the estimation's quality. The *sklearn.covariance* package provides tools for accurately estimating a population's covariance matrix under various settings.

We assume that the observations are independent and identically distributed (i.i.d.).

Empirical covariance

The covariance matrix of a data set is known to be well approximated by the classical *maximum likelihood estimator* (or "empirical covariance"), provided the number of observations is large enough compared to the number of features (the variables describing the observations). More precisely, the Maximum Likelihood Estimator of a sample is an unbiased estimator of the corresponding population's covariance matrix.

The empirical covariance matrix of a sample can be computed using the *empirical_covariance* function of the package, or by fitting an *EmpiricalCovariance* object to the data sample with the *EmpiricalCovariance.fit* method. Be careful that results depend on whether the data are centered, so one may want to use the `assume_centered` parameter accurately. More precisely, if `assume_centered=False`, then the test set is supposed to have the same mean vector as the training set. If not, both should be centered by the user, and `assume_centered=True` should be used.

Examples:

- See *Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood* for an example on how to fit an *EmpiricalCovariance* object to data.

Shrunk Covariance

Basic shrinkage

Despite being an unbiased estimator of the covariance matrix, the Maximum Likelihood Estimator is not a good estimator of the eigenvalues of the covariance matrix, so the precision matrix obtained from its inversion is not accurate. Sometimes, it even occurs that the empirical covariance matrix cannot be inverted for numerical reasons. To avoid such an inversion problem, a transformation of the empirical covariance matrix has been introduced: the `shrinkage`.

In scikit-learn, this transformation (with a user-defined shrinkage coefficient) can be directly applied to a pre-computed covariance with the *`shrunk_covariance`* method. Also, a shrunk estimator of the covariance can be fitted to data with a *`ShrunkCovariance`* object and its *`ShrunkCovariance.fit`* method. Again, results depend on whether the data are centered, so one may want to use the `assume_centered` parameter accurately.

Mathematically, this shrinkage consists in reducing the ratio between the smallest and the largest eigenvalues of the empirical covariance matrix. It can be done by simply shifting every eigenvalue according to a given offset, which is equivalent of finding the l2-penalized Maximum Likelihood Estimator of the covariance matrix. In practice, shrinkage boils down to a simple a convex transformation : $\Sigma_{\text{shrunk}} = (1-\alpha)\hat{\Sigma} + \alpha\frac{\text{Tr}\hat{\Sigma}}{p}\text{Id}$.

Choosing the amount of shrinkage, α amounts to setting a bias/variance trade-off, and is discussed below.

Examples:

- See *Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood* for an example on how to fit a *`ShrunkCovariance`* object to data.

Ledoit-Wolf shrinkage

In their 2004 paper[1], O. Ledoit and M. Wolf propose a formula to compute the optimal shrinkage coefficient α that minimizes the Mean Squared Error between the estimated and the real covariance matrix.

The Ledoit-Wolf estimator of the covariance matrix can be computed on a sample with the *`ledoit_wolf`* function of the *`sklearn.covariance`* package, or it can be otherwise obtained by fitting a *`LedoitWolf`* object to the same sample.

Note: Case when population covariance matrix is isotropic

It is important to note that when the number of samples is much larger than the number of features, one would expect that no shrinkage would be necessary. The intuition behind this is that if the population covariance is full rank, when the number of sample grows, the sample covariance will also become positive definite. As a result, no shrinkage would necessary and the method should automatically do this.

This, however, is not the case in the Ledoit-Wolf procedure when the population covariance happens to be a multiple of the identity matrix. In this case, the Ledoit-Wolf shrinkage estimate approaches 1 as the number of samples increases. This indicates that the optimal estimate of the covariance matrix in the Ledoit-Wolf sense is multiple of the identity. Since the population covariance is already a multiple of the identity matrix, the Ledoit-Wolf solution is indeed a reasonable estimate.

Oracle Approximating Shrinkage

Under the assumption that the data are Gaussian distributed, Chen et al.[2] derived a formula aimed at choosing a shrinkage coefficient that yields a smaller Mean Squared Error than the one given by Ledoit and Wolf's formula. The resulting estimator is known as the Oracle Shrinkage Approximating estimator of the covariance.

The OAS estimator of the covariance matrix can be computed on a sample with the `oas` function of the `sklearn.covariance` package, or it can be otherwise obtained by fitting an `OAS` object to the same sample.

Sparse inverse covariance

The matrix inverse of the covariance matrix, often called the precision matrix, is proportional to the partial correlation matrix. It gives the partial independence relationship. In other words, if two features are independent conditionally on the others, the corresponding coefficient in the precision matrix will be zero. This is why it makes sense to estimate a sparse precision matrix: the estimation of the covariance matrix is better conditioned by learning independence relations from the data. This is known as *covariance selection*.

In the small-samples situation, in which `n_samples` is on the order of `n_features` or smaller, sparse inverse covariance estimators tend to work better than shrunk covariance estimators. However, in the opposite situation, or for very correlated data, they can be numerically unstable. In addition, unlike shrinkage estimators, sparse estimators are able to recover off-diagonal structure.

The `GraphicalLasso` estimator uses an l1 penalty to enforce sparsity on the precision matrix: the higher its `alpha` parameter, the more sparse the precision matrix. The corresponding `GraphicalLassoCV` object uses cross-validation to automatically set the `alpha` parameter.

Note: Structure recovery

Recovering a graphical structure from correlations in the data is a challenging thing. If you are interested in such recovery keep in mind that:

- Recovery is easier from a correlation matrix than a covariance matrix: standardize your observations before running `GraphicalLasso`
- If the underlying graph has nodes with much more connections than the average node, the algorithm will miss some of these connections.

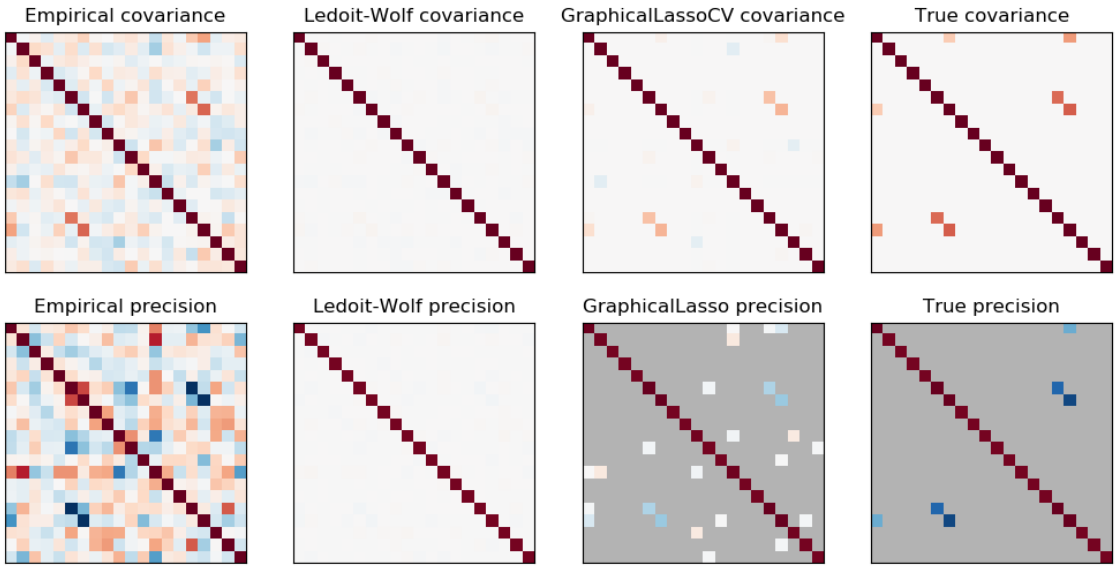

Fig. 8: *A comparison of maximum likelihood, shrinkage and sparse estimates of the covariance and precision matrix in the very small samples settings.*

- If your number of observations is not large compared to the number of edges in your underlying graph, you will not recover it.
- Even if you are in favorable recovery conditions, the alpha parameter chosen by cross-validation (e.g. using the `GraphicalLassoCV` object) will lead to selecting too many edges. However, the relevant edges will have heavier weights than the irrelevant ones.

The mathematical formulation is the following:

$$\hat{K} = \text{argmin}_K \left(\text{tr} S K - \text{logdet} K + \alpha \|K\|_1 \right)$$

Where K is the precision matrix to be estimated, and S is the sample covariance matrix. $\|K\|_1$ is the sum of the absolute values of off-diagonal coefficients of K. The algorithm employed to solve this problem is the GLasso algorithm, from the Friedman 2008 Biostatistics paper. It is the same algorithm as in the R `glasso` package.

Examples:

- *Sparse inverse covariance estimation*: example on synthetic data showing some recovery of a structure, and comparing to other covariance estimators.
- *Visualizing the stock market structure*: example on real stock market data, finding which symbols are most linked.

Robust Covariance Estimation

Real data sets are often subject to measurement or recording errors. Regular but uncommon observations may also appear for a variety of reasons. Observations which are very uncommon are called outliers. The empirical covariance estimator and the shrunk covariance estimators presented above are very sensitive to the presence of outliers in the data. Therefore, one should use robust covariance estimators to estimate the covariance of its real data sets. Alternatively, robust covariance estimators can be used to perform outlier detection and discard/downweight some observations according to further processing of the data.

The `sklearn.covariance` package implements a robust estimator of covariance, the Minimum Covariance Determinant[3].

Minimum Covariance Determinant

The Minimum Covariance Determinant estimator is a robust estimator of a data set's covariance introduced by P.J. Rousseeuw in[3]. The idea is to find a given proportion (h) of "good" observations which are not outliers and compute their empirical covariance matrix. This empirical covariance matrix is then rescaled to compensate the performed selection of observations ("consistency step"). Having computed the Minimum Covariance Determinant estimator, one can give weights to observations according to their Mahalanobis distance, leading to a reweighted estimate of the covariance matrix of the data set ("reweighting step").

Rousseeuw and Van Driessen[4] developed the FastMCD algorithm in order to compute the Minimum Covariance Determinant. This algorithm is used in scikit-learn when fitting an MCD object to data. The FastMCD algorithm also computes a robust estimate of the data set location at the same time.

Raw estimates can be accessed as `raw_location_` and `raw_covariance_` attributes of a *`MinCovDet`* robust covariance estimator object.

References:

Examples:

- See *Robust vs Empirical covariance estimate* for an example on how to fit a *`MinCovDet`* object to data and see how the estimate remains accurate despite the presence of outliers.
- See *Robust covariance estimation and Mahalanobis distances relevance* to visualize the difference between *`EmpiricalCovariance`* and *`MinCovDet`* covariance estimators in terms of Mahalanobis distance (so we get a better estimate of the precision matrix too).

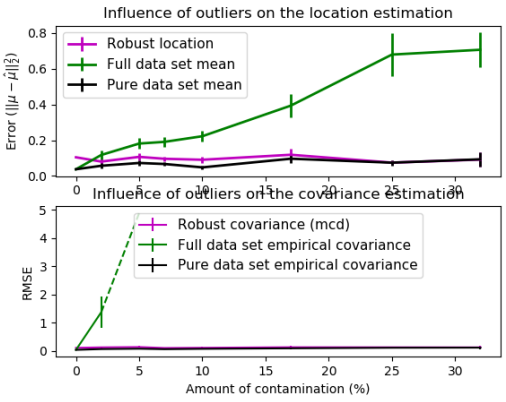
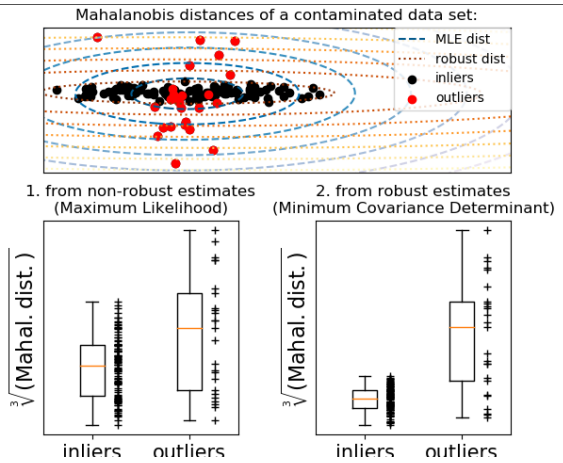
Influence of outliers on location and covariance estimates	Separating inliers from outliers using a Mahalanobis distance
	




4.2.7 Novelty and Outlier Detection

Many applications require being able to decide whether a new observation belongs to the same distribution as existing observations (it is an *inlier*), or should be considered as different (it is an *outlier*). Often, this ability is used to clean real data sets. Two important distinctions must be made:

outlier detection The training data contains outliers which are defined as observations that are far from the others. Outlier detection estimators thus try to fit the regions where the training data is the most concentrated, ignoring the deviant observations.

novelty detection The training data is not polluted by outliers and we are interested in detecting whether a **new** observation is an outlier. In this context an outlier is also called a novelty.

Outlier detection and novelty detection are both used for anomaly detection, where one is interested in detecting abnormal or unusual observations. Outlier detection is then also known as unsupervised anomaly detection and novelty detection as semi-supervised anomaly detection. In the context of outlier detection, the outliers/anomalies cannot form a dense cluster as available estimators assume that the outliers/anomalies are located in low density regions. On the contrary, in the context of novelty detection, novelties/anomalies can form a dense cluster as long as they are in a low density region of the training data, considered as normal in this context.

The scikit-learn project provides a set of machine learning tools that can be used both for novelty or outlier detection. This strategy is implemented with objects learning in an unsupervised way from the data:

```
estimator.fit(X_train)
```

new observations can then be sorted as inliers or outliers with a `predict` method:

```
estimator.predict(X_test)
```

Inliers are labeled 1, while outliers are labeled -1. The predict method makes use of a threshold on the raw scoring function computed by the estimator. This scoring function is accessible through the `score_samples` method, while the threshold can be controlled by the `contamination` parameter.

The `decision_function` method is also defined from the scoring function, in such a way that negative values are outliers and non-negative ones are inliers:

```
estimator.decision_function(X_test)
```

Note that *neighbors.LocalOutlierFactor* does not support predict, decision_function and score_samples methods by default but only a fit_predict method, as this estimator was originally meant to be applied for outlier detection. The scores of abnormality of the training samples are accessible through the negative_outlier_factor_ attribute.

If you really want to use *neighbors.LocalOutlierFactor* for novelty detection, i.e. predict labels or compute the score of abnormality of new unseen data, you can instantiate the estimator with the novelty parameter set to True before fitting the estimator. In this case, fit_predict is not available.

Warning: Novelty detection with Local Outlier Factor

When novelty is set to True be aware that you must only use predict, decision_function and score_samples on new unseen data and not on the training samples as this would lead to wrong results. The scores of abnormality of the training samples are always accessible through the negative_outlier_factor_ attribute.

The behavior of *neighbors.LocalOutlierFactor* is summarized in the following table.

Method	Outlier detection	Novelty detection
fit_predict	OK	Not available
predict	Not available	Use only on new data
decision_function	Not available	Use only on new data
score_samples	Use negative_outlier_factor_	Use only on new data

Overview of outlier detection methods

A comparison of the outlier detection algorithms in scikit-learn. Local Outlier Factor (LOF) does not show a decision boundary in black as it has no predict method to be applied on new data when it is used for outlier detection.

ensemble.IsolationForest and *neighbors.LocalOutlierFactor* perform reasonably well on the data sets considered here. The *svm.OneClassSVM* is known to be sensitive to outliers and thus does not perform very well for outlier detection. Finally, *covariance.EllipticEnvelope* assumes the data is Gaussian and learns an ellipse. For more details on the different estimators refer to the example *Comparing anomaly detection algorithms for outlier detection on toy datasets* and the sections hereunder.

Examples:

- See *Comparing anomaly detection algorithms for outlier detection on toy datasets* for a comparison of the *svm.OneClassSVM*, the *ensemble.IsolationForest*, the *neighbors.LocalOutlierFactor* and *covariance.EllipticEnvelope*.

Novelty Detection

Consider a data set of n observations from the same distribution described by p features. Consider now that we add one more observation to that data set. Is the new observation so different from the others that we can doubt it is regular? (i.e. does it come from the same distribution?) Or on the contrary, is it so similar to the other that we cannot distinguish it from the original observations? This is the question addressed by the novelty detection tools and methods.

In general, it is about to learn a rough, close frontier delimiting the contour of the initial observations distribution, plotted in embedding p-dimensional space. Then, if further observations lay within the frontier-delimited subspace,

.00s

they are considered as coming from the same population than the initial observations. Otherwise, if they lay outside the frontier, we can say that they are abnormal with a given confidence in our assessment.

The One-Class SVM has been introduced by Schölkopf et al. for that purpose and implemented in the *Support Vector Machines* module in the `svm.OneClassSVM` object. It requires the choice of a kernel and a scalar parameter to define a frontier. The RBF kernel is usually chosen although there exists no exact formula or algorithm to set its bandwidth parameter. This is the default in the scikit-learn implementation. The ν parameter, also known as the margin of the One-Class SVM, corresponds to the probability of finding a new, but regular, observation outside the frontier.

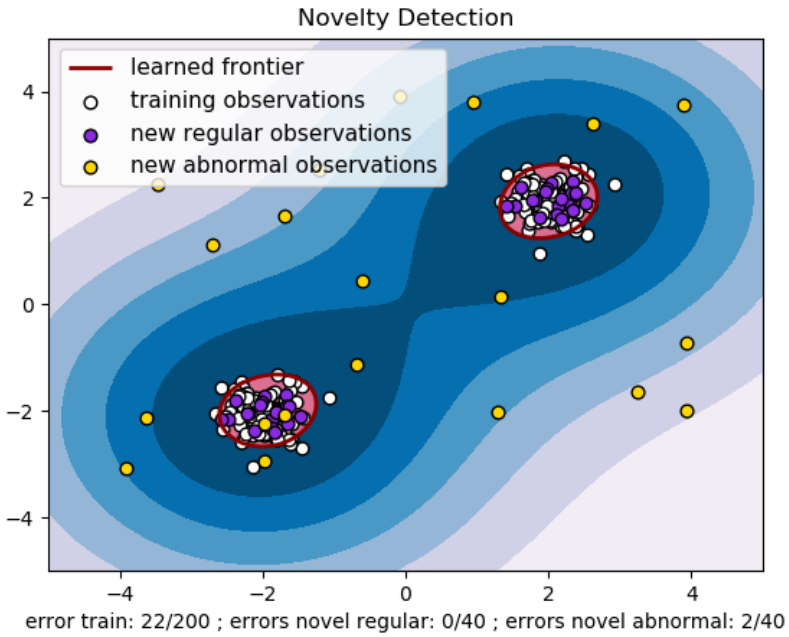
Examples:

- See *One-class SVM with non-linear kernel (RBF)* for visualizing the frontier learned around some data by a `svm.OneClassSVM` object.
- *Species distribution modeling*



Outlier Detection

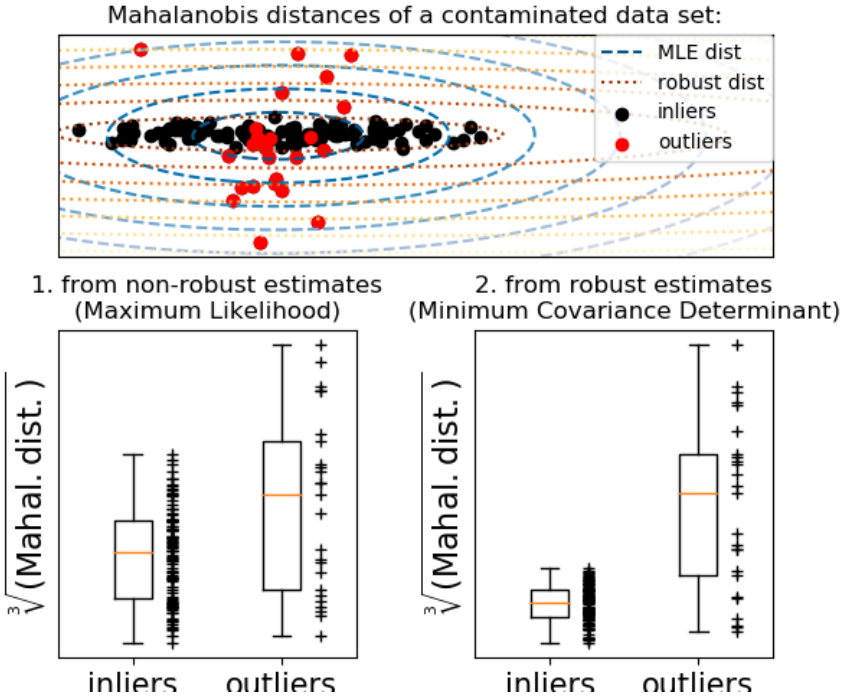
Outlier detection is similar to novelty detection in the sense that the goal is to separate a core of regular observations from some polluting ones, called *outliers*. Yet, in the case of outlier detection, we don't have a clean data set representing the population of regular observations that can be used to train any tool.

Fitting an elliptic envelope

One common way of performing outlier detection is to assume that the regular data come from a known distribution (e.g. data are Gaussian distributed). From this assumption, we generally try to define the "shape" of the data, and can define outlying observations as observations which stand far enough from the fit shape.

The scikit-learn provides an object `covariance.EllipticEnvelope` that fits a robust covariance estimate to the data, and thus fits an ellipse to the central data points, ignoring points outside the central mode.

For instance, assuming that the inlier data are Gaussian distributed, it will estimate the inlier location and covariance in a robust way (i.e. without being influenced by outliers). The Mahalanobis distances obtained from this estimate is used to derive a measure of outlyingness. This strategy is illustrated below.



Examples:

- See *Robust covariance estimation and Mahalanobis distances relevance* for an illustration of the difference between using a standard (`covariance.EmpiricalCovariance`) or a robust estimate (`covariance.MinCovDet`) of location and covariance to assess the degree of outlyingness of an observation.

References:

- Rousseeuw, P.J., Van Driessen, K. "A fast algorithm for the minimum covariance determinant estimator" Technometrics 41(3), 212 (1999)

Isolation Forest

One efficient way of performing outlier detection in high-dimensional datasets is to use random forests. The *ensemble.IsolationForest* 'isolates' observations by randomly selecting a feature and then randomly selecting a split value between the maximum and minimum values of the selected feature.

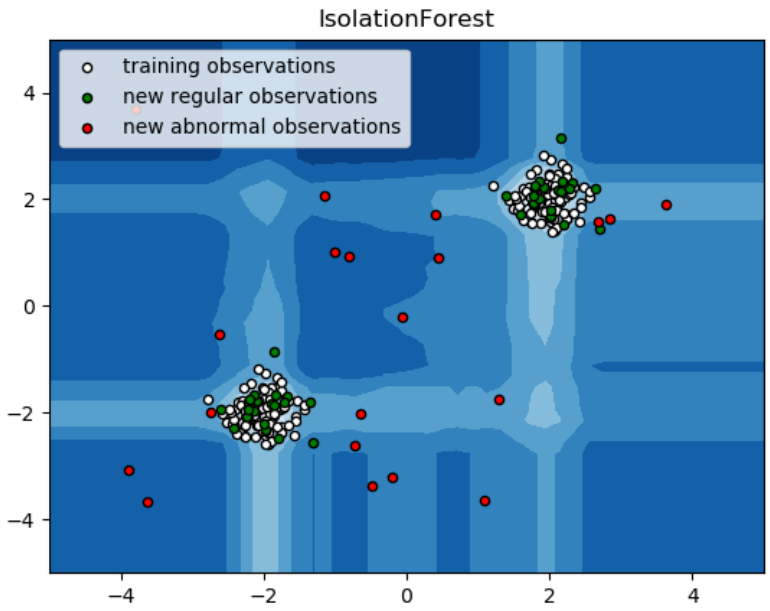
Since recursive partitioning can be represented by a tree structure, the number of splittings required to isolate a sample is equivalent to the path length from the root node to the terminating node.

This path length, averaged over a forest of such random trees, is a measure of normality and our decision function.

Random partitioning produces noticeably shorter paths for anomalies. Hence, when a forest of random trees collectively produce shorter path lengths for particular samples, they are highly likely to be anomalies.

The implementation of *ensemble.IsolationForest* is based on an ensemble of *tree.ExtraTreeRegressor*. Following Isolation Forest original paper, the maximum depth of each tree is set to $\lceil \log_2(n) \rceil$ where n is the number of samples used to build the tree (see (Liu et al., 2008) for more details).

This algorithm is illustrated below.



The *ensemble.IsolationForest* supports `warm_start=True` which allows you to add more trees to an already fitted model:

```
>>> from sklearn.ensemble import IsolationForest
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [0, 0], [-20, 50], [3, 5]])
>>> clf = IsolationForest(n_estimators=10, warm_start=True)
>>> clf.fit(X)  # fit 10 trees
>>> clf.set_params(n_estimators=20)  # add 10 more trees
>>> clf.fit(X)  # fit the added trees
```

Examples:

- See *IsolationForest example* for an illustration of the use of IsolationForest.
- See *Comparing anomaly detection algorithms for outlier detection on toy datasets* for a comparison of `ensemble.IsolationForest` with `neighbors.LocalOutlierFactor`, `svm.OneClassSVM` (tuned to perform like an outlier detection method) and a covariance-based outlier detection with `covariance.EllipticEnvelope`.

References:

- Liu, Fei Tony, Ting, Kai Ming and Zhou, Zhi-Hua. "Isolation forest." Data Mining, 2008. ICDM'08. Eighth IEEE International Conference on.

Local Outlier Factor

Another efficient way to perform outlier detection on moderately high dimensional datasets is to use the Local Outlier Factor (LOF) algorithm.

The `neighbors.LocalOutlierFactor` (LOF) algorithm computes a score (called local outlier factor) reflecting the degree of abnormality of the observations. It measures the local density deviation of a given data point with respect to its neighbors. The idea is to detect the samples that have a substantially lower density than their neighbors.

In practice the local density is obtained from the k-nearest neighbors. The LOF score of an observation is equal to the ratio of the average local density of his k-nearest neighbors, and its own local density: a normal instance is expected to have a local density similar to that of its neighbors, while abnormal data are expected to have much smaller local density.

The number k of neighbors considered, (alias parameter n_neighbors) is typically chosen 1) greater than the minimum number of objects a cluster has to contain, so that other objects can be local outliers relative to this cluster, and 2) smaller than the maximum number of close by objects that can potentially be local outliers. In practice, such informations are generally not available, and taking n_neighbors=20 appears to work well in general. When the proportion of outliers is high (i.e. greater than 10 %, as in the example below), n_neighbors should be greater (n_neighbors=35 in the example below).

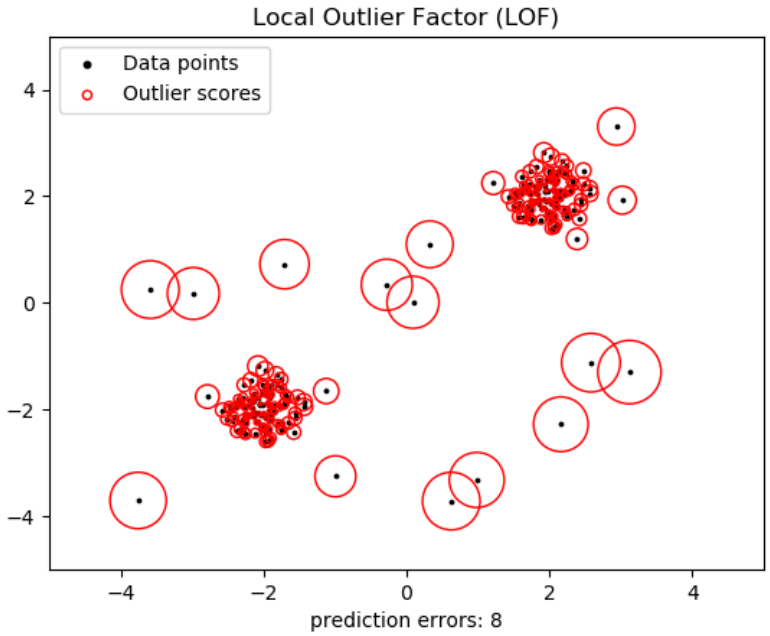
The strength of the LOF algorithm is that it takes both local and global properties of datasets into consideration: it can perform well even in datasets where abnormal samples have different underlying densities. The question is not, how isolated the sample is, but how isolated it is with respect to the surrounding neighborhood.

When applying LOF for outlier detection, there are no `predict`, `decision_function` and `score_samples` methods but only a `fit_predict` method. The scores of abnormality of the training samples are accessible through the `negative_outlier_factor_` attribute. Note that `predict`, `decision_function` and `score_samples` can be used on new unseen data when LOF is applied for novelty detection, i.e. when the `novelty` parameter is set to `True`. See *Novelty detection with Local Outlier Factor*.

This strategy is illustrated below.

Examples:

- See *Outlier detection with Local Outlier Factor (LOF)* for an illustration of the use of `neighbors.LocalOutlierFactor`.



- See *Comparing anomaly detection algorithms for outlier detection on toy datasets* for a comparison with other anomaly detection methods.

References:

- Breunig, Kriegel, Ng, and Sander (2000) LOF: identifying density-based local outliers. Proc. ACM SIGMOD

Novelty detection with Local Outlier Factor

To use *neighbors.LocalOutlierFactor* for novelty detection, i.e. predict labels or compute the score of abnormality of new unseen data, you need to instantiate the estimator with the `novelty` parameter set to `True` before fitting the estimator:

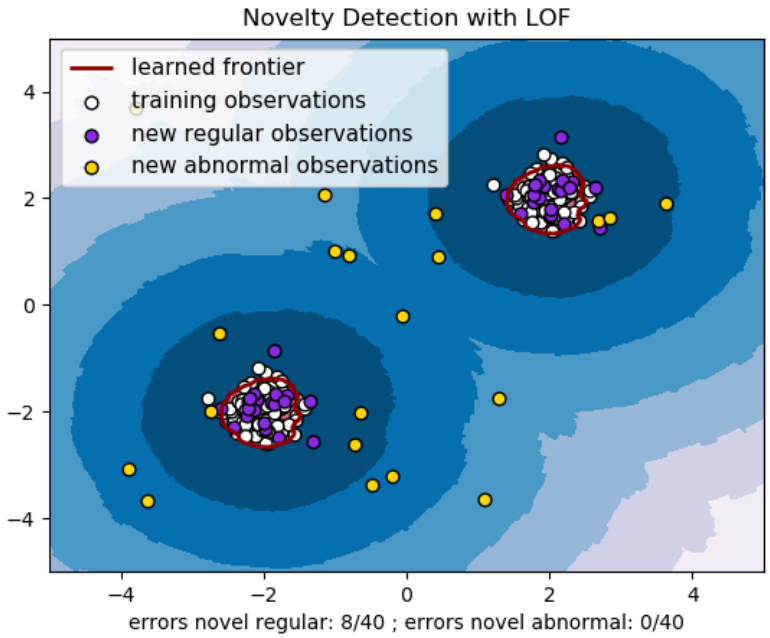
```
lof = LocalOutlierFactor(novelty=True)
lof.fit(X_train)
```

Note that `fit_predict` is not available in this case.

Warning: Novelty detection with Local Outlier Factor‘

When `novelty` is set to `True` be aware that you must only use `predict`, `decision_function` and `score_samples` on new unseen data and not on the training samples as this would lead to wrong results. The scores of abnormality of the training samples are always accessible through the `negative_outlier_factor_` attribute.

Novelty detection with Local Outlier Factor is illustrated below.



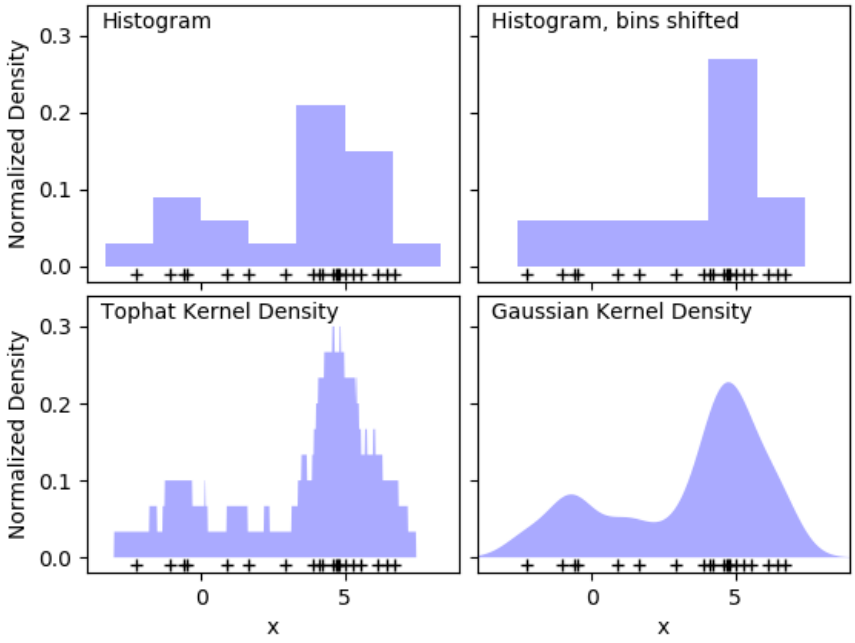
4.2.8 Density Estimation

Density estimation walks the line between unsupervised learning, feature engineering, and data modeling. Some of the most popular and useful density estimation techniques are mixture models such as Gaussian Mixtures (`sklearn.mixture.GaussianMixture`), and neighbor-based approaches such as the kernel density estimate (`sklearn.neighbors.KernelDensity`). Gaussian Mixtures are discussed more fully in the context of *clustering*, because the technique is also useful as an unsupervised clustering scheme.

Density estimation is a very simple concept, and most people are already familiar with one common density estimation technique: the histogram.

Density Estimation: Histograms

A histogram is a simple visualization of data where bins are defined, and the number of data points within each bin is tallied. An example of a histogram can be seen in the upper-left panel of the following figure:



A major problem with histograms, however, is that the choice of binning can have a disproportionate effect on the resulting visualization. Consider the upper-right panel of the above figure. It shows a histogram over the same data, with the bins shifted right. The results of the two visualizations look entirely different, and might lead to different interpretations of the data.

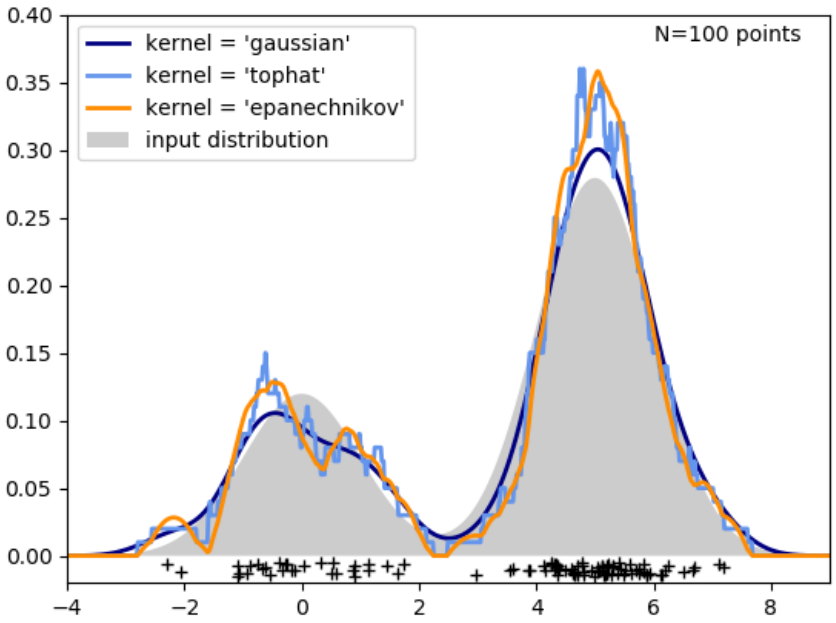
Intuitively, one can also think of a histogram as a stack of blocks, one block per point. By stacking the blocks in the appropriate grid space, we recover the histogram. But what if, instead of stacking the blocks on a regular grid, we center each block on the point it represents, and sum the total height at each location? This idea leads to the lower-left visualization. It is perhaps not as clean as a histogram, but the fact that the data drive the block locations mean that it is a much better representation of the underlying data.

This visualization is an example of a *kernel density estimation*, in this case with a top-hat kernel (i.e. a square block at each point). We can recover a smoother distribution by using a smoother kernel. The bottom-right plot shows a Gaussian kernel density estimate, in which each point contributes a Gaussian curve to the total. The result is a smooth density estimate which is derived from the data, and functions as a powerful non-parametric model of the distribution of points.

Kernel Density Estimation

Kernel density estimation in scikit-learn is implemented in the `sklearn.neighbors.KernelDensity` estimator, which uses the Ball Tree or KD Tree for efficient queries (see *Nearest Neighbors* for a discussion of these). Though the above example uses a 1D data set for simplicity, kernel density estimation can be performed in any number of dimensions, though in practice the curse of dimensionality causes its performance to degrade in high dimensions.

In the following figure, 100 points are drawn from a bimodal distribution, and the kernel density estimates are shown for three choices of kernels:



It's clear how the kernel shape affects the smoothness of the resulting distribution. The scikit-learn kernel density estimator can be used as follows:

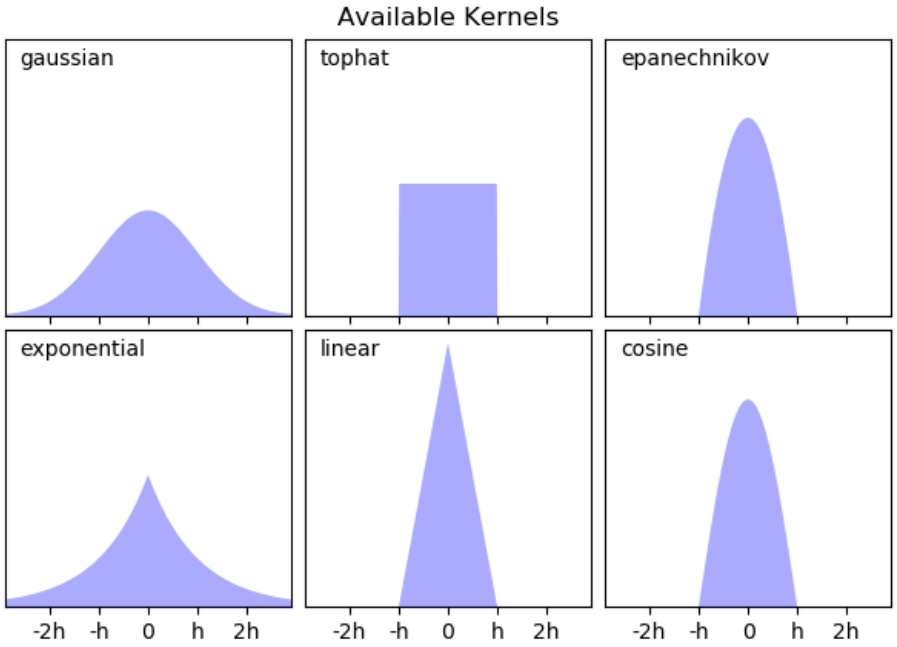
```
>>> from sklearn.neighbors import KernelDensity
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
>>> kde = KernelDensity(kernel='gaussian', bandwidth=0.2).fit(X)
>>> kde.score_samples(X)
array([-0.41075698, -0.41075698, -0.41076071, -0.41075698, -0.41075698,
       -0.41076071])
```

Here we have used `kernel='gaussian'`, as seen above. Mathematically, a kernel is a positive function $K(x; h)$ which is controlled by the bandwidth parameter h. Given this kernel form, the density estimate at a point y within a group of points $x_i; i = 1 \cdots N$ is given by:

$$\rho_K(y) = \sum_{i=1}^{N} K((y - x_i)/h)$$

The bandwidth here acts as a smoothing parameter, controlling the tradeoff between bias and variance in the result. A large bandwidth leads to a very smooth (i.e. high-bias) density distribution. A small bandwidth leads to an unsmooth (i.e. high-variance) density distribution.

sklearn.neighbors.KernelDensity implements several common kernel forms, which are shown in the following figure:



The form of these kernels is as follows:

- Gaussian kernel (`kernel = 'gaussian'`)

  $K(x; h) \propto \exp(-\frac{x^2}{2h^2})$

- Tophat kernel (`kernel = 'tophat'`)

  $K(x; h) \propto 1$ if $x < h$

- Epanechnikov kernel (`kernel = 'epanechnikov'`)

  $K(x; h) \propto 1 - \frac{x^2}{h^2}$

- Exponential kernel (`kernel = 'exponential'`)

  $K(x; h) \propto \exp(-x/h)$

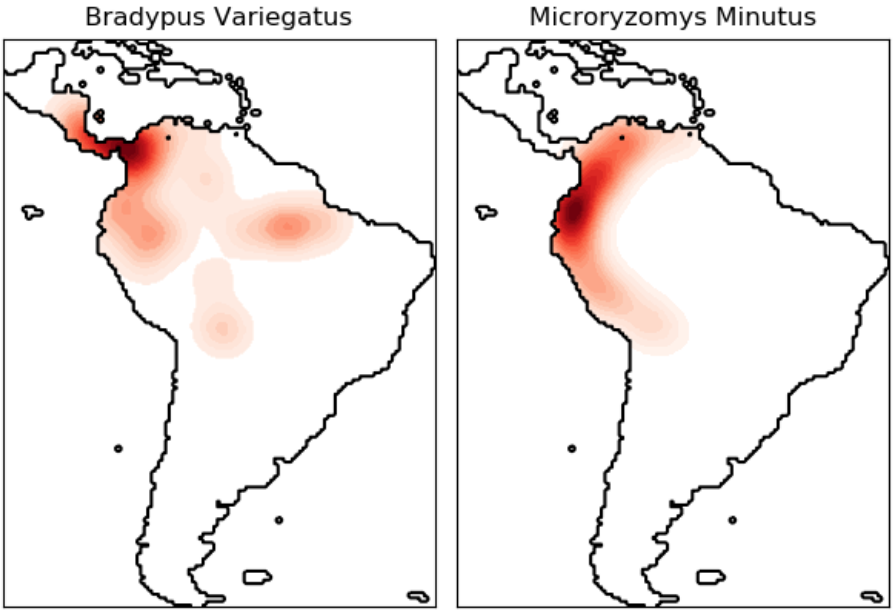
- Linear kernel (`kernel = 'linear'`)

  $K(x; h) \propto 1 - x/h$ if $x < h$

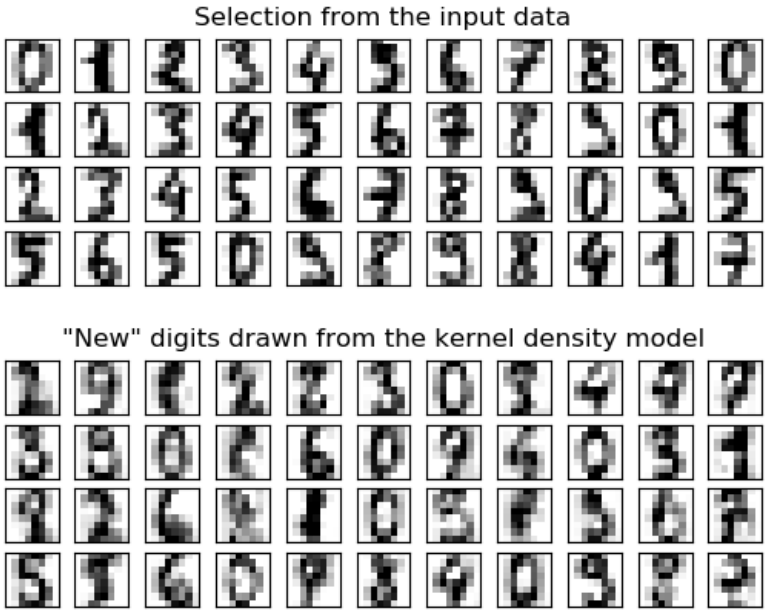
- Cosine kernel (`kernel = 'cosine'`)

  $K(x; h) \propto \cos(\frac{\pi x}{2h})$ if $x < h$

The kernel density estimator can be used with any of the valid distance metrics (see *sklearn.neighbors.DistanceMetric* for a list of available metrics), though the results are properly normalized only for the Euclidean metric. One particularly useful metric is the Haversine distance which measures the angular distance between points on a sphere. Here is an example of using a kernel density estimate for a visualization of geospatial data, in this case the distribution of observations of two different species on the South American continent:



One other useful application of kernel density estimation is to learn a non-parametric generative model of a dataset in order to efficiently draw new samples from this generative model. Here is an example of using this process to create a new set of hand-written digits, using a Gaussian kernel learned on a PCA projection of the data:



The "new" data consists of linear combinations of the input data, with weights probabilistically drawn given the KDE model.

Examples:

- *Simple 1D Kernel Density Estimation*: computation of simple kernel density estimates in one dimension.
- *Kernel Density Estimation*: an example of using Kernel Density estimation to learn a generative model of the hand-written digits data, and drawing new samples from this model.
- *Kernel Density Estimate of Species Distributions*: an example of Kernel Density estimation using the Haversine distance metric to visualize geospatial data

4.2.9 Neural network models (unsupervised)

Restricted Boltzmann machines

Restricted Boltzmann machines (RBM) are unsupervised nonlinear feature learners based on a probabilistic model. The features extracted by an RBM or a hierarchy of RBMs often give good results when fed into a linear classifier such as a linear SVM or a perceptron.

The model makes assumptions regarding the distribution of inputs. At the moment, scikit-learn only provides `BernoulliRBM`, which assumes the inputs are either binary values or values between 0 and 1, each encoding the probability that the specific feature would be turned on.

The RBM tries to maximize the likelihood of the data using a particular graphical model. The parameter learning algorithm used (*Stochastic Maximum Likelihood*) prevents the representations from straying far from the input data, which makes them capture interesting regularities, but makes the model less useful for small datasets, and usually not useful for density estimation.

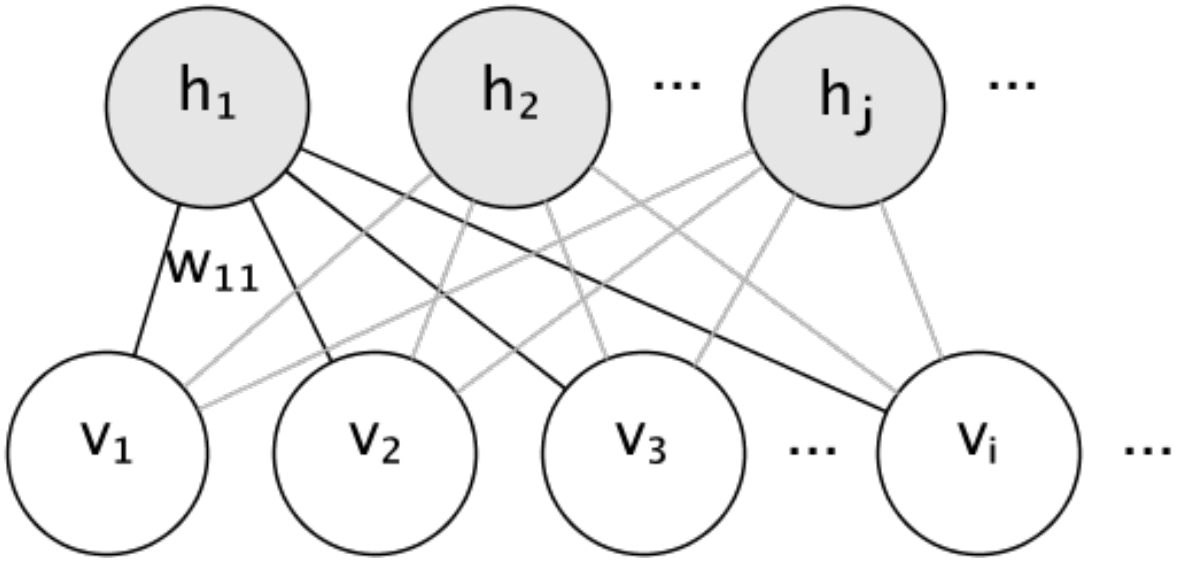
The method gained popularity for initializing deep neural networks with the weights of independent RBMs. This method is known as unsupervised pre-training.

Examples:

- *Restricted Boltzmann Machine features for digit classification*

Graphical model and parametrization

The graphical model of an RBM is a fully-connected bipartite graph.



The nodes are random variables whose states depend on the state of the other nodes they are connected to. The model is therefore parameterized by the weights of the connections, as well as one intercept (bias) term for each visible and hidden unit, omitted from the image for simplicity.

The energy function measures the quality of a joint assignment:

$$E(\mathbf{v}, \mathbf{h}) = -\sum_i \sum_j w_{ij} v_i h_j - \sum_i b_i v_i - \sum_j c_j h_j$$

In the formula above, $\mathbf{b}$ and $\mathbf{c}$ are the intercept vectors for the visible and hidden layers, respectively. The joint

probability of the model is defined in terms of the energy:

$$P(\mathbf{v}, \mathbf{h}) = \frac{e^{-E(\mathbf{v},\mathbf{h})}}{Z}$$

The word *restricted* refers to the bipartite structure of the model, which prohibits direct interaction between hidden units, or between visible units. This means that the following conditional independencies are assumed:

$$h_i \perp h_j | \mathbf{v}$$
$$v_i \perp v_j | \mathbf{h}$$

The bipartite structure allows for the use of efficient block Gibbs sampling for inference.

Bernoulli Restricted Boltzmann machines

In the `BernoulliRBM`, all units are binary stochastic units. This means that the input data should either be binary, or real-valued between 0 and 1 signifying the probability that the visible unit would turn on or off. This is a good model for character recognition, where the interest is on which pixels are active and which aren't. For images of natural scenes it no longer fits because of background, depth and the tendency of neighbouring pixels to take the same values.

The conditional probability distribution of each unit is given by the logistic sigmoid activation function of the input it receives:

$$P(v_i = 1|\mathbf{h}) = \sigma(\sum_j w_{ij} h_j + b_i)$$
$$P(h_i = 1|\mathbf{v}) = \sigma(\sum_i w_{ij} v_i + c_j)$$

where σ is the logistic sigmoid function:

$$\sigma(x) = \frac{1}{1 + e^{-x}}$$

Stochastic Maximum Likelihood learning

The training algorithm implemented in `BernoulliRBM` is known as Stochastic Maximum Likelihood (SML) or Persistent Contrastive Divergence (PCD). Optimizing maximum likelihood directly is infeasible because of the form of the data likelihood:

$$\log P(v) = \log \sum_h e^{-E(v,h)} - \log \sum_{x,y} e^{-E(x,y)}$$

For simplicity the equation above is written for a single training example. The gradient with respect to the weights is formed of two terms corresponding to the ones above. They are usually known as the positive gradient and the negative gradient, because of their respective signs. In this implementation, the gradients are estimated over mini-batches of samples.

In maximizing the log-likelihood, the positive gradient makes the model prefer hidden states that are compatible with the observed training data. Because of the bipartite structure of RBMs, it can be computed efficiently. The negative gradient, however, is intractable. Its goal is to lower the energy of joint states that the model prefers, therefore making it stay true to the data. It can be approximated by Markov chain Monte Carlo using block Gibbs sampling by iteratively sampling each of v and h given the other, until the chain mixes. Samples generated in this way are sometimes referred as fantasy particles. This is inefficient and it is difficult to determine whether the Markov chain mixes.

The Contrastive Divergence method suggests to stop the chain after a small number of iterations, k, usually even 1. This method is fast and has low variance, but the samples are far from the model distribution.

Persistent Contrastive Divergence addresses this. Instead of starting a new chain each time the gradient is needed, and performing only one Gibbs sampling step, in PCD we keep a number of chains (fantasy particles) that are updated k Gibbs steps after each weight update. This allows the particles to explore the space more thoroughly.

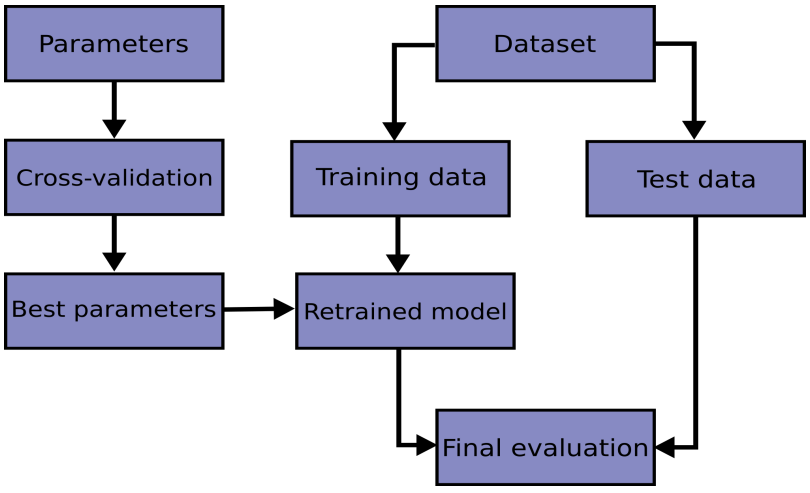
4.3 Model selection and evaluation

4.3.1 Cross-validation: evaluating estimator performance

Learning the parameters of a prediction function and testing it on the same data is a methodological mistake: a model that would just repeat the labels of the samples that it has just seen would have a perfect score but would fail to predict anything useful on yet-unseen data. This situation is called **overfitting**. To avoid it, it is common practice when performing a (supervised) machine learning experiment to hold out part of the available data as a **test set** `X_test, y_test`. Note that the word "experiment" is not intended to denote academic use only, because even in commercial settings machine learning usually starts out experimentally. Here is a flowchart of typical cross validation workflow in model training. The best parameters can be determined by *grid search* techniques.



In scikit-learn a random split into training and test sets can be quickly computed with the *train_test_split* helper function. Let's load the iris data set to fit a linear support vector machine on it:

```
>>> import numpy as np
>>> from sklearn.model_selection import train_test_split
>>> from sklearn import datasets
>>> from sklearn import svm

>>> X, y = datasets.load_iris(return_X_y=True)
>>> X.shape, y.shape
((150, 4), (150,))
```

We can now quickly sample a training set while holding out 40% of the data for testing (evaluating) our classifier:

```
>>> X_train, X_test, y_train, y_test = train_test_split(
...     X, y, test_size=0.4, random_state=0)

>>> X_train.shape, y_train.shape
((90, 4), (90,))
>>> X_test.shape, y_test.shape
((60, 4), (60,))

>>> clf = svm.SVC(kernel='linear', C=1).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.96...
```

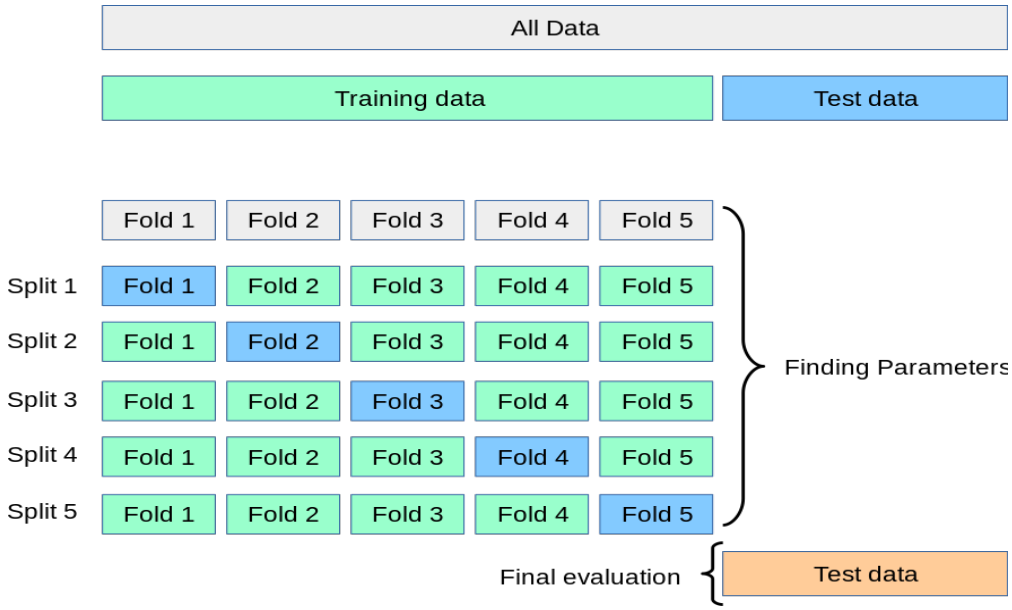
When evaluating different settings ("hyperparameters") for estimators, such as the `C` setting that must be manually set for an SVM, there is still a risk of overfitting *on the test set* because the parameters can be tweaked until the estimator performs optimally. This way, knowledge about the test set can "leak" into the model and evaluation metrics no longer report on generalization performance. To solve this problem, yet another part of the dataset can be held out as a so-called "validation set": training proceeds on the training set, after which evaluation is done on the validation set, and when the experiment seems to be successful, final evaluation can be done on the test set.

However, by partitioning the available data into three sets, we drastically reduce the number of samples which can be used for learning the model, and the results can depend on a particular random choice for the pair of (train, validation) sets.

A solution to this problem is a procedure called cross-validation (CV for short). A test set should still be held out for final evaluation, but the validation set is no longer needed when doing CV. In the basic approach, called *k*-fold CV, the training set is split into *k* smaller sets (other approaches are described below, but generally follow the same principles). The following procedure is followed for each of the *k* "folds":

- A model is trained using $k - 1$ of the folds as training data;
- the resulting model is validated on the remaining part of the data (i.e., it is used as a test set to compute a performance measure such as accuracy).

The performance measure reported by *k*-fold cross-validation is then the average of the values computed in the loop. This approach can be computationally expensive, but does not waste too much data (as is the case when fixing an arbitrary validation set), which is a major advantage in problems such as inverse inference where the number of samples is very small.



Computing cross-validated metrics

The simplest way to use cross-validation is to call the *cross_val_score* helper function on the estimator and the dataset.

The following example demonstrates how to estimate the accuracy of a linear kernel support vector machine on the iris dataset by splitting the data, fitting a model and computing the score 5 consecutive times (with different splits each time):

```
>>> from sklearn.model_selection import cross_val_score
>>> clf = svm.SVC(kernel='linear', C=1)
>>> scores = cross_val_score(clf, X, y, cv=5)
>>> scores
array([0.96..., 1.  ..., 0.96..., 0.96..., 1.        ])
```

The mean score and the 95% confidence interval of the score estimate are hence given by:

```
>>> print("Accuracy: %0.2f (+/- %0.2f)" % (scores.mean(), scores.std() * 2))
Accuracy: 0.98 (+/- 0.03)
```

By default, the score computed at each CV iteration is the `score` method of the estimator. It is possible to change this by using the scoring parameter:

```
>>> from sklearn import metrics
>>> scores = cross_val_score(
...     clf, X, y, cv=5, scoring='f1_macro')
>>> scores
array([0.96..., 1.  ..., 0.96..., 0.96..., 1.        ])
```

See *The scoring parameter: defining model evaluation rules* for details. In the case of the Iris dataset, the samples are balanced across target classes hence the accuracy and the F1-score are almost equal.

When the `cv` argument is an integer, *cross_val_score* uses the *KFold* or *StratifiedKFold* strategies by default, the latter being used if the estimator derives from *ClassifierMixin*.

It is also possible to use other cross validation strategies by passing a cross validation iterator instead, for instance:

```
>>> from sklearn.model_selection import ShuffleSplit
>>> n_samples = X.shape[0]
>>> cv = ShuffleSplit(n_splits=5, test_size=0.3, random_state=0)
>>> cross_val_score(clf, X, y, cv=cv)
array([0.977..., 0.977..., 1.  ..., 0.955..., 1.        ])
```

Another option is to use an iterable yielding (train, test) splits as arrays of indices, for example:

```
>>> def custom_cv_2folds(X):
...     n = X.shape[0]
...     i = 1
...     while i <= 2:
...         idx = np.arange(n * (i - 1) / 2, n * i / 2, dtype=int)
...         yield idx, idx
...         i += 1
...
>>> custom_cv = custom_cv_2folds(X)
>>> cross_val_score(clf, X, y, cv=custom_cv)
array([1.        , 0.973...])
```

Data transformation with held out data

Just as it is important to test a predictor on data held-out from training, preprocessing (such as standardization, feature selection, etc.) and similar *data transformations* similarly should be learnt from a training set and applied to held-out data for prediction:

```
>>> from sklearn import preprocessing
>>> X_train, X_test, y_train, y_test = train_test_split(
...     X, y, test_size=0.4, random_state=0)
>>> scaler = preprocessing.StandardScaler().fit(X_train)
>>> X_train_transformed = scaler.transform(X_train)
>>> clf = svm.SVC(C=1).fit(X_train_transformed, y_train)
>>> X_test_transformed = scaler.transform(X_test)
>>> clf.score(X_test_transformed, y_test)
0.9333...
```

A *Pipeline* makes it easier to compose estimators, providing this behavior under cross-validation:

```
>>> from sklearn.pipeline import make_pipeline
>>> clf = make_pipeline(preprocessing.StandardScaler(), svm.SVC(C=1))
>>> cross_val_score(clf, X, y, cv=cv)
array([0.977..., 0.933..., 0.955..., 0.933..., 0.977...])
```

See *Pipelines and composite estimators*.

The cross_validate function and multiple metric evaluation

The *cross_validate* function differs from *cross_val_score* in two ways:

- It allows specifying multiple metrics for evaluation.
- It returns a dict containing fit-times, score-times (and optionally training scores as well as fitted estimators) in addition to the test score.

For single metric evaluation, where the scoring parameter is a string, callable or None, the keys will be - `['test_score', 'fit_time', 'score_time']`

And for multiple metric evaluation, the return value is a dict with the following keys - `['test_<scorer1_name>', 'test_<scorer2_name>', 'test_<scorer...>', 'fit_time', 'score_time']`

`return_train_score` is set to `False` by default to save computation time. To evaluate the scores on the training set as well you need to be set to `True`.

You may also retain the estimator fitted on each training set by setting `return_estimator=True`.

The multiple metrics can be specified either as a list, tuple or set of predefined scorer names:

```
>>> from sklearn.model_selection import cross_validate
>>> from sklearn.metrics import recall_score
>>> scoring = ['precision_macro', 'recall_macro']
>>> clf = svm.SVC(kernel='linear', C=1, random_state=0)
>>> scores = cross_validate(clf, X, y, scoring=scoring)
>>> sorted(scores.keys())
['fit_time', 'score_time', 'test_precision_macro', 'test_recall_macro']
>>> scores['test_recall_macro']
array([0.96..., 1.  ..., 0.96..., 0.96..., 1.        ])
```

Or as a dict mapping scorer name to a predefined or custom scoring function:

```
>>> from sklearn.metrics import make_scorer
>>> scoring = {'prec_macro': 'precision_macro',
...            'rec_macro': make_scorer(recall_score, average='macro')}
>>> scores = cross_validate(clf, X, y, scoring=scoring,
...                         cv=5, return_train_score=True)
>>> sorted(scores.keys())
['fit_time', 'score_time', 'test_prec_macro', 'test_rec_macro',
 'train_prec_macro', 'train_rec_macro']
>>> scores['train_rec_macro']
array([0.97..., 0.97..., 0.99..., 0.98..., 0.98...])
```

Here is an example of `cross_validate` using a single metric:

```
>>> scores = cross_validate(clf, X, y,
...                         scoring='precision_macro', cv=5,
...                         return_estimator=True)
>>> sorted(scores.keys())
['estimator', 'fit_time', 'score_time', 'test_score']
```

Obtaining predictions by cross-validation

The function *cross_val_predict* has a similar interface to *cross_val_score*, but returns, for each element in the input, the prediction that was obtained for that element when it was in the test set. Only cross-validation strategies that assign all elements to a test set exactly once can be used (otherwise, an exception is raised).

Warning: Note on inappropriate usage of cross_val_predict

The result of *cross_val_predict* may be different from those obtained using *cross_val_score* as the elements are grouped in different ways. The function *cross_val_score* takes an average over cross-validation folds, whereas *cross_val_predict* simply returns the labels (or probabilities) from several distinct models undistinguished. Thus, *cross_val_predict* is not an appropriate measure of generalisation error.

The function *cross_val_predict* is appropriate for:

- Visualization of predictions obtained from different models.
- Model blending: When predictions of one supervised estimator are used to train another estimator in ensemble methods.

The available cross validation iterators are introduced in the following section.

Examples

- *Receiver Operating Characteristic (ROC) with cross validation*,
- *Recursive feature elimination with cross-validation*,
- *Parameter estimation using grid search with cross-validation*,
- *Sample pipeline for text feature extraction and evaluation*,
- *Plotting Cross-Validated Predictions*,
- *Nested versus non-nested cross-validation*.

Cross validation iterators

The following sections list utilities to generate indices that can be used to generate dataset splits according to different cross validation strategies.

Cross-validation iterators for i.i.d. data

Assuming that some data is Independent and Identically Distributed (i.i.d.) is making the assumption that all samples stem from the same generative process and that the generative process is assumed to have no memory of past generated samples.

The following cross-validators can be used in such cases.

NOTE

While i.i.d. data is a common assumption in machine learning theory, it rarely holds in practice. If one knows that the samples have been generated using a time-dependent process, it's safer to use a *time-series aware cross-validation scheme* Similarly if we know that the generative process has a group structure (samples from collected from different subjects, experiments, measurement devices) it safer to use *group-wise cross-validation*.

K-fold

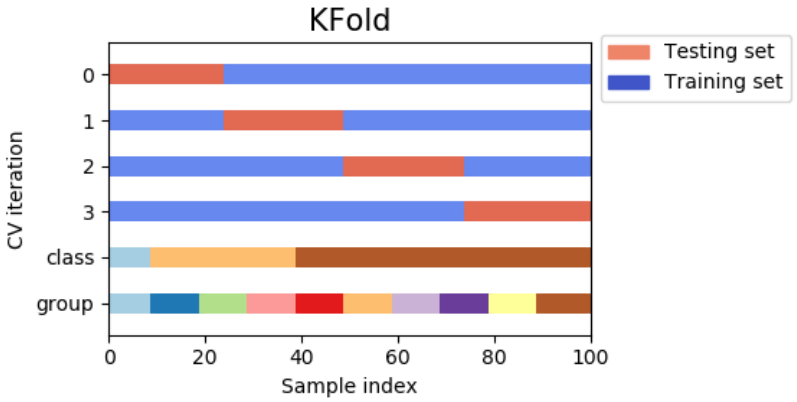
`KFold` divides all the samples in k groups of samples, called folds (if $k = n$, this is equivalent to the *Leave One Out* strategy), of equal sizes (if possible). The prediction function is learned using $k - 1$ folds, and the fold left out is used for test.

Example of 2-fold cross-validation on a dataset with 4 samples:

```
>>> import numpy as np
>>> from sklearn.model_selection import KFold

>>> X = ["a", "b", "c", "d"]
>>> kf = KFold(n_splits=2)
>>> for train, test in kf.split(X):
...     print("%s %s" % (train, test))
[2 3] [0 1]
[0 1] [2 3]
```

Here is a visualization of the cross-validation behavior. Note that `KFold` is not affected by classes or groups.



Each fold is constituted by two arrays: the first one is related to the *training set*, and the second one to the *test set*. Thus, one can create the training/test sets using numpy indexing:

```
>>> X = np.array([[0., 0.], [1., 1.], [-1., -1.], [2., 2.]])
>>> y = np.array([0, 1, 0, 1])
>>> X_train, X_test, y_train, y_test = X[train], X[test], y[train], y[test]
```

Repeated K-Fold

RepeatedKFold repeats K-Fold n times. It can be used when one requires to run *KFold* n times, producing different splits in each repetition.

Example of 2-fold K-Fold repeated 2 times:

```
>>> import numpy as np
>>> from sklearn.model_selection import RepeatedKFold
>>> X = np.array([[1, 2], [3, 4], [1, 2], [3, 4]])
>>> random_state = 12883823
>>> rkf = RepeatedKFold(n_splits=2, n_repeats=2, random_state=random_state)
>>> for train, test in rkf.split(X):
...     print("%s %s" % (train, test))
...
[2 3] [0 1]
[0 1] [2 3]
[0 2] [1 3]
[1 3] [0 2]
```

Similarly, *RepeatedStratifiedKFold* repeats Stratified K-Fold n times with different randomization in each repetition.

Leave One Out (LOO)

LeaveOneOut (or LOO) is a simple cross-validation. Each learning set is created by taking all the samples except one, the test set being the sample left out. Thus, for n samples, we have n different training sets and n different tests set. This cross-validation procedure does not waste much data as only one sample is removed from the training set:

```
>>> from sklearn.model_selection import LeaveOneOut

>>> X = [1, 2, 3, 4]
>>> loo = LeaveOneOut()
>>> for train, test in loo.split(X):
...     print("%s %s" % (train, test))
[1 2 3] [0]
[0 2 3] [1]
[0 1 3] [2]
[0 1 2] [3]
```

Potential users of LOO for model selection should weigh a few known caveats. When compared with k-fold cross validation, one builds n models from n samples instead of k models, where $n > k$. Moreover, each is trained on $n - 1$ samples rather than $(k - 1)n/k$. In both ways, assuming k is not too large and $k < n$, LOO is more computationally expensive than k-fold cross validation.

In terms of accuracy, LOO often results in high variance as an estimator for the test error. Intuitively, since $n - 1$ of the n samples are used to build each model, models constructed from folds are virtually identical to each other and to the model built from the entire training set.

However, if the learning curve is steep for the training size in question, then 5- or 10- fold cross validation can overestimate the generalization error.

As a general rule, most authors, and empirical evidence, suggest that 5- or 10- fold cross validation should be preferred to LOO.

Leave P Out (LPO)

LeavePOut is very similar to *LeaveOneOut* as it creates all the possible training/test sets by removing p samples from the complete set. For n samples, this produces $\binom{n}{p}$ train-test pairs. Unlike *LeaveOneOut* and *KFold*, the test sets will overlap for $p > 1$.

Example of Leave-2-Out on a dataset with 4 samples:

```
>>> from sklearn.model_selection import LeavePOut

>>> X = np.ones(4)
>>> lpo = LeavePOut(p=2)
>>> for train, test in lpo.split(X):
...     print("%s %s" % (train, test))
[2 3] [0 1]
[1 3] [0 2]
[1 2] [0 3]
[0 3] [1 2]
[0 2] [1 3]
[0 1] [2 3]
```

Random permutations cross-validation a.k.a. Shuffle & Split

ShuffleSplit

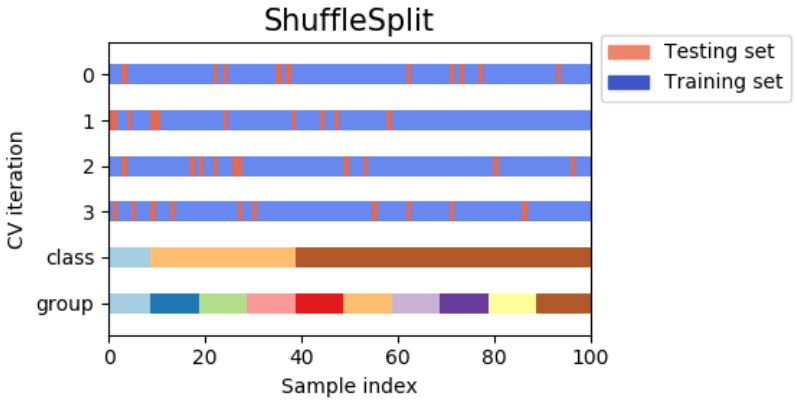
The *ShuffleSplit* iterator will generate a user defined number of independent train / test dataset splits. Samples are first shuffled and then split into a pair of train and test sets.

It is possible to control the randomness for reproducibility of the results by explicitly seeding the `random_state` pseudo random number generator.

Here is a usage example:

```
>>> from sklearn.model_selection import ShuffleSplit
>>> X = np.arange(10)
>>> ss = ShuffleSplit(n_splits=5, test_size=0.25, random_state=0)
>>> for train_index, test_index in ss.split(X):
...     print("%s %s" % (train_index, test_index))
[9 1 6 7 3 0 5] [2 8 4]
[2 9 8 0 6 7 4] [3 5 1]
[4 5 1 0 6 9 7] [2 3 8]
[2 7 5 8 0 3 4] [6 1 9]
[4 1 0 6 8 9 3] [5 2 7]
```

Here is a visualization of the cross-validation behavior. Note that *ShuffleSplit* is not affected by classes or groups.



ShuffleSplit is thus a good alternative to *KFold* cross validation that allows a finer control on the number of iterations and the proportion of samples on each side of the train / test split.

Cross-validation iterators with stratification based on class labels.

Some classification problems can exhibit a large imbalance in the distribution of the target classes: for instance there could be several times more negative samples than positive samples. In such cases it is recommended to use stratified sampling as implemented in *StratifiedKFold* and *StratifiedShuffleSplit* to ensure that relative class frequencies is approximately preserved in each train and validation fold.

Stratified k-fold

StratifiedKFold is a variation of *k-fold* which returns *stratified* folds: each set contains approximately the same percentage of samples of each target class as the complete set.

Here is an example of stratified 3-fold cross-validation on a dataset with 50 samples from two unbalanced classes. We show the number of samples in each class and compare with *KFold*.

```
>>> from sklearn.model_selection import StratifiedKFold, KFold
>>> import numpy as np
>>> X, y = np.ones((50, 1)), np.hstack(([0] * 45, [1] * 5))
>>> skf = StratifiedKFold(n_splits=3)
>>> for train, test in skf.split(X, y):
...     print('train -  {}   |   test -  {}'.format(
```

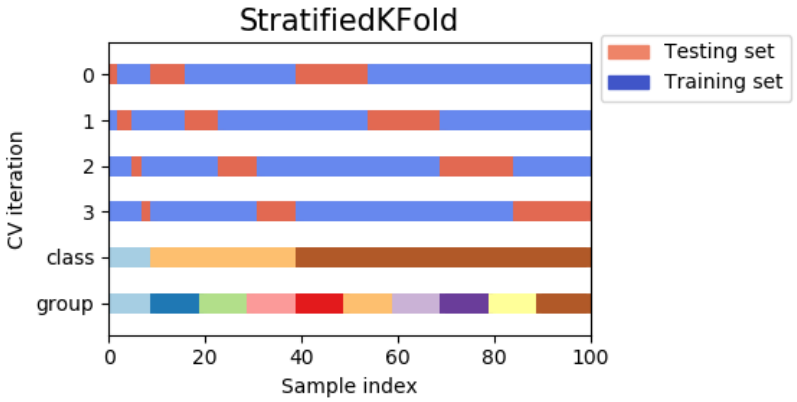
(continues on next page)

(continued from previous page)

```
...          np.bincount(y[train]), np.bincount(y[test])))
train -  [30  3]   |   test -  [15  2]
train -  [30  3]   |   test -  [15  2]
train -  [30  4]   |   test -  [15  1]
>>> kf = KFold(n_splits=3)
>>> for train, test in kf.split(X, y):
...     print('train -  {}   |   test -  {}'.format(
...          np.bincount(y[train]), np.bincount(y[test])))
train -  [28  5]   |   test -  [17]
train -  [28  5]   |   test -  [17]
train -  [34]   |   test -  [11  5]
```

We can see that *StratifiedKFold* preserves the class ratios (approximately 1 / 10) in both train and test dataset.

Here is a visualization of the cross-validation behavior.



RepeatedStratifiedKFold can be used to repeat Stratified K-Fold n times with different randomization in each repetition.

Stratified Shuffle Split

StratifiedShuffleSplit is a variation of *ShuffleSplit*, which returns stratified splits, *i.e* which creates splits by preserving the same percentage for each target class as in the complete set.

Here is a visualization of the cross-validation behavior.

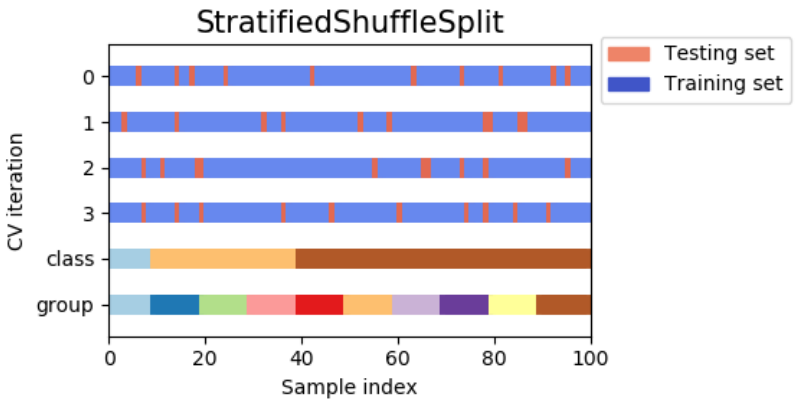
Cross-validation iterators for grouped data.

The i.i.d. assumption is broken if the underlying generative process yield groups of dependent samples.

Such a grouping of data is domain specific. An example would be when there is medical data collected from multiple patients, with multiple samples taken from each patient. And such data is likely to be dependent on the individual group. In our example, the patient id for each sample will be its group identifier.

In this case we would like to know if a model trained on a particular set of groups generalizes well to the unseen groups. To measure this, we need to ensure that all the samples in the validation fold come from groups that are not represented at all in the paired training fold.

The following cross-validation splitters can be used to do that. The grouping identifier for the samples is specified via the `groups` parameter.



Group k-fold

GroupKFold is a variation of k-fold which ensures that the same group is not represented in both testing and training sets. For example if the data is obtained from different subjects with several samples per-subject and if the model is flexible enough to learn from highly person specific features it could fail to generalize to new subjects. *GroupKFold* makes it possible to detect this kind of overfitting situations.

Imagine you have three subjects, each with an associated number from 1 to 3:

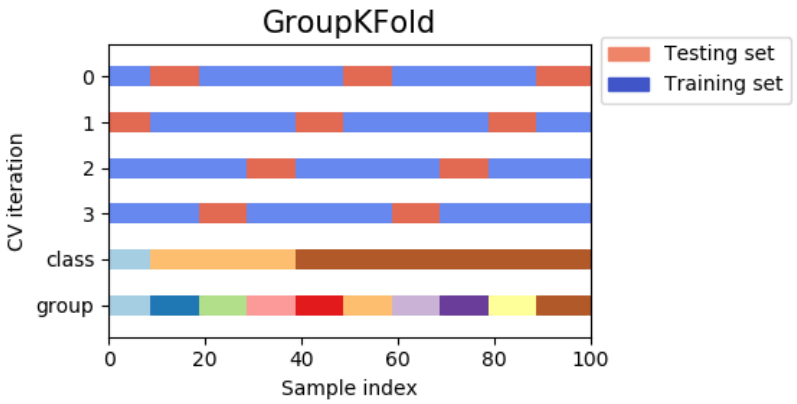
```
>>> from sklearn.model_selection import GroupKFold

>>> X = [0.1, 0.2, 2.2, 2.4, 2.3, 4.55, 5.8, 8.8, 9, 10]
>>> y = ["a", "b", "b", "b", "c", "c", "c", "d", "d", "d"]
>>> groups = [1, 1, 1, 2, 2, 2, 3, 3, 3, 3]

>>> gkf = GroupKFold(n_splits=3)
>>> for train, test in gkf.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
[0 1 2 3 4 5] [6 7 8 9]
[0 1 2 6 7 8 9] [3 4 5]
[3 4 5 6 7 8 9] [0 1 2]
```

Each subject is in a different testing fold, and the same subject is never in both testing and training. Notice that the folds do not have exactly the same size due to the imbalance in the data.

Here is a visualization of the cross-validation behavior.



Leave One Group Out

LeaveOneGroupOut is a cross-validation scheme which holds out the samples according to a third-party provided array of integer groups. This group information can be used to encode arbitrary domain specific pre-defined cross-validation folds.

Each training set is thus constituted by all the samples except the ones related to a specific group.

For example, in the cases of multiple experiments, *LeaveOneGroupOut* can be used to create a cross-validation based on the different experiments: we create a training set using the samples of all the experiments except one:

```
>>> from sklearn.model_selection import LeaveOneGroupOut

>>> X = [1, 5, 10, 50, 60, 70, 80]
>>> y = [0, 1, 1, 2, 2, 2, 2]
>>> groups = [1, 1, 2, 2, 3, 3, 3]
>>> logo = LeaveOneGroupOut()
>>> for train, test in logo.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
[2 3 4 5 6] [0 1]
[0 1 4 5 6] [2 3]
[0 1 2 3] [4 5 6]
```

Another common application is to use time information: for instance the groups could be the year of collection of the samples and thus allow for cross-validation against time-based splits.

Leave P Groups Out

LeavePGroupsOut is similar as *LeaveOneGroupOut*, but removes samples related to P groups for each training/test set.

Example of Leave-2-Group Out:

```
>>> from sklearn.model_selection import LeavePGroupsOut

>>> X = np.arange(6)
>>> y = [1, 1, 1, 2, 2, 2]
>>> groups = [1, 1, 2, 2, 3, 3]
>>> lpgo = LeavePGroupsOut(n_groups=2)
>>> for train, test in lpgo.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
[4 5] [0 1 2 3]
[2 3] [0 1 4 5]
[0 1] [2 3 4 5]
```

Group Shuffle Split

The *GroupShuffleSplit* iterator behaves as a combination of *ShuffleSplit* and *LeavePGroupsOut*, and generates a sequence of randomized partitions in which a subset of groups are held out for each split.

Here is a usage example:

```
>>> from sklearn.model_selection import GroupShuffleSplit

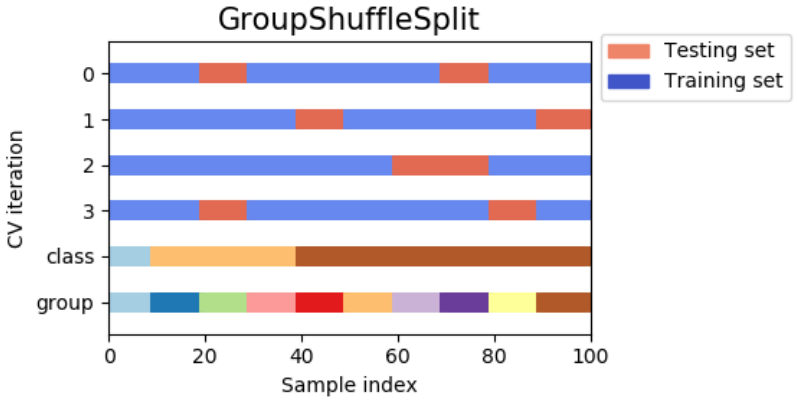
>>> X = [0.1, 0.2, 2.2, 2.4, 2.3, 4.55, 5.8, 0.001]
```

(continues on next page)

(continued from previous page)

```
>>> y = ["a", "b", "b", "b", "c", "c", "c", "a"]
>>> groups = [1, 1, 2, 2, 3, 3, 4, 4]
>>> gss = GroupShuffleSplit(n_splits=4, test_size=0.5, random_state=0)
>>> for train, test in gss.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
...
[0 1 2 3] [4 5 6 7]
[2 3 6 7] [0 1 4 5]
[2 3 4 5] [0 1 6 7]
[4 5 6 7] [0 1 2 3]
```

Here is a visualization of the cross-validation behavior.



This class is useful when the behavior of *LeavePGroupsOut* is desired, but the number of groups is large enough that generating all possible partitions with P groups withheld would be prohibitively expensive. In such a scenario, *GroupShuffleSplit* provides a random sample (with replacement) of the train / test splits generated by *LeavePGroupsOut*.

Predefined Fold-Splits / Validation-Sets

For some datasets, a pre-defined split of the data into training- and validation fold or into several cross-validation folds already exists. Using *PredefinedSplit* it is possible to use these folds e.g. when searching for hyperparameters.

For example, when using a validation set, set the `test_fold` to 0 for all samples that are part of the validation set, and to -1 for all other samples.

Cross validation of time series data

Time series data is characterised by the correlation between observations that are near in time (*autocorrelation*). However, classical cross-validation techniques such as *KFold* and *ShuffleSplit* assume the samples are independent and identically distributed, and would result in unreasonable correlation between training and testing instances (yielding poor estimates of generalisation error) on time series data. Therefore, it is very important to evaluate our model for time series data on the "future" observations least like those that are used to train the model. To achieve this, one solution is provided by *TimeSeriesSplit*.

Time Series Split

TimeSeriesSplit is a variation of *k-fold* which returns first k folds as train set and the $(k+1)$ th fold as test set. Note that unlike standard cross-validation methods, successive training sets are supersets of those that come before them. Also, it adds all surplus data to the first training partition, which is always used to train the model.

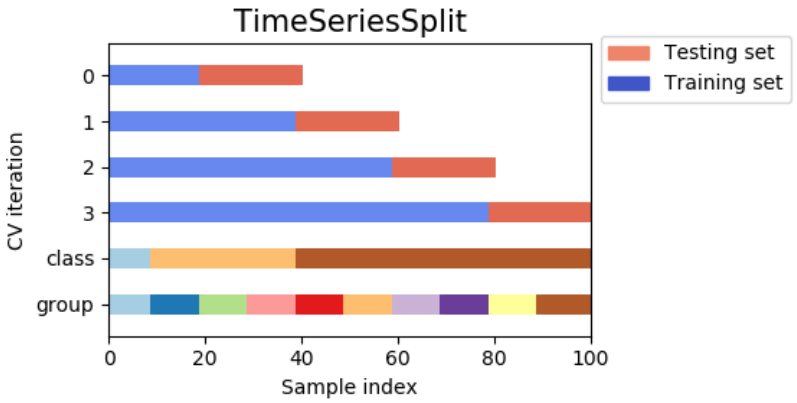
This class can be used to cross-validate time series data samples that are observed at fixed time intervals.

Example of 3-split time series cross-validation on a dataset with 6 samples:

```
>>> from sklearn.model_selection import TimeSeriesSplit

>>> X = np.array([[1, 2], [3, 4], [1, 2], [3, 4], [1, 2], [3, 4]])
>>> y = np.array([1, 2, 3, 4, 5, 6])
>>> tscv = TimeSeriesSplit(n_splits=3)
>>> print(tscv)
TimeSeriesSplit(max_train_size=None, n_splits=3)
>>> for train, test in tscv.split(X):
...     print("%s %s" % (train, test))
[0 1 2] [3]
[0 1 2 3] [4]
[0 1 2 3 4] [5]
```

Here is a visualization of the cross-validation behavior.



A note on shuffling

If the data ordering is not arbitrary (e.g. samples with the same class label are contiguous), shuffling it first may be essential to get a meaningful cross- validation result. However, the opposite may be true if the samples are not independently and identically distributed. For example, if samples correspond to news articles, and are ordered by their time of publication, then shuffling the data will likely lead to a model that is overfit and an inflated validation score: it will be tested on samples that are artificially similar (close in time) to training samples.

Some cross validation iterators, such as *KFold*, have an inbuilt option to shuffle the data indices before splitting them. Note that:

- This consumes less memory than shuffling the data directly.
- By default no shuffling occurs, including for the (stratified) K fold cross- validation performed by specifying `cv=some_integer` to *cross_val_score*, grid search, etc. Keep in mind that *train_test_split* still returns a random split.

- The `random_state` parameter defaults to `None`, meaning that the shuffling will be different every time `KFold(..., shuffle=True)` is iterated. However, `GridSearchCV` will use the same shuffling for each set of parameters validated by a single call to its `fit` method.
- To get identical results for each split, set `random_state` to an integer.

Cross validation and model selection

Cross validation iterators can also be used to directly perform model selection using Grid Search for the optimal hyperparameters of the model. This is the topic of the next section: *Tuning the hyper-parameters of an estimator*.

4.3.2 Tuning the hyper-parameters of an estimator

Hyper-parameters are parameters that are not directly learnt within estimators. In scikit-learn they are passed as arguments to the constructor of the estimator classes. Typical examples include `C`, `kernel` and `gamma` for Support Vector Classifier, `alpha` for Lasso, etc.

It is possible and recommended to search the hyper-parameter space for the best *cross validation* score.

Any parameter provided when constructing an estimator may be optimized in this manner. Specifically, to find the names and current values for all parameters for a given estimator, use:

```
estimator.get_params()
```

A search consists of:

- an estimator (regressor or classifier such as `sklearn.svm.SVC()`);
- a parameter space;
- a method for searching or sampling candidates;
- a cross-validation scheme; and
- a *score function*.

Some models allow for specialized, efficient parameter search strategies, *outlined below*. Two generic approaches to sampling search candidates are provided in scikit-learn: for given values, *`GridSearchCV`* exhaustively considers all parameter combinations, while *`RandomizedSearchCV`* can sample a given number of candidates from a parameter space with a specified distribution. After describing these tools we detail *best practice* applicable to both approaches.

Note that it is common that a small subset of those parameters can have a large impact on the predictive or computation performance of the model while others can be left to their default values. It is recommended to read the docstring of the estimator class to get a finer understanding of their expected behavior, possibly by reading the enclosed reference to the literature.

Exhaustive Grid Search

The grid search provided by *`GridSearchCV`* exhaustively generates candidates from a grid of parameter values specified with the `param_grid` parameter. For instance, the following `param_grid`:

```
param_grid = [
  {'C': [1, 10, 100, 1000], 'kernel': ['linear']},
  {'C': [1, 10, 100, 1000], 'gamma': [0.001, 0.0001], 'kernel': ['rbf']},
 ]
```

specifies that two grids should be explored: one with a linear kernel and C values in [1, 10, 100, 1000], and the second one with an RBF kernel, and the cross-product of C values ranging in [1, 10, 100, 1000] and gamma values in [0.001, 0.0001].

The *GridSearchCV* instance implements the usual estimator API: when "fitting" it on a dataset all the possible combinations of parameter values are evaluated and the best combination is retained.

Examples:

- See *Parameter estimation using grid search with cross-validation* for an example of Grid Search computation on the digits dataset.
- See *Sample pipeline for text feature extraction and evaluation* for an example of Grid Search coupling parameters from a text documents feature extractor (n-gram count vectorizer and TF-IDF transformer) with a classifier (here a linear SVM trained with SGD with either elastic net or L2 penalty) using a `pipeline.Pipeline` instance.
- See *Nested versus non-nested cross-validation* for an example of Grid Search within a cross validation loop on the iris dataset. This is the best practice for evaluating the performance of a model with grid search.
- See *Demonstration of multi-metric evaluation on cross_val_score and GridSearchCV* for an example of *GridSearchCV* being used to evaluate multiple metrics simultaneously.
- See *Balance model complexity and cross-validated score* for an example of using `refit=callable` interface in *GridSearchCV*. The example shows how this interface adds certain amount of flexibility in identifying the "best" estimator. This interface can also be used in multiple metrics evaluation.

Randomized Parameter Optimization

While using a grid of parameter settings is currently the most widely used method for parameter optimization, other search methods have more favourable properties. *RandomizedSearchCV* implements a randomized search over parameters, where each setting is sampled from a distribution over possible parameter values. This has two main benefits over an exhaustive search:

- A budget can be chosen independent of the number of parameters and possible values.
- Adding parameters that do not influence the performance does not decrease efficiency.

Specifying how parameters should be sampled is done using a dictionary, very similar to specifying parameters for *GridSearchCV*. Additionally, a computation budget, being the number of sampled candidates or sampling iterations, is specified using the `n_iter` parameter. For each parameter, either a distribution over possible values or a list of discrete choices (which will be sampled uniformly) can be specified:

```
{'C': scipy.stats.expon(scale=100), 'gamma': scipy.stats.expon(scale=.1),
  'kernel': ['rbf'], 'class_weight':['balanced', None]}
```

This example uses the `scipy.stats` module, which contains many useful distributions for sampling parameters, such as `expon`, `gamma`, `uniform` or `randint`.

In principle, any function can be passed that provides a `rvs` (random variate sample) method to sample a value. A call to the `rvs` function should provide independent random samples from possible parameter values on consecutive calls.

Warning: The distributions in `scipy.stats` prior to version scipy 0.16 do not allow specifying a random state. Instead, they use the global numpy random state, that can be seeded via `np.random.seed` or set using `np.random.set_state`. However, beginning scikit-learn 0.18, the *`sklearn.model_selection`* module sets the random state provided by the user if scipy >= 0.16 is also available.

For continuous parameters, such as `C` above, it is important to specify a continuous distribution to take full advantage of the randomization. This way, increasing `n_iter` will always lead to a finer search.

A continuous log-uniform random variable is available through `loguniform`. This is a continuous version of log-spaced parameters. For example to specify `C` above, `loguniform(1, 100)` can be used instead of `[1, 10, 100]` or `np.logspace(0, 2, num=1000)`. This is an alias to SciPy's stats.reciprocal.

Mirroring the example above in grid search, we can specify a continuous random variable that is log-uniformly distributed between `1e0` and `1e3`:

```
from sklearn.utils.fixes import loguniform
{'C': loguniform(1e0, 1e3),
 'gamma': loguniform(1e-4, 1e-3),
 'kernel': ['rbf'],
 'class_weight':['balanced', None]}
```

Examples:

- *Comparing randomized search and grid search for hyperparameter estimation* compares the usage and efficiency of randomized search and grid search.

Tips for parameter search

Specifying an objective metric

By default, parameter search uses the `score` function of the estimator to evaluate a parameter setting. These are the *`sklearn.metrics.accuracy_score`* for classification and *`sklearn.metrics.r2_score`* for regression. For some applications, other scoring functions are better suited (for example in unbalanced classification, the accuracy score is often uninformative). An alternative scoring function can be specified via the `scoring` parameter to *`GridSearchCV`*, *`RandomizedSearchCV`* and many of the specialized cross-validation tools described below. See *The scoring parameter: defining model evaluation rules* for more details.

Specifying multiple metrics for evaluation

`GridSearchCV` and `RandomizedSearchCV` allow specifying multiple metrics for the `scoring` parameter.

Multimetric scoring can either be specified as a list of strings of predefined scores names or a dict mapping the scorer name to the scorer function and/or the predefined scorer name(s). See *Using multiple metric evaluation* for more details.

When specifying multiple metrics, the `refit` parameter must be set to the metric (string) for which the `best_params_` will be found and used to build the `best_estimator_` on the whole dataset. If the search should not be refit, set `refit=False`. Leaving refit to the default value `None` will result in an error when using multiple metrics.

See *Demonstration of multi-metric evaluation on cross_val_score and GridSearchCV* for an example usage.

Composite estimators and parameter spaces

GridSearchCV and *RandomizedSearchCV* allow searching over parameters of composite or nested estimators such as *Pipeline*, *ColumnTransformer*, *VotingClassifier* or *CalibratedClassifierCV* using a dedicated `<estimator>__<parameter>` syntax:

```
>>> from sklearn.model_selection import GridSearchCV
>>> from sklearn.calibration import CalibratedClassifierCV
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.datasets import make_moons
>>> X, y = make_moons()
>>> calibrated_forest = CalibratedClassifierCV(
...     base_estimator=RandomForestClassifier(n_estimators=10))
>>> param_grid = {
...     'base_estimator__max_depth': [2, 4, 6, 8]}
>>> search = GridSearchCV(calibrated_forest, param_grid, cv=5)
>>> search.fit(X, y)
GridSearchCV(cv=5,
             estimator=CalibratedClassifierCV(...),
             param_grid={'base_estimator__max_depth': [2, 4, 6, 8]})
```

Here, `<estimator>` is the parameter name of the nested estimator, in this case `base_estimator`. If the meta-estimator is constructed as a collection of estimators as in `pipeline.Pipeline`, then `<estimator>` refers to the name of the estimator, see *Nested parameters*. In practice, there can be several levels of nesting:

```
>>> from sklearn.pipeline import Pipeline
>>> from sklearn.feature_selection import SelectKBest
>>> pipe = Pipeline([
...     ('select', SelectKBest()),
...     ('model', calibrated_forest)])
>>> param_grid = {
...     'select__k': [1, 2],
...     'model__base_estimator__max_depth': [2, 4, 6, 8]}
>>> search = GridSearchCV(pipe, param_grid, cv=5).fit(X, y)
```

Model selection: development and evaluation

Model selection by evaluating various parameter settings can be seen as a way to use the labeled data to "train" the parameters of the grid.

When evaluating the resulting model it is important to do it on held-out samples that were not seen during the grid search process: it is recommended to split the data into a **development set** (to be fed to the `GridSearchCV` instance) and an **evaluation set** to compute performance metrics.

This can be done by using the *train_test_split* utility function.

Parallelism

GridSearchCV and *RandomizedSearchCV* evaluate each parameter setting independently. Computations can be run in parallel if your OS supports it, by using the keyword `n_jobs=-1`. See function signature for more details.

Robustness to failure

Some parameter settings may result in a failure to `fit` one or more folds of the data. By default, this will cause the entire search to fail, even if some parameter settings could be fully evaluated. Setting `error_score=0` (or `=np.NaN`) will make the procedure robust to such failure, issuing a warning and setting the score for that fold to 0 (or `NaN`), but completing the search.

Alternatives to brute force parameter search

Model specific cross-validation

Some models can fit data for a range of values of some parameter almost as efficiently as fitting the estimator for a single value of the parameter. This feature can be leveraged to perform a more efficient cross-validation used for model selection of this parameter.

The most common parameter amenable to this strategy is the parameter encoding the strength of the regularizer. In this case we say that we compute the **regularization path** of the estimator.

Here is the list of such models:

linear_model.ElasticNetCV([l1_ratio, eps, ...])	Elastic Net model with iterative fitting along a regularization path.
linear_model.LarsCV([fit_intercept, ...])	Cross-validated Least Angle Regression model.
linear_model.LassoCV([eps, n_alphas, ...])	Lasso linear model with iterative fitting along a regularization path.
linear_model.LassoLarsCV([fit_intercept, ...])	Cross-validated Lasso, using the LARS algorithm.
linear_model.LogisticRegressionCV([Cs, ...])	Logistic Regression CV (aka logit, MaxEnt) classifier.
linear_model.MultiTaskElasticNetCV([...])	Multi-task L1/L2 ElasticNet with built-in cross-validation.
linear_model.MultiTaskLassoCV([eps, ...])	Multi-task Lasso model trained with L1/L2 mixed-norm as regularizer.
linear_model.OrthogonalMatchingPursuitCV([...])	Cross-validated Orthogonal Matching Pursuit model (OMP).
linear_model.RidgeCV([alphas, ...])	Ridge regression with built-in cross-validation.
linear_model.RidgeClassifierCV([alphas, ...])	Ridge classifier with built-in cross-validation.

sklearn.linear_model.ElasticNetCV

class sklearn.linear_model.**ElasticNetCV**(*l1_ratio=0.5*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *fit_intercept=True*, *normalize=False*, *precompute='auto'*, *max_iter=1000*, *tol=0.0001*, *cv=None*, *copy_X=True*, *verbose=0*, *n_jobs=None*, *positive=False*, *random_state=None*, *selection='cyclic'*)

Elastic Net model with iterative fitting along a regularization path.

See glossary entry for *cross-validation estimator*.

Read more in the *User Guide*.

Parameters

l1_ratio [float or array of floats, optional] float between 0 and 1 passed to ElasticNet (scaling between l1 and l2 penalties). For `l1_ratio = 0` the penalty is an L2 penalty. For `l1_ratio = 1` it is an L1 penalty. For `0 < l1_ratio < 1`, the penalty is a combination of L1 and L2 This parameter can be a list, in which case the different values are tested by cross-validation and the one giving the best prediction score is used. Note that a good choice of list of values for l1_ratio is often to put more values close to 1 (i.e. Lasso) and less close to 0 (i.e. Ridge), as in `[.1, .5, .7, .9, .95, .99, 1]`

eps [float, optional] Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`.

n_alphas [int, optional] Number of alphas along the regularization path, used for each l1_ratio.

alphas [numpy array, optional] List of alphas where to compute the models. If None alphas are set automatically

fit_intercept [boolean] whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

normalize [boolean, optional, default False] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use *`sklearn.preprocessing.StandardScaler`* before calling `fit` on an estimator with `normalize=False`.

precompute [True | False | 'auto' | array-like] Whether to use a precomputed Gram matrix to speed up calculations. If set to `'auto'` let us decide. The Gram matrix can also be passed as argument.

max_iter [int, optional] The maximum number of iterations

tol [float, optional] The tolerance for the optimization: if the updates are smaller than `tol`, the optimization code checks the dual gap for optimality and continues until it is smaller than `tol`.

cv [int, cross-validation generator or an iterable, optional] Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 5-fold cross-validation,
- integer, to specify the number of folds.
- *CV splitter*,
- An iterable yielding (train, test) splits as arrays of indices.

For integer/None inputs, `KFold` is used.

Refer *User Guide* for the various cross-validation strategies that can be used here.

Changed in version 0.22: `cv` default value if None changed from 3-fold to 5-fold.

copy_X [boolean, optional, default True] If `True`, X will be copied; else, it may be overwritten.

verbose [bool or integer] Amount of verbosity.

n_jobs [int or None, optional (default=None)] Number of CPUs to use during the cross validation. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

positive [bool, optional] When set to `True`, forces the coefficients to be positive.

random_state [int, RandomState instance or None, optional, default None] The seed of the pseudo random number generator that selects a random feature to update. If int, random_state is the seed used by the random number generator; If RandomState instance, random_state is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`. Used when `selection` == 'random'.

selection [str, default 'cyclic'] If set to 'random', a random coefficient is updated every iteration rather than looping over features sequentially by default. This (setting to 'random') often leads to significantly faster convergence especially when tol is higher than 1e-4.

Attributes

alpha_ [float] The amount of penalization chosen by cross validation

l1_ratio_ [float] The compromise between l1 and l2 penalization chosen by cross validation

coef_ [array, shape (n_features,) | (n_targets, n_features)] Parameter vector (w in the cost function formula),

intercept_ [float | array, shape (n_targets, n_features)] Independent term in the decision function.

mse_path_ [array, shape (n_l1_ratio, n_alpha, n_folds)] Mean square error for the test set on each fold, varying l1_ratio and alpha.

alphas_ [numpy array, shape (n_alphas,) or (n_l1_ratio, n_alphas)] The grid of alphas used for fitting, for each l1_ratio.

n_iter_ [int] number of iterations run by the coordinate descent solver to reach the specified tolerance for the optimal alpha.

enet_path

ElasticNet

Notes

For an example, see *examples/linear_model/plot_lasso_model_selection.py*.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

The parameter l1_ratio corresponds to alpha in the glmnet R package while alpha corresponds to the lambda parameter in glmnet. More specifically, the optimization objective is:

```
1 / (2 * n_samples) * ||y - Xw||^2_2
+ alpha * l1_ratio * ||w||_1
+ 0.5 * alpha * (1 - l1_ratio) * ||w||^2_2
```

If you are interested in controlling the L1 and L2 penalty separately, keep in mind that this is equivalent to:

```
a * L1 + b * L2
```

for:

```
alpha = a + b and l1_ratio = a / (a + b).
```

Examples

```
>>> from sklearn.linear_model import ElasticNetCV
>>> from sklearn.datasets import make_regression
```

```
>>> X, y = make_regression(n_features=2, random_state=0)
>>> regr = ElasticNetCV(cv=5, random_state=0)
>>> regr.fit(X, y)
ElasticNetCV(cv=5, random_state=0)
>>> print(regr.alpha_)
0.199...
>>> print(regr.intercept_)
0.398...
>>> print(regr.predict([[0, 0]]))
[0.398...]
```

Methods

fit(self, X, y)	Fit linear model with coordinate descent
get_params(self[, deep])	Get parameters for this estimator.
path(X, y[, l1_ratio, eps, n_alphas, ...])	Compute elastic net path with coordinate descent.
predict(self, X)	Predict using the linear model.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__ (*self*, *l1_ratio=0.5*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *fit_intercept=True*, *normalize=False*, *precompute='auto'*, *max_iter=1000*, *tol=0.0001*, *cv=None*, *copy_X=True*, *verbose=0*, *n_jobs=None*, *positive=False*, *random_state=None*, *selection='cyclic'*)

Initialize self. See help(type(self)) for accurate signature.

fit (*self*, *X*, *y*)

Fit linear model with coordinate descent

Fit is on grid of alphas and best alpha estimated by cross-validation.

Parameters

X [{array-like}, shape (n_samples, n_features)] Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If y is mono-output, X can be sparse.

y [array-like, shape (n_samples,) or (n_samples, n_targets)] Target values

get_params(*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

static path(*X*, *y*, *l1_ratio=0.5*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *precompute='auto'*, *Xy=None*, *copy_X=True*, *coef_init=None*, *verbose=False*, *return_n_iter=False*, *positive=False*, *check_input=True*, ***params*)
Compute elastic net path with coordinate descent.

The elastic net optimization function varies for mono and multi-outputs.

For mono-output tasks it is:

```
1 / (2 * n_samples) * ||y - Xw||^2_2
+ alpha * l1_ratio * ||w||_1
+ 0.5 * alpha * (1 - l1_ratio) * ||w||^2_2
```

For multi-output tasks it is:

```
(1 / (2 * n_samples)) * ||Y - XW||^Fro_2
+ alpha * l1_ratio * ||W||_21
+ 0.5 * alpha * (1 - l1_ratio) * ||W||_Fro^2
```

Where:

```
||W||_21 = \sum_i \sqrt{\sum_j w_{ij}^2}
```

i.e. the sum of norm of each row.

Read more in the *User Guide*.

Parameters

X [{array-like}, shape (n_samples, n_features)] Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If `y` is mono-output then `X` can be sparse.

y [ndarray, shape (n_samples,) or (n_samples, n_outputs)] Target values.

l1_ratio [float, optional] Number between 0 and 1 passed to elastic net (scaling between l1 and l2 penalties). `l1_ratio=1` corresponds to the Lasso.

eps [float] Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`.

n_alphas [int, optional] Number of alphas along the regularization path.

alphas [ndarray, optional] List of alphas where to compute the models. If None alphas are set automatically.

precompute [True | False | 'auto' | array-like] Whether to use a precomputed Gram matrix to speed up calculations. If set to `'auto'` let us decide. The Gram matrix can also be passed as argument.

Xy [array-like, optional] Xy = np.dot(X.T, y) that can be precomputed. It is useful only when the Gram matrix is precomputed.

copy_X [bool, optional, default True] If `True`, X will be copied; else, it may be overwritten.

coef_init [array, shape (n_features,) | None] The initial values of the coefficients.

verbose [bool or int] Amount of verbosity.

return_n_iter [bool] Whether to return the number of iterations or not.

positive [bool, default False] If set to True, forces coefficients to be positive. (Only allowed when `y.ndim == 1`).

check_input [bool, default True] Skip input validation checks, including the Gram matrix when provided assuming there are handled by the caller when check_input=False.

****params** [kwargs] Keyword arguments passed to the coordinate descent solver.

Returns

alphas [array, shape (n_alphas,)] The alphas along the path where models are computed.

coefs [array, shape (n_features, n_alphas) or (n_outputs, n_features, n_alphas)] Coefficients along the path.

dual_gaps [array, shape (n_alphas,)] The dual gaps at the end of the optimization for each alpha.

n_iters [array-like, shape (n_alphas,)] The number of iterations taken by the coordinate descent optimizer to reach the specified tolerance for each alpha. (Is returned when `return_n_iter` is set to True).

See also:

MultiTaskElasticNet

MultiTaskElasticNetCV

ElasticNet

ElasticNetCV

Notes

For an example, see *examples/linear_model/plot_lasso_coordinate_descent_path.py*.

predict (*self*, *X*)

Predict using the linear model.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape (n_samples,)] Returns predicted values.

score (*self*, *X*, *y*, *sample_weight=None*)

Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params(*self*, ***params*)
Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

sklearn.linear_model.LarsCV

class sklearn.linear_model.**LarsCV**(*fit_intercept=True*, *verbose=False*, *max_iter=500*, *normalize=True*, *precompute='auto'*, *cv=None*, *max_n_alphas=1000*, *n_jobs=None*, *eps=2.220446049250313e-16*, *copy_X=True*)
Cross-validated Least Angle Regression model.

See glossary entry for *cross-validation estimator*.

Read more in the *User Guide*.

Parameters

fit_intercept [bool, default=True] whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

verbose [bool or int, default=False] Sets the verbosity amount

max_iter [int, default=500] Maximum number of iterations to perform.

normalize [bool, default=True] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use *`sklearn.preprocessing.StandardScaler`* before calling `fit` on an estimator with `normalize=False`.

precompute [bool, 'auto' or array-like , default='auto'] Whether to use a precomputed Gram matrix to speed up calculations. If set to `'auto'` let us decide. The Gram matrix cannot be passed as argument since we will use only subsets of X.

cv [int, cross-validation generator or an iterable, default=None] Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 5-fold cross-validation,
- integer, to specify the number of folds.
- *CV splitter*,
- An iterable yielding (train, test) splits as arrays of indices.

For integer/None inputs, `KFold` is used.

Refer *User Guide* for the various cross-validation strategies that can be used here.

Changed in version 0.22: `cv` default value if None changed from 3-fold to 5-fold.

max_n_alphas [int, default=1000] The maximum number of points on the path used to compute the residuals in the cross-validation

n_jobs [int or None, default=None] Number of CPUs to use during the cross validation. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

eps [float, optional] The machine-precision regularization in the computation of the Cholesky diagonal factors. Increase this for very ill-conditioned systems. By default, `np.finfo(np.float).eps` is used.

copy_X [bool, default=True] If `True`, X will be copied; else, it may be overwritten.

Attributes

coef_ [array-like of shape (n_features,)] parameter vector (w in the formulation formula)

intercept_ [float] independent term in decision function

coef_path_ [array-like of shape (n_features, n_alphas)] the varying values of the coefficients along the path

alpha_ [float] the estimated regularization parameter alpha

alphas_ [array-like of shape (n_alphas,)] the different values of alpha along the path

cv_alphas_ [array-like of shape (n_cv_alphas,)] all the values of alpha along the path for the different folds

mse_path_ [array-like of shape (n_folds, n_cv_alphas)] the mean square error on left-out for each fold along the path (alpha values given by `cv_alphas`)

n_iter_ [array-like or int] the number of iterations run by Lars with the optimal alpha.

See also:

`lars_path`*, *`LassoLars`*, *`LassoLarsCV`

Examples

```
>>> from sklearn.linear_model import LarsCV
>>> from sklearn.datasets import make_regression
>>> X, y = make_regression(n_samples=200, noise=4.0, random_state=0)
>>> reg = LarsCV(cv=5).fit(X, y)
>>> reg.score(X, y)
0.9996...
>>> reg.alpha_
0.0254...
>>> reg.predict(X[:1,])
array([154.0842...])
```

Methods

fit(self, X, y)	Fit the model using X, y as training data.
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict using the linear model.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__ (*self*, *fit_intercept=True*, *verbose=False*, *max_iter=500*, *normalize=True*, *precompute='auto'*, *cv=None*, *max_n_alphas=1000*, *n_jobs=None*, *eps=2.220446049250313e-16*, *copy_X=True*)
Initialize self. See help(type(self)) for accurate signature.

fit (*self*, *X*, *y*)
Fit the model using X, y as training data.

Parameters

X [array-like of shape (n_samples, n_features)] Training data.

y [array-like of shape (n_samples,)] Target values.

Returns

self [object] returns an instance of self.

get_params (*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict (*self*, *X*)
Predict using the linear model.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape (n_samples,)] Returns predicted values.

score(*self*, *X*, *y*, *sample_weight=None*)

Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params(*self*, ***params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

sklearn.linear_model.LassoCV

class sklearn.linear_model.**LassoCV**(*eps=0.001*, *n_alphas=100*, *alphas=None*, *fit_intercept=True*, *normalize=False*, *precompute='auto'*, *max_iter=1000*, *tol=0.0001*, *copy_X=True*, *cv=None*, *verbose=False*, *n_jobs=None*, *positive=False*, *random_state=None*, *selection='cyclic'*)

Lasso linear model with iterative fitting along a regularization path.

See glossary entry for *cross-validation estimator*.

The best model is selected by cross-validation.

The optimization objective for Lasso is:

```
(1 / (2 * n_samples)) * ||y - Xw||^2_2 + alpha * ||w||_1
```

Read more in the *User Guide*.

Parameters

eps [float, optional] Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`.

n_alphas [int, optional] Number of alphas along the regularization path

alphas [numpy array, optional] List of alphas where to compute the models. If `None` alphas are set automatically

fit_intercept [boolean, default True] whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

normalize [boolean, optional, default False] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use *`sklearn.preprocessing.StandardScaler`* before calling `fit` on an estimator with `normalize=False`.

precompute [True | False | 'auto' | array-like] Whether to use a precomputed Gram matrix to speed up calculations. If set to `'auto'` let us decide. The Gram matrix can also be passed as argument.

max_iter [int, optional] The maximum number of iterations

tol [float, optional] The tolerance for the optimization: if the updates are smaller than `tol`, the optimization code checks the dual gap for optimality and continues until it is smaller than `tol`.

copy_X [boolean, optional, default True] If `True`, X will be copied; else, it may be overwritten.

cv [int, cross-validation generator or an iterable, optional] Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 5-fold cross-validation,
- integer, to specify the number of folds.
- *CV splitter*,
- An iterable yielding (train, test) splits as arrays of indices.

For integer/None inputs, `KFold` is used.

Refer *User Guide* for the various cross-validation strategies that can be used here.

Changed in version 0.22: `cv` default value if None changed from 3-fold to 5-fold.

verbose [bool or integer] Amount of verbosity.

n_jobs [int or None, optional (default=None)] Number of CPUs to use during the cross validation. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

positive [bool, optional] If positive, restrict regression coefficients to be positive

random_state [int, RandomState instance or None, optional, default None] The seed of the pseudo random number generator that selects a random feature to update. If int, random_state is the seed used by the random number generator; If RandomState instance,

random_state is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`. Used when `selection` == 'random'.

selection [str, default 'cyclic'] If set to 'random', a random coefficient is updated every iteration rather than looping over features sequentially by default. This (setting to 'random') often leads to significantly faster convergence especially when tol is higher than 1e-4.

Attributes

alpha_ [float] The amount of penalization chosen by cross validation

coef_ [array, shape (n_features,) | (n_targets, n_features)] parameter vector (w in the cost function formula)

intercept_ [float | array, shape (n_targets,)] independent term in decision function.

mse_path_ [array, shape (n_alphas, n_folds)] mean square error for the test set on each fold, varying alpha

alphas_ [numpy array, shape (n_alphas,)] The grid of alphas used for fitting

dual_gap_ [ndarray, shape ()] The dual gap at the end of the optimization for the optimal alpha (`alpha_`).

n_iter_ [int] number of iterations run by the coordinate descent solver to reach the specified tolerance for the optimal alpha.

LassoLars

Lasso

LassoLarsCV

Notes

For an example, see *examples/linear_model/plot_lasso_model_selection.py*.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

Examples

```
>>> from sklearn.linear_model import LassoCV
>>> from sklearn.datasets import make_regression
>>> X, y = make_regression(noise=4, random_state=0)
>>> reg = LassoCV(cv=5, random_state=0).fit(X, y)
>>> reg.score(X, y)
0.9993...
>>> reg.predict(X[:1,])
array([-78.4951...])
```

Methods

fit(self, X, y)	Fit linear model with coordinate descent
get_params(self[, deep])	Get parameters for this estimator.
path(X, y[, eps, n_alphas, alphas, ...])	Compute Lasso path with coordinate descent
predict(self, X)	Predict using the linear model.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__(*self*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *fit_intercept=True*, *normalize=False*, *precompute='auto'*, *max_iter=1000*, *tol=0.0001*, *copy_X=True*, *cv=None*, *verbose=False*, *n_jobs=None*, *positive=False*, *random_state=None*, *selection='cyclic'*)

Initialize self. See help(type(self)) for accurate signature.

fit(*self*, *X*, *y*)

Fit linear model with coordinate descent

Fit is on grid of alphas and best alpha estimated by cross-validation.

Parameters

X [{array-like}, shape (n_samples, n_features)] Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If y is mono-output, X can be sparse.

y [array-like, shape (n_samples,) or (n_samples, n_targets)] Target values

get_params(*self*, *deep=True*)

Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

static path(*X*, *y*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *precompute='auto'*, *Xy=None*, *copy_X=True*, *coef_init=None*, *verbose=False*, *return_n_iter=False*, *positive=False*, ***params*)

Compute Lasso path with coordinate descent

The Lasso optimization function varies for mono and multi-outputs.

For mono-output tasks it is:

```
(1 / (2 * n_samples)) * ||y - Xw||^2_2 + alpha * ||w||_1
```

For multi-output tasks it is:

```
(1 / (2 * n_samples)) * ||Y - XW||^2_Fro + alpha * ||W||_21
```

Where:

```
||W||_21 = \sum_i \sqrt{\sum_j w_{ij}^2}
```

i.e. the sum of norm of each row.

Read more in the *User Guide*.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If `y` is mono-output then `X` can be sparse.

y [ndarray, shape (n_samples,), or (n_samples, n_outputs)] Target values

eps [float, optional] Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`

n_alphas [int, optional] Number of alphas along the regularization path

alphas [ndarray, optional] List of alphas where to compute the models. If `None` alphas are set automatically

precompute [True | False | 'auto' | array-like] Whether to use a precomputed Gram matrix to speed up calculations. If set to `'auto'` let us decide. The Gram matrix can also be passed as argument.

Xy [array-like, optional] Xy = np.dot(X.T, y) that can be precomputed. It is useful only when the Gram matrix is precomputed.

copy_X [boolean, optional, default True] If `True`, X will be copied; else, it may be overwritten.

coef_init [array, shape (n_features,) | None] The initial values of the coefficients.

verbose [bool or integer] Amount of verbosity.

return_n_iter [bool] whether to return the number of iterations or not.

positive [bool, default False] If set to True, forces coefficients to be positive. (Only allowed when `y.ndim == 1`).

****params** [kwargs] keyword arguments passed to the coordinate descent solver.

Returns

alphas [array, shape (n_alphas,)] The alphas along the path where models are computed.

coefs [array, shape (n_features, n_alphas) or (n_outputs, n_features, n_alphas)] Coefficients along the path.

dual_gaps [array, shape (n_alphas,)] The dual gaps at the end of the optimization for each alpha.

n_iters [array-like, shape (n_alphas,)] The number of iterations taken by the coordinate descent optimizer to reach the specified tolerance for each alpha.

See also:

lars_path

Lasso

LassoLars

LassoCV

LassoLarsCV

sklearn.decomposition.sparse_encode

Notes

For an example, see *examples/linear_model/plot_lasso_coordinate_descent_path.py*.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

Note that in certain cases, the Lars solver may be significantly faster to implement this functionality. In particular, linear interpolation can be used to retrieve model coefficients between the values output by lars_path

Examples

Comparing lasso_path and lars_path with interpolation:

```
>>> X = np.array([[1, 2, 3.1], [2.3, 5.4, 4.3]]).T
>>> y = np.array([1, 2, 3.1])
>>> # Use lasso_path to compute a coefficient path
>>> _, coef_path, _ = lasso_path(X, y, alphas=[5., 1., .5])
>>> print(coef_path)
[[0.          0.          0.46874778]
 [0.2159048   0.4425765   0.23689075]]
```

```
>>> # Now use lars_path and 1D linear interpolation to compute the
>>> # same path
>>> from sklearn.linear_model import lars_path
>>> alphas, active, coef_path_lars = lars_path(X, y, method='lasso')
>>> from scipy import interpolate
>>> coef_path_continuous = interpolate.interp1d(alphas[::-1],
...                                             coef_path_lars[:, ::-1])
>>> print(coef_path_continuous([5., 1., .5]))
[[0.          0.          0.46915237]
 [0.2159048   0.4425765   0.23668876]]
```

predict (*self*, *X*)

Predict using the linear model.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape (n_samples,)] Returns predicted values.

score (*self*, *X*, *y*, *sample_weight=None*)

Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params(*self*, ***params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

Examples using `sklearn.linear_model.LassoCV`

- *Combine predictors using stacking*
- *Feature selection using SelectFromModel and LassoCV*
- *Lasso model selection: Cross-Validation / AIC / BIC*
- *Cross-validation on diabetes Dataset Exercise*

sklearn.linear_model.LassoLarsCV

class sklearn.linear_model.**LassoLarsCV**(*fit_intercept=True*, *verbose=False*, *max_iter=500*, *normalize=True*, *precompute='auto'*, *cv=None*, *max_n_alphas=1000*, *n_jobs=None*, *eps=2.220446049250313e-16*, *copy_X=True*, *positive=False*)

Cross-validated Lasso, using the LARS algorithm.

See glossary entry for *cross-validation estimator*.

The optimization objective for Lasso is:

```
(1 / (2 * n_samples)) * ||y - Xw||^2_2 + alpha * ||w||_1
```

Read more in the *User Guide*.

Parameters

fit_intercept [bool, default=True] whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

verbose [bool or int, default=False] Sets the verbosity amount

max_iter [int, default=500] Maximum number of iterations to perform.

normalize [bool, default=True] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use *`sklearn.preprocessing.StandardScaler`* before calling `fit` on an estimator with `normalize=False`.

precompute [bool or 'auto' , default='auto'] Whether to use a precomputed Gram matrix to speed up calculations. If set to `'auto'` let us decide. The Gram matrix cannot be passed as argument since we will use only subsets of X.

cv [int, cross-validation generator or an iterable, default=None] Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 5-fold cross-validation,
- integer, to specify the number of folds.
- *CV splitter*,
- An iterable yielding (train, test) splits as arrays of indices.

For integer/None inputs, `KFold` is used.

Refer *User Guide* for the various cross-validation strategies that can be used here.

Changed in version 0.22: `cv` default value if None changed from 3-fold to 5-fold.

max_n_alphas [int, default=1000] The maximum number of points on the path used to compute the residuals in the cross-validation

n_jobs [int or None, default=None] Number of CPUs to use during the cross validation. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

eps [float, optional] The machine-precision regularization in the computation of the Cholesky diagonal factors. Increase this for very ill-conditioned systems. By default, `np.finfo(np.float).eps` is used.

copy_X [bool, default=True] If True, X will be copied; else, it may be overwritten.

positive [bool, default=False] Restrict coefficients to be >= 0. Be aware that you might want to remove fit_intercept which is set True by default. Under the positive restriction the model coefficients do not converge to the ordinary-least-squares solution for small values of alpha. Only coefficients up to the smallest alpha value (`alphas_[alphas_ > 0.].min()` when fit_path=True) reached by the stepwise Lars-Lasso algorithm are typically in congruence with the solution of the coordinate descent Lasso estimator. As a consequence using LassoLarsCV only makes sense for problems where a sparse solution is expected and/or reached.

Attributes

coef_ [array-like of shape (n_features,)] parameter vector (w in the formulation formula)

intercept_ [float] independent term in decision function.

coef_path_ [array-like of shape (n_features, n_alphas)] the varying values of the coefficients along the path

alpha_ [float] the estimated regularization parameter alpha

alphas_ [array-like of shape (n_alphas,)] the different values of alpha along the path

cv_alphas_ [array-like of shape (n_cv_alphas,)] all the values of alpha along the path for the different folds

mse_path_ [array-like of shape (n_folds, n_cv_alphas)] the mean square error on left-out for each fold along the path (alpha values given by `cv_alphas`)

n_iter_ [array-like or int] the number of iterations run by Lars with the optimal alpha.

See also:

lars_path, *LassoLars*, *LarsCV*, *LassoCV*

Notes

The object solves the same problem as the LassoCV object. However, unlike the LassoCV, it find the relevant alphas values by itself. In general, because of this property, it will be more stable. However, it is more fragile to heavily multicollinear datasets.

It is more efficient than the LassoCV if only a small number of features are selected compared to the total number, for instance if there are very few samples compared to the number of features.

Examples

```
>>> from sklearn.linear_model import LassoLarsCV
>>> from sklearn.datasets import make_regression
>>> X, y = make_regression(noise=4.0, random_state=0)
>>> reg = LassoLarsCV(cv=5).fit(X, y)
>>> reg.score(X, y)
0.9992...
>>> reg.alpha_
0.0484...
>>> reg.predict(X[:1,])
array([-77.8723...])
```

Methods

fit(self, X, y)	Fit the model using X, y as training data.
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict using the linear model.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__(*self*, *fit_intercept=True*, *verbose=False*, *max_iter=500*, *normalize=True*, *precompute='auto'*, *cv=None*, *max_n_alphas=1000*, *n_jobs=None*, *eps=2.220446049250313e-16*, *copy_X=True*, *positive=False*)
Initialize self. See help(type(self)) for accurate signature.

fit(*self*, *X*, *y*)
Fit the model using X, y as training data.

Parameters

X [array-like of shape (n_samples, n_features)] Training data.

y [array-like of shape (n_samples,)] Target values.

Returns

self [object] returns an instance of self.

get_params (*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict (*self*, *X*)
Predict using the linear model.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape (n_samples,)] Returns predicted values.

score (*self*, *X*, *y*, *sample_weight=None*)
Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params(*self*, ***params*)
Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

Examples using `sklearn.linear_model.LassoLarsCV`

- *Lasso model selection: Cross-Validation / AIC / BIC*

`sklearn.linear_model`.LogisticRegressionCV

class sklearn.linear_model.**LogisticRegressionCV**(*Cs=10*, *fit_intercept=True*, *cv=None*, *dual=False*, *penalty='l2'*, *scoring=None*, *solver='lbfgs'*, *tol=0.0001*, *max_iter=100*, *class_weight=None*, *n_jobs=None*, *verbose=0*, *refit=True*, *intercept_scaling=1.0*, *multi_class='auto'*, *random_state=None*, *l1_ratios=None*)

Logistic Regression CV (aka logit, MaxEnt) classifier.

See glossary entry for *cross-validation estimator*.

This class implements logistic regression using liblinear, newton-cg, sag of lbfgs optimizer. The newton-cg, sag and lbfgs solvers support only L2 regularization with primal formulation. The liblinear solver supports both L1 and L2 regularization, with a dual formulation only for the L2 penalty. Elastic-Net penalty is only supported by the saga solver.

For the grid of `Cs` values and `l1_ratios` values, the best hyperparameter is selected by the cross-validator *`StratifiedKFold`*, but it can be changed using the *cv* parameter. The 'newton-cg', 'sag', 'saga' and 'lbfgs' solvers can warm-start the coefficients (see *Glossary*).

Read more in the *User Guide*.

Parameters

Cs [int or list of floats, default=10] Each of the values in Cs describes the inverse of regularization strength. If Cs is as an int, then a grid of Cs values are chosen in a logarithmic scale between 1e-4 and 1e4. Like in support vector machines, smaller values specify stronger regularization.

fit_intercept [bool, default=True] Specifies if a constant (a.k.a. bias or intercept) should be added to the decision function.

cv [int or cross-validation generator, default=None] The default cross-validation generator used is Stratified K-Folds. If an integer is provided, then it is the number of folds used. See the module *`sklearn.model_selection`* module for the list of possible cross-validation objects.

Changed in version 0.22: `cv` default value if None changed from 3-fold to 5-fold.

dual [bool, default=False] Dual or primal formulation. Dual formulation is only implemented for l2 penalty with liblinear solver. Prefer dual=False when n_samples > n_features.

penalty [{'l1', 'l2', 'elasticnet'}, default='l2'] Used to specify the norm used in the penalization. The 'newton-cg', 'sag' and 'lbfgs' solvers support only l2 penalties. 'elasticnet' is only supported by the 'saga' solver.

scoring [str or callable, default=None] A string (see model evaluation documentation) or a scorer callable object / function with signature `scorer(estimator, X, y)`. For a list of scoring functions that can be used, look at *`sklearn.metrics`*. The default scoring option used is 'accuracy'.

solver [{'newton-cg', 'lbfgs', 'liblinear', 'sag', 'saga'}, default='lbfgs'] Algorithm to use in the optimization problem.

- For small datasets, 'liblinear' is a good choice, whereas 'sag' and 'saga' are faster for large ones.
- For multiclass problems, only 'newton-cg', 'sag', 'saga' and 'lbfgs' handle multinomial loss; 'liblinear' is limited to one-versus-rest schemes.
- 'newton-cg', 'lbfgs' and 'sag' only handle L2 penalty, whereas 'liblinear' and 'saga' handle L1 penalty.
- 'liblinear' might be slower in LogisticRegressionCV because it does not handle warm-starting.

Note that 'sag' and 'saga' fast convergence is only guaranteed on features with approximately the same scale. You can preprocess the data with a scaler from sklearn.preprocessing.

New in version 0.17: Stochastic Average Gradient descent solver.

New in version 0.19: SAGA solver.

tol [float, default=1e-4] Tolerance for stopping criteria.

max_iter [int, default=100] Maximum number of iterations of the optimization algorithm.

class_weight [dict or 'balanced', default=None] Weights associated with classes in the form `{class_label: weight}`. If not given, all classes are supposed to have weight one.

The "balanced" mode uses the values of y to automatically adjust weights inversely proportional to class frequencies in the input data as `n_samples / (n_classes * np.bincount(y))`.

Note that these weights will be multiplied with sample_weight (passed through the fit method) if sample_weight is specified.

New in version 0.17: class_weight == 'balanced'

n_jobs [int, default=None] Number of CPU cores used during the cross-validation loop. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

verbose [int, default=0] For the 'liblinear', 'sag' and 'lbfgs' solvers set verbose to any positive number for verbosity.

refit [bool, default=True] If set to True, the scores are averaged across all folds, and the coefs and the C that corresponds to the best score is taken, and a final refit is done using these parameters. Otherwise the coefs, intercepts and C that correspond to the best scores across folds are averaged.

intercept_scaling [float, default=1] Useful only when the solver 'liblinear' is used and self.fit_intercept is set to True. In this case, x becomes [x, self.intercept_scaling], i.e. a "synthetic" feature with constant value equal to intercept_scaling is appended to the instance vector. The intercept becomes `intercept_scaling * synthetic_feature_weight`.

Note! the synthetic feature weight is subject to l1/l2 regularization as all other features. To lessen the effect of regularization on synthetic feature weight (and therefore on the intercept) intercept_scaling has to be increased.

multi_class [{'auto, 'ovr', 'multinomial'}, default='auto'] If the option chosen is 'ovr', then a binary problem is fit for each label. For 'multinomial' the loss minimised is the multinomial loss fit across the entire probability distribution, *even when the data is binary*. 'multinomial' is unavailable when solver='liblinear'. 'auto' selects 'ovr' if the data is binary, or if solver='liblinear', and otherwise selects 'multinomial'.

New in version 0.18: Stochastic Average Gradient descent solver for 'multinomial' case.

Changed in version 0.22: Default changed from 'ovr' to 'auto' in 0.22.

random_state [int, RandomState instance, default=None] If int, random_state is the seed used by the random number generator; If RandomState instance, random_state is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`. Used when `solver='sag'` or `solver='liblinear'`. Note that this only applies to the solver and not the cross-validation generator.

l1_ratios [list of float, default=None] The list of Elastic-Net mixing parameter, with `0 <= l1_ratio <= 1`. Only used if `penalty='elasticnet'`. A value of 0 is equivalent to using `penalty='l2'`, while 1 is equivalent to using `penalty='l1'`. For `0 < l1_ratio <1`, the penalty is a combination of L1 and L2.

Attributes

classes_ [ndarray of shape (n_classes,)] A list of class labels known to the classifier.

coef_ [ndarray of shape (1, n_features) or (n_classes, n_features)] Coefficient of the features in the decision function.

`coef_` is of shape (1, n_features) when the given problem is binary.

intercept_ [ndarray of shape (1,) or (n_classes,)] Intercept (a.k.a. bias) added to the decision function.

If `fit_intercept` is set to False, the intercept is set to zero. `intercept_` is of shape(1,) when the problem is binary.

Cs_ [ndarray of shape (n_cs)] Array of C i.e. inverse of regularization parameter values used for cross-validation.

l1_ratios_ [ndarray of shape (n_l1_ratios)] Array of l1_ratios used for cross-validation. If no l1_ratio is used (i.e. penalty is not 'elasticnet'), this is set to `[None]`

coefs_paths_ [ndarray of shape (n_folds, n_cs, n_features) or (n_folds, n_cs, n_features + 1)] dict with classes as the keys, and the path of coefficients obtained during cross-validating across each fold and then across each Cs after doing an OvR for the corresponding class as values. If the 'multi_class' option is set to 'multinomial', then the coefs_paths are the coefficients corresponding to each class. Each dict value has shape `(n_folds, n_cs, n_features)` or `(n_folds, n_cs, n_features + 1)` depending on whether the intercept is fit or not. If `penalty='elasticnet'`, the shape is `(n_folds, n_cs, n_l1_ratios_, n_features)` or `(n_folds, n_cs, n_l1_ratios_, n_features + 1)`.

scores_ [dict] dict with classes as the keys, and the values as the grid of scores obtained during cross-validating each fold, after doing an OvR for the corresponding class. If the 'multi_class' option given is 'multinomial' then the same scores are repeated across all classes, since this is the multinomial class. Each dict value has shape `(n_folds, n_cs` or `(n_folds, n_cs, n_l1_ratios)` if `penalty='elasticnet'`.

C_ [ndarray of shape (n_classes,) or (n_classes - 1,)] Array of C that maps to the best scores across every class. If refit is set to False, then for each class, the best C is the average of the C's that correspond to the best scores for each fold. `C_` is of shape(n_classes,) when the problem is binary.

l1_ratio_ [ndarray of shape (n_classes,) or (n_classes - 1,)] Array of l1_ratio that maps to the best scores across every class. If refit is set to False, then for each class, the best l1_ratio is the average of the l1_ratio's that correspond to the best scores for each fold. `l1_ratio_` is of shape(n_classes,) when the problem is binary.

n_iter_ [ndarray of shape (n_classes, n_folds, n_cs) or (1, n_folds, n_cs)] Actual number of iterations for all classes, folds and Cs. In the binary or multinomial cases, the first dimension is equal to 1. If `penalty='elasticnet'`, the shape is `(n_classes, n_folds, n_cs, n_l1_ratios)` or `(1, n_folds, n_cs, n_l1_ratios)`.

LogisticRegression

Examples

```
>>> from sklearn.datasets import load_iris
>>> from sklearn.linear_model import LogisticRegressionCV
>>> X, y = load_iris(return_X_y=True)
>>> clf = LogisticRegressionCV(cv=5, random_state=0).fit(X, y)
>>> clf.predict(X[:2, :])
array([0, 0])
>>> clf.predict_proba(X[:2, :]).shape
(2, 3)
>>> clf.score(X, y)
0.98...
```

Methods

decision_function(self, X)	Predict confidence scores for samples.
densify(self)	Convert coefficient matrix to dense array format.
fit(self, X, y[, sample_weight])	Fit the model according to the given training data.
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict class labels for samples in X.
predict_log_proba(self, X)	Predict logarithm of probability estimates.
predict_proba(self, X)	Probability estimates.
score(self, X, y[, sample_weight])	Returns the score using the `scoring` option on the given test data and labels.
set_params(self, **params)	Set the parameters of this estimator.
sparsify(self)	Convert coefficient matrix to sparse format.

__init__(*self*, *Cs=10*, *fit_intercept=True*, *cv=None*, *dual=False*, *penalty='l2'*, *scoring=None*, *solver='lbfgs'*, *tol=0.0001*, *max_iter=100*, *class_weight=None*, *n_jobs=None*, *verbose=0*, *refit=True*, *intercept_scaling=1.0*, *multi_class='auto'*, *random_state=None*, *l1_ratios=None*)
Initialize self. See help(type(self)) for accurate signature.

decision_function(*self*, *X*)
Predict confidence scores for samples.

The confidence score for a sample is the signed distance of that sample to the hyperplane.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

array, shape=(n_samples,) if n_classes == 2 else (n_samples, n_classes) Confidence scores per (sample, class) combination. In the binary case, confidence score for self.classes_[1] where >0 means this class would be predicted.

densify(*self*)
Convert coefficient matrix to dense array format.

Converts the `coef_` member (back) to a numpy.ndarray. This is the default format of `coef_` and is required for fitting, so calling this method is only required on models that have previously been sparsified; otherwise, it is a no-op.

Returns

self Fitted estimator.

fit(*self*, *X*, *y*, *sample_weight=None*)
Fit the model according to the given training data.

Parameters

X [{array-like, sparse matrix} of shape (n_samples, n_features)] Training vector, where n_samples is the number of samples and n_features is the number of features.

y [array-like of shape (n_samples,)] Target vector relative to X.

sample_weight [array-like of shape (n_samples,) default=None] Array of weights that are assigned to individual samples. If not provided, then each sample is given unit weight.

Returns

self [object]

get_params(*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict(*self*, *X*)
Predict class labels for samples in X.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape [n_samples]] Predicted class label per sample.

predict_log_proba (*self*, *X*)

Predict logarithm of probability estimates.

The returned estimates for all classes are ordered by the label of classes.

Parameters

X [array-like of shape (n_samples, n_features)] Vector to be scored, where `n_samples` is the number of samples and `n_features` is the number of features.

Returns

T [array-like of shape (n_samples, n_classes)] Returns the log-probability of the sample for each class in the model, where classes are ordered as they are in `self.classes_`.

predict_proba (*self*, *X*)

Probability estimates.

The returned estimates for all classes are ordered by the label of classes.

For a multi_class problem, if multi_class is set to be "multinomial" the softmax function is used to find the predicted probability of each class. Else use a one-vs-rest approach, i.e calculate the probability of each class assuming it to be positive using the logistic function. and normalize these values across all the classes.

Parameters

X [array-like of shape (n_samples, n_features)] Vector to be scored, where `n_samples` is the number of samples and `n_features` is the number of features.

Returns

T [array-like of shape (n_samples, n_classes)] Returns the probability of the sample for each class in the model, where classes are ordered as they are in `self.classes_`.

score (*self*, *X*, *y*, *sample_weight=None*)

Returns the score using the `scoring` option on the given test data and labels.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples.

y [array-like of shape (n_samples,)] True labels for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] Score of self.predict(X) wrt. y.

set_params (*self*, ***params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

sparsify(*self*)

Convert coefficient matrix to sparse format.

Converts the `coef_` member to a scipy.sparse matrix, which for L1-regularized models can be much more memory- and storage-efficient than the usual numpy.ndarray representation.

The `intercept_` member is not converted.

Returns

self Fitted estimator.

Notes

For non-sparse models, i.e. when there are not many zeros in `coef_`, this may actually *increase* memory usage, so use this method with care. A rule of thumb is that the number of zero elements, which can be computed with `(coef_ == 0).sum()`, must be more than 50% for this to provide significant benefits.

After calling this method, further fitting with the partial_fit method (if any) will not work until you call densify.

sklearn.linear_model.MultiTaskElasticNetCV

class sklearn.linear_model.**MultiTaskElasticNetCV**(*l1_ratio=0.5*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *fit_intercept=True*, *normalize=False*, *max_iter=1000*, *tol=0.0001*, *cv=None*, *copy_X=True*, *verbose=0*, *n_jobs=None*, *random_state=None*, *selection='cyclic'*)

Multi-task L1/L2 ElasticNet with built-in cross-validation.

See glossary entry for *cross-validation estimator*.

The optimization objective for MultiTaskElasticNet is:

```
(1 / (2 * n_samples)) * ||Y - XW||^Fro_2
+ alpha * l1_ratio * ||W||_21
+ 0.5 * alpha * (1 - l1_ratio) * ||W||_Fro^2
```

Where:

```
||W||_21 = \sum_i \sqrt{\sum_j w_{ij}^2}
```

i.e. the sum of norm of each row.

Read more in the *User Guide*.

New in version 0.15.

Parameters

l1_ratio [float or array of floats] The ElasticNet mixing parameter, with 0 < l1_ratio <= 1. For l1_ratio = 1 the penalty is an L1/L2 penalty. For l1_ratio = 0 it is an L2 penalty. For `0 < l1_ratio < 1`, the penalty is a combination of L1/L2 and L2. This parameter can be a list, in which case the different values are tested by cross-validation and the one giving the best prediction score is used. Note that a good choice of list of values for l1_ratio is often

to put more values close to 1 (i.e. Lasso) and less close to 0 (i.e. Ridge), as in `[.1, .5, .7, .9, .95, .99, 1]`

eps [float, optional] Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`.

n_alphas [int, optional] Number of alphas along the regularization path

alphas [array-like, optional] List of alphas where to compute the models. If not provided, set automatically.

fit_intercept [boolean] whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

normalize [boolean, optional, default False] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use *`sklearn.preprocessing.StandardScaler`* before calling `fit` on an estimator with `normalize=False`.

max_iter [int, optional] The maximum number of iterations

tol [float, optional] The tolerance for the optimization: if the updates are smaller than `tol`, the optimization code checks the dual gap for optimality and continues until it is smaller than `tol`.

cv [int, cross-validation generator or an iterable, optional] Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 5-fold cross-validation,
- integer, to specify the number of folds.
- *CV splitter*,
- An iterable yielding (train, test) splits as arrays of indices.

For integer/None inputs, `KFold` is used.

Refer *User Guide* for the various cross-validation strategies that can be used here.

Changed in version 0.22: `cv` default value if None changed from 3-fold to 5-fold.

copy_X [boolean, optional, default True] If `True`, X will be copied; else, it may be overwritten.

verbose [bool or integer] Amount of verbosity.

n_jobs [int or None, optional (default=None)] Number of CPUs to use during the cross validation. Note that this is used only if multiple values for l1_ratio are given. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

random_state [int, RandomState instance or None, optional, default None] The seed of the pseudo random number generator that selects a random feature to update. If int, random_state is the seed used by the random number generator; If RandomState instance, random_state is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`. Used when `selection` == 'random'.

selection [str, default 'cyclic'] If set to 'random', a random coefficient is updated every iteration rather than looping over features sequentially by default. This (setting to 'random') often leads to significantly faster convergence especially when tol is higher than 1e-4.

Attributes

intercept_ [array, shape (n_tasks,)] Independent term in decision function.

coef_ [array, shape (n_tasks, n_features)] Parameter vector (W in the cost function formula). Note that `coef_` stores the transpose of `W`, `W.T`.

alpha_ [float] The amount of penalization chosen by cross validation

mse_path_ [array, shape (n_alphas, n_folds) or (n_l1_ratio, n_alphas, n_folds)] mean square error for the test set on each fold, varying alpha

alphas_ [numpy array, shape (n_alphas,) or (n_l1_ratio, n_alphas)] The grid of alphas used for fitting, for each l1_ratio

l1_ratio_ [float] best l1_ratio obtained by cross-validation.

n_iter_ [int] number of iterations run by the coordinate descent solver to reach the specified tolerance for the optimal alpha.

MultiTaskElasticNet

ElasticNetCV

MultiTaskLassoCV

Notes

The algorithm used to fit the model is coordinate descent.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

Examples

```
>>> from sklearn import linear_model
>>> clf = linear_model.MultiTaskElasticNetCV(cv=3)
>>> clf.fit([[0,0], [1, 1], [2, 2]],
...         [[0, 0], [1, 1], [2, 2]])
MultiTaskElasticNetCV(cv=3)
>>> print(clf.coef_)
[[0.52875032 0.46958558]
 [0.52875032 0.46958558]]
>>> print(clf.intercept_)
[0.00166409 0.00166409]
```

Methods

fit(self, X, y)	Fit linear model with coordinate descent
get_params(self[, deep])	Get parameters for this estimator.
path(X, y[, l1_ratio, eps, n_alphas, ...])	Compute elastic net path with coordinate descent.
predict(self, X)	Predict using the linear model.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__ (*self*, *l1_ratio=0.5*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *fit_intercept=True*, *normalize=False*, *max_iter=1000*, *tol=0.0001*, *cv=None*, *copy_X=True*, *verbose=0*, *n_jobs=None*, *random_state=None*, *selection='cyclic'*)
Initialize self. See help(type(self)) for accurate signature.

fit (*self*, *X*, *y*)
Fit linear model with coordinate descent

Fit is on grid of alphas and best alpha estimated by cross-validation.

Parameters

X [{array-like}, shape (n_samples, n_features)] Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If y is mono-output, X can be sparse.

y [array-like, shape (n_samples,) or (n_samples, n_targets)] Target values

get_params (*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

static path (*X*, *y*, *l1_ratio=0.5*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *precompute='auto'*, *Xy=None*, *copy_X=True*, *coef_init=None*, *verbose=False*, *return_n_iter=False*, *positive=False*, *check_input=True*, ***params*)
Compute elastic net path with coordinate descent.

The elastic net optimization function varies for mono and multi-outputs.

For mono-output tasks it is:

```
1 / (2 * n_samples) * ||y - Xw||^2_2
+ alpha * l1_ratio * ||w||_1
+ 0.5 * alpha * (1 - l1_ratio) * ||w||^2_2
```

For multi-output tasks it is:

```
(1 / (2 * n_samples)) * ||Y - XW||^Fro_2
+ alpha * l1_ratio * ||W||_21
+ 0.5 * alpha * (1 - l1_ratio) * ||W||_Fro^2
```

Where:

```
||W||_21 = \sum_i \sqrt{\sum_j w_{ij}^2}
```

i.e. the sum of norm of each row.

Read more in the *User Guide*.

Parameters

X [{array-like}, shape (n_samples, n_features)] Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If `y` is mono-output then `X` can be sparse.

y [ndarray, shape (n_samples,) or (n_samples, n_outputs)] Target values.

l1_ratio [float, optional] Number between 0 and 1 passed to elastic net (scaling between l1 and l2 penalties). `l1_ratio=1` corresponds to the Lasso.

eps [float] Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`.

n_alphas [int, optional] Number of alphas along the regularization path.

alphas [ndarray, optional] List of alphas where to compute the models. If None alphas are set automatically.

precompute [True | False | 'auto' | array-like] Whether to use a precomputed Gram matrix to speed up calculations. If set to `'auto'` let us decide. The Gram matrix can also be passed as argument.

Xy [array-like, optional] Xy = np.dot(X.T, y) that can be precomputed. It is useful only when the Gram matrix is precomputed.

copy_X [bool, optional, default True] If `True`, X will be copied; else, it may be overwritten.

coef_init [array, shape (n_features,) | None] The initial values of the coefficients.

verbose [bool or int] Amount of verbosity.

return_n_iter [bool] Whether to return the number of iterations or not.

positive [bool, default False] If set to True, forces coefficients to be positive. (Only allowed when `y.ndim == 1`).

check_input [bool, default True] Skip input validation checks, including the Gram matrix when provided assuming there are handled by the caller when check_input=False.

****params** [kwargs] Keyword arguments passed to the coordinate descent solver.

Returns

alphas [array, shape (n_alphas,)] The alphas along the path where models are computed.

coefs [array, shape (n_features, n_alphas) or (n_outputs, n_features, n_alphas)] Coefficients along the path.

dual_gaps [array, shape (n_alphas,)] The dual gaps at the end of the optimization for each alpha.

n_iters [array-like, shape (n_alphas,)] The number of iterations taken by the coordinate descent optimizer to reach the specified tolerance for each alpha. (Is returned when `return_n_iter` is set to True).

MultiTaskElasticNet

MultiTaskElasticNetCV

ElasticNet

ElasticNetCV

Notes

For an example, see *examples/linear_model/plot_lasso_coordinate_descent_path.py*.

predict(*self*, *X*)

Predict using the linear model.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape (n_samples,)] Returns predicted values.

score (*self*, *X*, *y*, *sample_weight=None*)

Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params (*self*, ***params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

sklearn.linear_model.MultiTaskLassoCV

class sklearn.linear_model.**MultiTaskLassoCV**(*eps=0.001*, *n_alphas=100*, *alphas=None*, *fit_intercept=True*, *normalize=False*, *max_iter=1000*, *tol=0.0001*, *copy_X=True*, *cv=None*, *verbose=False*, *n_jobs=None*, *random_state=None*, *selection='cyclic'*)

Multi-task Lasso model trained with L1/L2 mixed-norm as regularizer.

See glossary entry for *cross-validation estimator*.

The optimization objective for MultiTaskLasso is:

```
(1 / (2 * n_samples)) * ||Y - XW||^Fro_2 + alpha * ||W||_21
```

Where:

```
||W||_21 = \sum_i \sqrt{\sum_j w_{ij}^2}
```

i.e. the sum of norm of each row.

Read more in the *User Guide*.

New in version 0.15.

Parameters

eps [float, optional] Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`.

n_alphas [int, optional] Number of alphas along the regularization path

alphas [array-like, optional] List of alphas where to compute the models. If not provided, set automatically.

fit_intercept [boolean] whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

normalize [boolean, optional, default False] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use *`sklearn.preprocessing.StandardScaler`* before calling `fit` on an estimator with `normalize=False`.

max_iter [int, optional] The maximum number of iterations.

tol [float, optional] The tolerance for the optimization: if the updates are smaller than `tol`, the optimization code checks the dual gap for optimality and continues until it is smaller than `tol`.

copy_X [boolean, optional, default True] If `True`, X will be copied; else, it may be overwritten.

cv [int, cross-validation generator or an iterable, optional] Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 5-fold cross-validation,
- integer, to specify the number of folds.
- *CV splitter*,
- An iterable yielding (train, test) splits as arrays of indices.

For integer/None inputs, `KFold` is used.

Refer *User Guide* for the various cross-validation strategies that can be used here.

Changed in version 0.22: `cv` default value if None changed from 3-fold to 5-fold.

verbose [bool or integer] Amount of verbosity.

n_jobs [int or None, optional (default=None)] Number of CPUs to use during the cross validation. Note that this is used only if multiple values for l1_ratio are given. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

random_state [int, RandomState instance or None, optional, default None] The seed of the pseudo random number generator that selects a random feature to update. If int, random_state is the seed used by the random number generator; If RandomState instance, random_state is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`. Used when `selection` == 'random'

selection [str, default 'cyclic'] If set to 'random', a random coefficient is updated every iteration rather than looping over features sequentially by default. This (setting to 'random') often leads to significantly faster convergence especially when tol is higher than 1e-4.

Attributes

intercept_ [array, shape (n_tasks,)] Independent term in decision function.

coef_ [array, shape (n_tasks, n_features)] Parameter vector (W in the cost function formula). Note that `coef_` stores the transpose of `W`, `W.T`.

alpha_ [float] The amount of penalization chosen by cross validation

mse_path_ [array, shape (n_alphas, n_folds)] mean square error for the test set on each fold, varying alpha

alphas_ [numpy array, shape (n_alphas,)] The grid of alphas used for fitting.

n_iter_ [int] number of iterations run by the coordinate descent solver to reach the specified tolerance for the optimal alpha.

MultiTaskElasticNetCV

Notes

The algorithm used to fit the model is coordinate descent.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

Examples

```
>>> from sklearn.linear_model import MultiTaskLassoCV
>>> from sklearn.datasets import make_regression
>>> from sklearn.metrics import r2_score
>>> X, y = make_regression(n_targets=2, noise=4, random_state=0)
>>> reg = MultiTaskLassoCV(cv=5, random_state=0).fit(X, y)
>>> r2_score(y, reg.predict(X))
0.9994...
>>> reg.alpha_
0.5713...
>>> reg.predict(X[:1,])
array([[153.7971...,  94.9015...]])
```

Methods

fit(self, X, y)	Fit linear model with coordinate descent
get_params(self[, deep])	Get parameters for this estimator.
path(X, y[, eps, n_alphas, alphas, ...])	Compute Lasso path with coordinate descent
predict(self, X)	Predict using the linear model.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__(*self*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *fit_intercept=True*, *normalize=False*, *max_iter=1000*, *tol=0.0001*, *copy_X=True*, *cv=None*, *verbose=False*, *n_jobs=None*, *random_state=None*, *selection='cyclic'*)

Initialize self. See help(type(self)) for accurate signature.

fit(*self*, *X*, *y*)

Fit linear model with coordinate descent

Fit is on grid of alphas and best alpha estimated by cross-validation.

Parameters

X [{array-like}, shape (n_samples, n_features)] Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If y is mono-output, X can be sparse.

y [array-like, shape (n_samples,) or (n_samples, n_targets)] Target values

get_params(*self*, *deep=True*)

Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

static path(*X*, *y*, *eps=0.001*, *n_alphas=100*, *alphas=None*, *precompute='auto'*, *Xy=None*, *copy_X=True*, *coef_init=None*, *verbose=False*, *return_n_iter=False*, *positive=False*, ***params*)

Compute Lasso path with coordinate descent

The Lasso optimization function varies for mono and multi-outputs.

For mono-output tasks it is:

```
(1 / (2 * n_samples)) * ||y - Xw||^2_2 + alpha * ||w||_1
```

For multi-output tasks it is:

```
(1 / (2 * n_samples)) * ||Y - XW||^2_Fro + alpha * ||W||_21
```

Where:

```
||W||_21 = \sum_i \sqrt{\sum_j w_{ij}^2}
```

i.e. the sum of norm of each row.

Read more in the *User Guide*.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If `y` is mono-output then `X` can be sparse.

y [ndarray, shape (n_samples,), or (n_samples, n_outputs)] Target values

eps [float, optional] Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`

n_alphas [int, optional] Number of alphas along the regularization path

alphas [ndarray, optional] List of alphas where to compute the models. If `None` alphas are set automatically

precompute [True | False | 'auto' | array-like] Whether to use a precomputed Gram matrix to speed up calculations. If set to `'auto'` let us decide. The Gram matrix can also be passed as argument.

Xy [array-like, optional] Xy = np.dot(X.T, y) that can be precomputed. It is useful only when the Gram matrix is precomputed.

copy_X [boolean, optional, default True] If `True`, X will be copied; else, it may be overwritten.

coef_init [array, shape (n_features,) | None] The initial values of the coefficients.

verbose [bool or integer] Amount of verbosity.

return_n_iter [bool] whether to return the number of iterations or not.

positive [bool, default False] If set to True, forces coefficients to be positive. (Only allowed when `y.ndim == 1`).

****params** [kwargs] keyword arguments passed to the coordinate descent solver.

Returns

alphas [array, shape (n_alphas,)] The alphas along the path where models are computed.

coefs [array, shape (n_features, n_alphas) or (n_outputs, n_features, n_alphas)] Coefficients along the path.

dual_gaps [array, shape (n_alphas,)] The dual gaps at the end of the optimization for each alpha.

n_iters [array-like, shape (n_alphas,)] The number of iterations taken by the coordinate descent optimizer to reach the specified tolerance for each alpha.

See also:

lars_path

Lasso

LassoLars

LassoCV

LassoLarsCV

sklearn.decomposition.sparse_encode

Notes

For an example, see *examples/linear_model/plot_lasso_coordinate_descent_path.py*.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

Note that in certain cases, the Lars solver may be significantly faster to implement this functionality. In particular, linear interpolation can be used to retrieve model coefficients between the values output by lars_path

Examples

Comparing lasso_path and lars_path with interpolation:

```
>>> X = np.array([[1, 2, 3.1], [2.3, 5.4, 4.3]]).T
>>> y = np.array([1, 2, 3.1])
>>> # Use lasso_path to compute a coefficient path
>>> _, coef_path, _ = lasso_path(X, y, alphas=[5., 1., .5])
>>> print(coef_path)
[[0.          0.          0.46874778]
 [0.2159048   0.4425765   0.23689075]]
```

```
>>> # Now use lars_path and 1D linear interpolation to compute the
>>> # same path
>>> from sklearn.linear_model import lars_path
>>> alphas, active, coef_path_lars = lars_path(X, y, method='lasso')
>>> from scipy import interpolate
>>> coef_path_continuous = interpolate.interp1d(alphas[::-1],
...                                             coef_path_lars[:, ::-1])
>>> print(coef_path_continuous([5., 1., .5]))
[[0.          0.          0.46915237]
 [0.2159048   0.4425765   0.23668876]]
```

predict (*self*, *X*)

Predict using the linear model.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape (n_samples,)] Returns predicted values.

score(*self*, *X*, *y*, *sample_weight=None*)
Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params(*self*, ***params*)
Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

sklearn.linear_model.OrthogonalMatchingPursuitCV

class sklearn.linear_model.**OrthogonalMatchingPursuitCV**(*copy=True*, *fit_intercept=True*, *normalize=True*, *max_iter=None*, *cv=None*, *n_jobs=None*, *verbose=False*)
Cross-validated Orthogonal Matching Pursuit model (OMP).

See glossary entry for *cross-validation estimator*.

Read more in the *User Guide*.

Parameters

copy [bool, optional] Whether the design matrix X must be copied by the algorithm. A false value is only helpful if X is already Fortran-ordered, otherwise a copy is made anyway.

fit_intercept [boolean, optional] whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

normalize [boolean, optional, default True] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use *`sklearn.preprocessing.StandardScaler`* before calling `fit` on an estimator with `normalize=False`.

max_iter [integer, optional] Maximum numbers of iterations to perform, therefore maximum features to include. 10% of `n_features` but at least 5 if available.

cv [int, cross-validation generator or an iterable, optional] Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 5-fold cross-validation,
- integer, to specify the number of folds.
- *CV splitter*,
- An iterable yielding (train, test) splits as arrays of indices.

For integer/None inputs, `KFold` is used.

Refer *User Guide* for the various cross-validation strategies that can be used here.

Changed in version 0.22: `cv` default value if None changed from 3-fold to 5-fold.

n_jobs [int or None, optional (default=None)] Number of CPUs to use during the cross validation. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

verbose [boolean or integer, optional] Sets the verbosity amount

Attributes

intercept_ [float or array, shape (n_targets,)] Independent term in decision function.

coef_ [array, shape (n_features,) or (n_targets, n_features)] Parameter vector (w in the problem formulation).

n_nonzero_coefs_ [int] Estimated number of non-zero coefficients giving the best mean squared error over the cross-validation folds.

n_iter_ [int or array-like] Number of active features across every target for the model refit with the best hyperparameters got by cross-validating across all folds.

>>> reg.n_nonzero_coefs_
10
>>> reg.predict(X[:1,])
array([-78.3854...])
```

Methods

fit(self, X, y)	Fit the model using X, y as training data.
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict using the linear model.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__(*self*, *copy=True*, *fit_intercept=True*, *normalize=True*, *max_iter=None*, *cv=None*, *n_jobs=None*, *verbose=False*)
Initialize self. See help(type(self)) for accurate signature.

fit(*self*, *X*, *y*)
Fit the model using X, y as training data.

Parameters

X [array-like, shape [n_samples, n_features]] Training data.

y [array-like, shape [n_samples]] Target values. Will be cast to X's dtype if necessary

Returns

self [object] returns an instance of self.

get_params(*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict(*self*, *X*)
Predict using the linear model.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape (n_samples,)] Returns predicted values.

score (*self*, *X*, *y*, *sample_weight=None*)

Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params (*self*, ***params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

Examples using `sklearn.linear_model.OrthogonalMatchingPursuitCV`

- *Orthogonal Matching Pursuit*

sklearn.linear_model.RidgeCV

class sklearn.linear_model.**RidgeCV**(*alphas=(0.1, 1.0, 10.0)*, *fit_intercept=True*, *normalize=False*, *scoring=None*, *cv=None*, *gcv_mode=None*, *store_cv_values=False*)

Ridge regression with built-in cross-validation.

See glossary entry for *cross-validation estimator*.

By default, it performs Generalized Cross-Validation, which is a form of efficient Leave-One-Out cross-validation.

Read more in the *User Guide*.

Parameters

alphas [ndarray of shape (n_alphas,), default=(0.1, 1.0, 10.0)] Array of alpha values to try. Regularization strength; must be a positive float. Regularization improves the conditioning of the problem and reduces the variance of the estimates. Larger values specify stronger regularization. Alpha corresponds to `C^-1` in other linear models such as LogisticRegression or LinearSVC. If using generalized cross-validation, alphas must be positive.

fit_intercept [bool, default=True] Whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

normalize [bool, default=False] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use *`sklearn.preprocessing.StandardScaler`* before calling `fit` on an estimator with `normalize=False`.

scoring [string, callable, default=None] A string (see model evaluation documentation) or a scorer callable object / function with signature `scorer(estimator, X, y)`. If None, the negative mean squared error if cv is 'auto' or None (i.e. when using generalized cross-validation), and r2 score otherwise.

cv [int, cross-validation generator or an iterable, default=None] Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the efficient Leave-One-Out cross-validation (also known as Generalized Cross-Validation).
- integer, to specify the number of folds.
- *CV splitter*,
- An iterable yielding (train, test) splits as arrays of indices.

For integer/None inputs, if `y` is binary or multiclass, *`sklearn.model_selection.StratifiedKFold`* is used, else, *`sklearn.model_selection.KFold`* is used.

Refer *User Guide* for the various cross-validation strategies that can be used here.

gcv_mode [{'auto', 'svd', eigen'}, default='auto'] Flag indicating which strategy to use when performing Generalized Cross-Validation. Options are:

```
'auto' : use 'svd' if n_samples > n_features, otherwise use 'eigen'
'svd' : force use of singular value decomposition of X when X is
    dense, eigenvalue decomposition of X^T.X when X is sparse.
'eigen' : force computation via eigendecomposition of X.X^T
```

The 'auto' mode is the default and is intended to pick the cheaper option of the two depending on the shape of the training data.

store_cv_values [bool, default=False] Flag indicating if the cross-validation values corresponding to each alpha should be stored in the `cv_values_` attribute (see below). This flag is only compatible with `cv=None` (i.e. using Generalized Cross-Validation).

Attributes

cv_values_ [ndarray of shape (n_samples, n_alphas) or shape (n_samples, n_targets, n_alphas), optional] Cross-validation values for each alpha (if `store_cv_values=True` and `cv=None`). After `fit()` has been called, this attribute will contain the mean squared errors (by default) or the values of the `{loss,score}_func` function (if provided in the constructor).

coef_ [ndarray of shape (n_features) or (n_targets, n_features)] Weight vector(s).

intercept_ [float or ndarray of shape (n_targets,)] Independent term in decision function. Set to 0.0 if `fit_intercept = False`.

alpha_ [float] Estimated regularization parameter.

See also:

Ridge Ridge regression

RidgeClassifier Ridge classifier

RidgeClassifierCV Ridge classifier with built-in cross validation

Examples

```
>>> from sklearn.datasets import load_diabetes
>>> from sklearn.linear_model import RidgeCV
>>> X, y = load_diabetes(return_X_y=True)
>>> clf = RidgeCV(alphas=[1e-3, 1e-2, 1e-1, 1]).fit(X, y)
>>> clf.score(X, y)
0.5166...
```

Methods

fit(self, X, y[, sample_weight])	Fit Ridge regression model with cv.
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict using the linear model.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__ (*self*, *alphas=(0.1, 1.0, 10.0)*, *fit_intercept=True*, *normalize=False*, *scoring=None*, *cv=None*, *gcv_mode=None*, *store_cv_values=False*)
Initialize self. See help(type(self)) for accurate signature.

fit (*self*, *X*, *y*, *sample_weight=None*)
Fit Ridge regression model with cv.

Parameters

X [ndarray of shape (n_samples, n_features)] Training data. If using GCV, will be cast to float64 if necessary.

y [ndarray of shape (n_samples,) or (n_samples, n_targets)] Target values. Will be cast to X's dtype if necessary.

sample_weight [float or ndarray of shape (n_samples,), default=None] Individual weights for each sample. If given a float, every sample will have the same weight.

Returns

self [object]

Notes

When sample_weight is provided, the selected hyperparameter may depend on whether we use generalized cross-validation (cv=None or cv='auto') or another form of cross-validation, because only generalized cross-validation takes the sample weights into account when computing the validation score.

get_params(*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict(*self*, *X*)
Predict using the linear model.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape (n_samples,)] Returns predicted values.

score(*self*, *X*, *y*, *sample_weight=None*)
Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params(*self*, ***params*)
Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

Examples using `sklearn.linear_model.RidgeCV`

- *Face completion with a multi-output estimators*
- *Combine predictors using stacking*
- *Effect of transforming the targets in regression model*

`sklearn.linear_model`.RidgeClassifierCV

class sklearn.linear_model.**RidgeClassifierCV**(*alphas=(0.1, 1.0, 10.0)*, *fit_intercept=True*, *normalize=False*, *scoring=None*, *cv=None*, *class_weight=None*, *store_cv_values=False*)

Ridge classifier with built-in cross-validation.

See glossary entry for *cross-validation estimator*.

By default, it performs Generalized Cross-Validation, which is a form of efficient Leave-One-Out cross-validation. Currently, only the n_features > n_samples case is handled efficiently.

Read more in the *User Guide*.

Parameters

alphas [ndarray of shape (n_alphas,), default=(0.1, 1.0, 10.0)] Array of alpha values to try. Regularization strength; must be a positive float. Regularization improves the conditioning of the problem and reduces the variance of the estimates. Larger values specify stronger regularization. Alpha corresponds to `C^-1` in other linear models such as LogisticRegression or LinearSVC.

fit_intercept [bool, default=True] Whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

normalize [bool, default=False] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use

sklearn.preprocessing.StandardScaler before calling `fit` on an estimator with `normalize=False`.

scoring [string, callable, default=None] A string (see model evaluation documentation) or a scorer callable object / function with signature `scorer(estimator, X, y)`.

cv [int, cross-validation generator or an iterable, default=None] Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the efficient Leave-One-Out cross-validation
- integer, to specify the number of folds.
- *CV splitter*,
- An iterable yielding (train, test) splits as arrays of indices.

Refer *User Guide* for the various cross-validation strategies that can be used here.

class_weight [dict or 'balanced', default=None] Weights associated with classes in the form `{class_label: weight}`. If not given, all classes are supposed to have weight one.

The "balanced" mode uses the values of y to automatically adjust weights inversely proportional to class frequencies in the input data as `n_samples / (n_classes * np.bincount(y))`

store_cv_values [bool, default=False] Flag indicating if the cross-validation values corresponding to each alpha should be stored in the `cv_values_` attribute (see below). This flag is only compatible with `cv=None` (i.e. using Generalized Cross-Validation).

Attributes

cv_values_ [ndarray of shape (n_samples, n_targets, n_alphas), optional] Cross-validation values for each alpha (if `store_cv_values=True` and `cv=None`). After `fit()` has been called, this attribute will contain the mean squared errors (by default) or the values of the `{loss,score}_func` function (if provided in the constructor). This attribute exists only when `store_cv_values` is True.

coef_ [ndarray of shape (1, n_features) or (n_targets, n_features)] Coefficient of the features in the decision function.

`coef_` is of shape (1, n_features) when the given problem is binary.

intercept_ [float or ndarray of shape (n_targets,)] Independent term in decision function. Set to 0.0 if `fit_intercept = False`.

alpha_ [float] Estimated regularization parameter

classes_ [ndarray of shape (n_classes,)] The classes labels.

See also:

Ridge Ridge regression

RidgeClassifier Ridge classifier

RidgeCV Ridge regression with built-in cross validation

Notes

For multi-class classification, n_class classifiers are trained in a one-versus-all approach. Concretely, this is implemented by taking advantage of the multi-variate response support in Ridge.

Examples

```
>>> from sklearn.datasets import load_breast_cancer
>>> from sklearn.linear_model import RidgeClassifierCV
>>> X, y = load_breast_cancer(return_X_y=True)
>>> clf = RidgeClassifierCV(alphas=[1e-3, 1e-2, 1e-1, 1]).fit(X, y)
>>> clf.score(X, y)
0.9630...
```

Methods

decision_function(self, X)	Predict confidence scores for samples.
fit(self, X, y[, sample_weight])	Fit Ridge classifier with cv.
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict class labels for samples in X.
score(self, X, y[, sample_weight])	Return the mean accuracy on the given test data and labels.
set_params(self, **params)	Set the parameters of this estimator.

__init__ (*self*, *alphas=(0.1, 1.0, 10.0)*, *fit_intercept=True*, *normalize=False*, *scoring=None*, *cv=None*, *class_weight=None*, *store_cv_values=False*)
Initialize self. See help(type(self)) for accurate signature.

decision_function (*self*, *X*)
Predict confidence scores for samples.

The confidence score for a sample is the signed distance of that sample to the hyperplane.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

array, shape=(n_samples,) if n_classes == 2 else (n_samples, n_classes) Confidence scores per (sample, class) combination. In the binary case, confidence score for self.classes_[1] where >0 means this class would be predicted.

fit (*self*, *X*, *y*, *sample_weight=None*)
Fit Ridge classifier with cv.

Parameters

X [ndarray of shape (n_samples, n_features)] Training vectors, where n_samples is the number of samples and n_features is the number of features. When using GCV, will be cast to float64 if necessary.

y [ndarray of shape (n_samples,)] Target values. Will be cast to X's dtype if necessary.

sample_weight [float or ndarray of shape (n_samples,), default=None] Individual weights for each sample. If given a float, every sample will have the same weight.

Returns

self [object]

get_params (*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict (*self*, *X*)
Predict class labels for samples in X.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape [n_samples]] Predicted class label per sample.

score (*self*, *X*, *y*, *sample_weight=None*)
Return the mean accuracy on the given test data and labels.

In multi-label classification, this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True labels for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] Mean accuracy of self.predict(X) wrt. y.

set_params (*self*, ***params*)
Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

Information Criterion

Some models can offer an information-theoretic closed-form formula of the optimal estimate of the regularization parameter by computing a single regularization path (instead of several when using cross-validation).

Here is the list of models benefiting from the Akaike Information Criterion (AIC) or the Bayesian Information Criterion (BIC) for automated model selection:

linear_model.LassoLarsIC([criterion, ...])	Lasso model fit with Lars using BIC or AIC for model selection

sklearn.linear_model.LassoLarsIC

class sklearn.linear_model.**LassoLarsIC**(*criterion='aic'*, *fit_intercept=True*, *verbose=False*, *normalize=True*, *precompute='auto'*, *max_iter=500*, *eps=2.220446049250313e-16*, *copy_X=True*, *positive=False*)

Lasso model fit with Lars using BIC or AIC for model selection

The optimization objective for Lasso is:

```
(1 / (2 * n_samples)) * ||y - Xw||^2_2 + alpha * ||w||_1
```

AIC is the Akaike information criterion and BIC is the Bayes Information criterion. Such criteria are useful to select the value of the regularization parameter by making a trade-off between the goodness of fit and the complexity of the model. A good model should explain well the data while being simple.

Read more in the *User Guide*.

Parameters

criterion [{'bic' , 'aic'}, default='aic'] The type of criterion to use.

fit_intercept [bool, default=True] whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (i.e. data is expected to be centered).

verbose [bool or int, default=False] Sets the verbosity amount

normalize [bool, default=True] This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use *`sklearn.preprocessing.StandardScaler`* before calling `fit` on an estimator with `normalize=False`.

precompute [bool, 'auto' or array-like, default='auto'] Whether to use a precomputed Gram matrix to speed up calculations. If set to `'auto'` let us decide. The Gram matrix can also be passed as argument.

max_iter [int, default=500] Maximum number of iterations to perform. Can be used for early stopping.

eps [float, optional] The machine-precision regularization in the computation of the Cholesky diagonal factors. Increase this for very ill-conditioned systems. Unlike the `tol` parameter in some iterative optimization-based algorithms, this parameter does not control the tolerance of the optimization. By default, `np.finfo(np.float).eps` is used

copy_X [bool, default=True] If True, X will be copied; else, it may be overwritten.

positive [bool, default=False] Restrict coefficients to be >= 0. Be aware that you might want to remove fit_intercept which is set True by default. Under the positive restriction the model coefficients do not converge to the ordinary-least-squares solution for small values of alpha. Only coefficients up to the smallest alpha value (`alphas_[alphas_ > 0.].min()` when fit_path=True) reached by the stepwise Lars-Lasso algorithm are typically in congruence with the solution of the coordinate descent Lasso estimator. As a consequence using LassoLarsIC only makes sense for problems where a sparse solution is expected and/or reached.

Attributes

coef_ [array-like of shape (n_features,)] parameter vector (w in the formulation formula)

intercept_ [float] independent term in decision function.

alpha_ [float] the alpha parameter chosen by the information criterion

n_iter_ [int] number of iterations run by lars_path to find the grid of alphas.

criterion_ [array-like of shape (n_alphas,)] The value of the information criteria ('aic', 'bic') across all alphas. The alpha which has the smallest information criterion is chosen. This value is larger by a factor of `n_samples` compared to Eqns. 2.15 and 2.16 in (Zou et al, 2007).

See also:

lars_path, *LassoLars*, *LassoLarsCV*

Notes

The estimation of the number of degrees of freedom is given by:

"On the degrees of freedom of the lasso" Hui Zou, Trevor Hastie, and Robert Tibshirani Ann. Statist. Volume 35, Number 5 (2007), 2173-2192.

https://en.wikipedia.org/wiki/Akaike_information_criterion https://en.wikipedia.org/wiki/Bayesian_information_criterion

Examples

```
>>> from sklearn import linear_model
>>> reg = linear_model.LassoLarsIC(criterion='bic')
>>> reg.fit([[-1, 1], [0, 0], [1, 1]], [-1.1111, 0, -1.1111])
LassoLarsIC(criterion='bic')
>>> print(reg.coef_)
[ 0.  -1.11...]
```

Methods

fit(self, X, y[, copy_X])	Fit the model using X, y as training data.
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict using the linear model.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__(*self*, *criterion='aic'*, *fit_intercept=True*, *verbose=False*, *normalize=True*, *precompute='auto'*, *max_iter=500*, *eps=2.220446049250313e-16*, *copy_X=True*, *positive=False*)
Initialize self. See help(type(self)) for accurate signature.

fit(*self*, *X*, *y*, *copy_X=None*)
Fit the model using X, y as training data.

Parameters

X [array-like of shape (n_samples, n_features)] training data.

y [array-like of shape (n_samples,)] target values. Will be cast to X's dtype if necessary

copy_X [bool, default=None] If provided, this parameter will override the choice of copy_X

made at instance creation. If `True`, X will be copied; else, it may be overwritten.

Returns

self [object] returns an instance of self.

get_params(*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict(*self*, *X*)
Predict using the linear model.

Parameters

X [array_like or sparse matrix, shape (n_samples, n_features)] Samples.

Returns

C [array, shape (n_samples,)] Returns predicted values.

score(*self*, *X*, *y*, *sample_weight=None*)
Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params(*self*, ***params*)
Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

Examples using `sklearn.linear_model.LassoLarsIC`

- *Lasso model selection: Cross-Validation / AIC / BIC*

Out of Bag Estimates

When using ensemble methods base upon bagging, i.e. generating new training sets using sampling with replacement, part of the training set remains unused. For each classifier in the ensemble, a different part of the training set is left out.

This left out portion can be used to estimate the generalization error without having to rely on a separate validation set. This estimate comes "for free" as no additional data is needed and can be used for model selection.

This is currently implemented in the following classes:

ensemble.RandomForestClassifier([...])	A random forest classifier.
ensemble.RandomForestRegressor([...])	A random forest regressor.
ensemble.ExtraTreesClassifier([...])	An extra-trees classifier.
ensemble.ExtraTreesRegressor([n_estimators, ...])	An extra-trees regressor.
ensemble.GradientBoostingClassifier([loss, ...])	Gradient Boosting for classification.
ensemble.GradientBoostingRegressor([loss, ...])	Gradient Boosting for regression.

`sklearn.ensemble`.RandomForestClassifier

class sklearn.ensemble.**RandomForestClassifier**(*n_estimators=100*, *criterion='gini'*, *max_depth=None*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_features='auto'*, *max_leaf_nodes=None*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *bootstrap=True*, *oob_score=False*, *n_jobs=None*, *random_state=None*, *verbose=0*, *warm_start=False*, *class_weight=None*, *ccp_alpha=0.0*, *max_samples=None*)

A random forest classifier.

A random forest is a meta estimator that fits a number of decision tree classifiers on various sub-samples of the dataset and uses averaging to improve the predictive accuracy and control over-fitting. The sub-sample size is always the same as the original input sample size but the samples are drawn with replacement if `bootstrap=True` (default).

Read more in the *User Guide*.

Parameters

n_estimators [integer, optional (default=100)] The number of trees in the forest.

Changed in version 0.22: The default value of `n_estimators` changed from 10 to 100 in 0.22.

criterion [string, optional (default="gini")] The function to measure the quality of a split. Supported criteria are "gini" for the Gini impurity and "entropy" for the information gain. Note: this parameter is tree-specific.

max_depth [integer or None, optional (default=None)] The maximum depth of the tree. If None, then nodes are expanded until all leaves are pure or until all leaves contain less than min_samples_split samples.

min_samples_split [int, float, optional (default=2)] The minimum number of samples required to split an internal node:

- If int, then consider `min_samples_split` as the minimum number.
- If float, then `min_samples_split` is a fraction and `ceil(min_samples_split * n_samples)` are the minimum number of samples for each split.

Changed in version 0.18: Added float values for fractions.

min_samples_leaf [int, float, optional (default=1)] The minimum number of samples required to be at a leaf node. A split point at any depth will only be considered if it leaves at least `min_samples_leaf` training samples in each of the left and right branches. This may have the effect of smoothing the model, especially in regression.

- If int, then consider `min_samples_leaf` as the minimum number.
- If float, then `min_samples_leaf` is a fraction and `ceil(min_samples_leaf * n_samples)` are the minimum number of samples for each node.

Changed in version 0.18: Added float values for fractions.

min_weight_fraction_leaf [float, optional (default=0.)] The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when sample_weight is not provided.

max_features [int, float, string or None, optional (default="auto")] The number of features to consider when looking for the best split:

- If int, then consider `max_features` features at each split.
- If float, then `max_features` is a fraction and `int(max_features * n_features)` features are considered at each split.
- If "auto", then `max_features=sqrt(n_features)`.
- If "sqrt", then `max_features=sqrt(n_features)` (same as "auto").
- If "log2", then `max_features=log2(n_features)`.
- If None, then `max_features=n_features`.

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than `max_features` features.

max_leaf_nodes [int or None, optional (default=None)] Grow trees with `max_leaf_nodes` in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

min_impurity_decrease [float, optional (default=0.)] A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

```
N_t / N * (impurity - N_t_R / N_t * right_impurity
                    - N_t_L / N_t * left_impurity)
```

where `N` is the total number of samples, `N_t` is the number of samples at the current node, `N_t_L` is the number of samples in the left child, and `N_t_R` is the number of samples in the right child.

`N`, `N_t`, `N_t_R` and `N_t_L` all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

min_impurity_split [float, (default=1e-7)] Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19. The default value of `min_impurity_split` will change from 1e-7 to 0 in 0.23 and it will be removed in 0.25. Use `min_impurity_decrease` instead.

bootstrap [boolean, optional (default=True)] Whether bootstrap samples are used when building trees. If False, the whole datset is used to build each tree.

oob_score [bool (default=False)] Whether to use out-of-bag samples to estimate the generalization accuracy.

n_jobs [int or None, optional (default=None)] The number of jobs to run in parallel. *fit*, *predict*, *decision_path* and *apply* are all parallelized over the trees. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

random_state [int, RandomState instance or None, optional (default=None)] Controls both the randomness of the bootstrapping of the samples used when building trees (if `bootstrap=True`) and the sampling of the features to consider when looking for the best split at each node (if `max_features < n_features`). See *Glossary* for details.

verbose [int, optional (default=0)] Controls the verbosity when fitting and predicting.

warm_start [bool, optional (default=False)] When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just fit a whole new forest. See *the Glossary*.

class_weight [dict, list of dicts, "balanced", "balanced_subsample" or None, optional (default=None)] Weights associated with classes in the form `{class_label: weight}`. If not given, all classes are supposed to have weight one. For multi-output problems, a list of dicts can be provided in the same order as the columns of y.

Note that for multioutput (including multilabel) weights should be defined for each class of every column in its own dict. For example, for four-class multilabel classification weights should be [{0: 1, 1: 1}, {0: 1, 1: 5}, {0: 1, 1: 1}, {0: 1, 1: 1}] instead of [{1:1}, {2:5}, {3:1}, {4:1}].

The "balanced" mode uses the values of y to automatically adjust weights inversely proportional to class frequencies in the input data as `n_samples / (n_classes * np.bincount(y))`

The "balanced_subsample" mode is the same as "balanced" except that weights are computed based on the bootstrap sample for every tree grown.

For multi-output, the weights of each column of y will be multiplied.

Note that these weights will be multiplied with sample_weight (passed through the fit method) if sample_weight is specified.

ccp_alpha [non-negative float, optional (default=0.0)] Complexity parameter used for Minimal Cost-Complexity Pruning. The subtree with the largest cost complexity that is smaller than `ccp_alpha` will be chosen. By default, no pruning is performed. See *Minimal Cost-Complexity Pruning* for details.

New in version 0.22.

max_samples [int or float, default=None] If bootstrap is True, the number of samples to draw from X to train each base estimator.

- If None (default), then draw `X.shape[0]` samples.
- If int, then draw `max_samples` samples.
- If float, then draw `max_samples * X.shape[0]` samples. Thus, `max_samples` should be in the interval `(0, 1)`.

New in version 0.22.

Attributes

base_estimator_ [DecisionTreeClassifier] The child estimator template used to create the collection of fitted sub-estimators.

estimators_ [list of DecisionTreeClassifier] The collection of fitted sub-estimators.

classes_ [array of shape (n_classes,) or a list of such arrays] The classes labels (single output problem), or a list of arrays of class labels (multi-output problem).

n_classes_ [int or list] The number of classes (single output problem), or a list containing the number of classes for each output (multi-output problem).

n_features_ [int] The number of features when `fit` is performed.

n_outputs_ [int] The number of outputs when `fit` is performed.

feature_importances_ [ndarray of shape (n_features,)] Return the feature importances (the higher, the more important the feature).

oob_score_ [float] Score of the training dataset obtained using an out-of-bag estimate. This attribute exists only when `oob_score` is True.

oob_decision_function_ [array of shape (n_samples, n_classes)] Decision function computed with out-of-bag estimate on the training set. If n_estimators is small it might be possible that a data point was never left out during the bootstrap. In this case, `oob_decision_function_` might contain NaN. This attribute exists only when `oob_score` is True.

See also:

DecisionTreeClassifier, *ExtraTreesClassifier*

Notes

The default values for the parameters controlling the size of the trees (e.g. `max_depth`, `min_samples_leaf`, etc.) lead to fully grown and unpruned trees which can potentially be very large on some data sets. To reduce memory consumption, the complexity and size of the trees should be controlled by setting those parameter values.

The features are always randomly permuted at each split. Therefore, the best found split may vary, even with the same training data, `max_features=n_features` and `bootstrap=False`, if the improvement of the criterion is identical for several splits enumerated during the search of the best split. To obtain a deterministic behaviour during fitting, `random_state` has to be fixed.

[1]
```

Methods

apply(self, X)	Apply trees in the forest to X, return leaf indices.
decision_path(self, X)	Return the decision path in the forest.
fit(self, X, y[, sample_weight])	Build a forest of trees from the training set (X, y).
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict class for X.
predict_log_proba(self, X)	Predict class log-probabilities for X.
predict_proba(self, X)	Predict class probabilities for X.
score(self, X, y[, sample_weight])	Return the mean accuracy on the given test data and labels.
set_params(self, **params)	Set the parameters of this estimator.

__init__(*self*, *n_estimators=100*, *criterion='gini'*, *max_depth=None*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_features='auto'*, *max_leaf_nodes=None*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *bootstrap=True*, *oob_score=False*, *n_jobs=None*, *random_state=None*, *verbose=0*, *warm_start=False*, *class_weight=None*, *ccp_alpha=0.0*, *max_samples=None*)

Initialize self. See help(type(self)) for accurate signature.

apply(*self*, *X*)
Apply trees in the forest to X, return leaf indices.

Parameters

X [{array-like or sparse matrix} of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

X_leaves [array_like, shape = [n_samples, n_estimators]] For each datapoint x in X and for each tree in the forest, return the index of the leaf x ends up in.

decision_path(*self*, *X*)
Return the decision path in the forest.

New in version 0.18.

Parameters

X [{array-like or sparse matrix} of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

indicator [sparse csr array, shape = [n_samples, n_nodes]] Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes.

n_nodes_ptr [array of size (n_estimators + 1,)] The columns from indicator[n_nodes_ptr[i]:n_nodes_ptr[i+1]] gives the indicator value for the i-th estimator.

property feature_importances_

Return the feature importances (the higher, the more important the feature).

Returns

feature_importances_ [array, shape = [n_features]] The values of this array sum to 1, unless all trees are single node trees consisting of only the root node, in which case it will be an array of zeros.

fit(*self*, *X*, *y*, *sample_weight=None*)
Build a forest of trees from the training set (X, y).

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The training input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csc_matrix`.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] The target values (class labels in classification, real numbers in regression).

sample_weight [array-like of shape (n_samples,), default=None] Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

Returns

self [object]

get_params(*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict(*self*, *X*)
Predict class for X.

The predicted class of an input sample is a vote by the trees in the forest, weighted by their probability estimates. That is, the predicted class is the one with highest mean probability estimate across the trees.

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] The predicted classes.

predict_log_proba(*self*, *X*)
Predict class log-probabilities for X.

The predicted class log-probabilities of an input sample is computed as the log of the mean predicted class probabilities of the trees in the forest.

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

p [array of shape (n_samples, n_classes), or a list of n_outputs] such arrays if n_outputs > 1. The class probabilities of the input samples. The order of the classes corresponds to that in the attribute *classes_*.

predict_proba(*self*, *X*)
Predict class probabilities for X.

The predicted class probabilities of an input sample are computed as the mean predicted class probabilities of the trees in the forest. The class probability of a single tree is the fraction of samples of the same class in a leaf.

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

p [array of shape (n_samples, n_classes), or a list of n_outputs] such arrays if n_outputs > 1. The class probabilities of the input samples. The order of the classes corresponds to that in the attribute *classes_*.

score(*self*, *X*, *y*, *sample_weight=None*)
Return the mean accuracy on the given test data and labels.

In multi-label classification, this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True labels for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] Mean accuracy of self.predict(X) wrt. y.

set_params(*self*, ***params*)
Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

sklearn.ensemble.RandomForestRegressor

class sklearn.ensemble.**RandomForestRegressor**(*n_estimators=100*, *criterion='mse'*, *max_depth=None*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_features='auto'*, *max_leaf_nodes=None*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *bootstrap=True*, *oob_score=False*, *n_jobs=None*, *random_state=None*, *verbose=0*, *warm_start=False*, *ccp_alpha=0.0*, *max_samples=None*)

A random forest regressor.

A random forest is a meta estimator that fits a number of classifying decision trees on various sub-samples of the dataset and uses averaging to improve the predictive accuracy and control over-fitting. The sub-sample size is always the same as the original input sample size but the samples are drawn with replacement if `bootstrap=True` (default).

Read more in the *User Guide*.

Parameters

n_estimators [integer, optional (default=10)] The number of trees in the forest.

Changed in version 0.22: The default value of `n_estimators` changed from 10 to 100 in 0.22.

criterion [string, optional (default="mse")] The function to measure the quality of a split. Supported criteria are "mse" for the mean squared error, which is equal to variance reduction as feature selection criterion, and "mae" for the mean absolute error.

New in version 0.18: Mean Absolute Error (MAE) criterion.

max_depth [integer or None, optional (default=None)] The maximum depth of the tree. If None, then nodes are expanded until all leaves are pure or until all leaves contain less than min_samples_split samples.

min_samples_split [int, float, optional (default=2)] The minimum number of samples required to split an internal node:

- If int, then consider `min_samples_split` as the minimum number.
- If float, then `min_samples_split` is a fraction and `ceil(min_samples_split * n_samples)` are the minimum number of samples for each split.

Changed in version 0.18: Added float values for fractions.

min_samples_leaf [int, float, optional (default=1)] The minimum number of samples required to be at a leaf node. A split point at any depth will only be considered if it leaves at least `min_samples_leaf` training samples in each of the left and right branches. This may have the effect of smoothing the model, especially in regression.

- If int, then consider `min_samples_leaf` as the minimum number.
- If float, then `min_samples_leaf` is a fraction and `ceil(min_samples_leaf * n_samples)` are the minimum number of samples for each node.

Changed in version 0.18: Added float values for fractions.

min_weight_fraction_leaf [float, optional (default=0.)] The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when sample_weight is not provided.

max_features [int, float, string or None, optional (default="auto")] The number of features to consider when looking for the best split:

- If int, then consider `max_features` features at each split.
- If float, then `max_features` is a fraction and `int(max_features * n_features)` features are considered at each split.
- If "auto", then `max_features=n_features`.
- If "sqrt", then `max_features=sqrt(n_features)`.
- If "log2", then `max_features=log2(n_features)`.
- If None, then `max_features=n_features`.

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than `max_features` features.

max_leaf_nodes [int or None, optional (default=None)] Grow trees with `max_leaf_nodes` in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

min_impurity_decrease [float, optional (default=0.)] A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

```
N_t / N * (impurity - N_t_R / N_t * right_impurity
                    - N_t_L / N_t * left_impurity)
```

where `N` is the total number of samples, `N_t` is the number of samples at the current node, `N_t_L` is the number of samples in the left child, and `N_t_R` is the number of samples in the right child.

`N`, `N_t`, `N_t_R` and `N_t_L` all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

min_impurity_split [float, (default=1e-7)] Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19. The default value of `min_impurity_split` will change from 1e-7 to 0 in 0.23 and it will be removed in 0.25. Use `min_impurity_decrease` instead.

bootstrap [boolean, optional (default=True)] Whether bootstrap samples are used when building trees. If False, the whole datset is used to build each tree.

oob_score [bool, optional (default=False)] whether to use out-of-bag samples to estimate the R^2 on unseen data.

n_jobs [int or None, optional (default=None)] The number of jobs to run in parallel. *fit*, *predict*, *decision_path* and *apply* are all parallelized over the trees. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

random_state [int, RandomState instance or None, optional (default=None)] Controls both the randomness of the bootstrapping of the samples used when building trees (if

bootstrap=True) and the sampling of the features to consider when looking for the best split at each node (if max_features < n_features). See *Glossary* for details.

verbose [int, optional (default=0)] Controls the verbosity when fitting and predicting.

warm_start [bool, optional (default=False)] When set to True, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just fit a whole new forest. See *the Glossary*.

ccp_alpha [non-negative float, optional (default=0.0)] Complexity parameter used for Minimal Cost-Complexity Pruning. The subtree with the largest cost complexity that is smaller than ccp_alpha will be chosen. By default, no pruning is performed. See *Minimal Cost-Complexity Pruning* for details.

New in version 0.22.

max_samples [int or float, default=None] If bootstrap is True, the number of samples to draw from X to train each base estimator.

- If None (default), then draw X.shape[0] samples.
- If int, then draw max_samples samples.
- If float, then draw max_samples * X.shape[0] samples. Thus, max_samples should be in the interval (0, 1).

New in version 0.22.

Attributes

base_estimator_ [DecisionTreeRegressor] The child estimator template used to create the collection of fitted sub-estimators.

estimators_ [list of DecisionTreeRegressor] The collection of fitted sub-estimators.

feature_importances_ [ndarray of shape (n_features,)] Return the feature importances (the higher, the more important the feature).

n_features_ [int] The number of features when fit is performed.

n_outputs_ [int] The number of outputs when fit is performed.

oob_score_ [float] Score of the training dataset obtained using an out-of-bag estimate. This attribute exists only when oob_score is True.

oob_prediction_ [ndarray of shape (n_samples,)] Prediction computed with out-of-bag estimate on the training set. This attribute exists only when oob_score is True.

See also:

DecisionTreeRegressor, *ExtraTreesRegressor*

Notes

The default values for the parameters controlling the size of the trees (e.g. max_depth, min_samples_leaf, etc.) lead to fully grown and unpruned trees which can potentially be very large on some data sets. To reduce memory consumption, the complexity and size of the trees should be controlled by setting those parameter values.

The features are always randomly permuted at each split. Therefore, the best found split may vary, even with the same training data, max_features=n_features and bootstrap=False, if the improvement of the criterion is identical for several splits enumerated during the search of the best split. To obtain a deterministic behaviour during fitting, random_state has to be fixed.

The default value `max_features="auto"` uses `n_features` rather than `n_features / 3`. The latter was originally suggested in [1], whereas the former was more recently justified empirically in [2].

[-8.32987858]
```

Methods

apply(self, X)	Apply trees in the forest to X, return leaf indices.
decision_path(self, X)	Return the decision path in the forest.
fit(self, X, y[, sample_weight])	Build a forest of trees from the training set (X, y).
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict regression target for X.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.

__init__(*self*, *n_estimators=100*, *criterion='mse'*, *max_depth=None*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_features='auto'*, *max_leaf_nodes=None*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *bootstrap=True*, *oob_score=False*, *n_jobs=None*, *random_state=None*, *verbose=0*, *warm_start=False*, *ccp_alpha=0.0*, *max_samples=None*)

Initialize self. See help(type(self)) for accurate signature.

apply(*self*, *X*)

Apply trees in the forest to X, return leaf indices.

Parameters

X [{array-like or sparse matrix} of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

X_leaves [array_like, shape = [n_samples, n_estimators]] For each datapoint x in X and for each tree in the forest, return the index of the leaf x ends up in.

decision_path (*self*, *X*)
Return the decision path in the forest.

New in version 0.18.

Parameters

X [{array-like or sparse matrix} of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

indicator [sparse csr array, shape = [n_samples, n_nodes]] Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes.

n_nodes_ptr [array of size (n_estimators + 1,)] The columns from indicator[n_nodes_ptr[i]:n_nodes_ptr[i+1]] gives the indicator value for the i-th estimator.

property feature_importances_

Return the feature importances (the higher, the more important the feature).

Returns

feature_importances_ [array, shape = [n_features]] The values of this array sum to 1, unless all trees are single node trees consisting of only the root node, in which case it will be an array of zeros.

fit (*self*, *X*, *y*, *sample_weight=None*)
Build a forest of trees from the training set (X, y).

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The training input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csc_matrix`.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] The target values (class labels in classification, real numbers in regression).

sample_weight [array-like of shape (n_samples,), default=None] Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

Returns

self [object]

get_params (*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict (*self*, *X*)
Predict regression target for X.

The predicted regression target of an input sample is computed as the mean predicted regression targets of the trees in the forest.

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] The predicted values.

score (*self*, *X*, *y*, *sample_weight=None*)
Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params (*self*, ***params*)
Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

Examples using `sklearn.ensemble.RandomForestRegressor`

- *Plot individual and voting regression predictions*
- *Comparing random forests and the multi-output meta estimator*
- *Combine predictors using stacking*
- *Prediction Latency*
- *Imputing missing values with variants of IterativeImputer*
- *Imputing missing values before building an estimator*

`sklearn.ensemble.ExtraTreesClassifier`

class sklearn.ensemble.**ExtraTreesClassifier**(*n_estimators=100*, *criterion='gini'*, *max_depth=None*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_features='auto'*, *max_leaf_nodes=None*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *bootstrap=False*, *oob_score=False*, *n_jobs=None*, *random_state=None*, *verbose=0*, *warm_start=False*, *class_weight=None*, *ccp_alpha=0.0*, *max_samples=None*)

An extra-trees classifier.

This class implements a meta estimator that fits a number of randomized decision trees (a.k.a. extra-trees) on various sub-samples of the dataset and uses averaging to improve the predictive accuracy and control over-fitting.

Read more in the *User Guide*.

Parameters

n_estimators [integer, optional (default=10)] The number of trees in the forest.

Changed in version 0.22: The default value of `n_estimators` changed from 10 to 100 in 0.22.

criterion [string, optional (default="gini")] The function to measure the quality of a split. Supported criteria are "gini" for the Gini impurity and "entropy" for the information gain.

max_depth [integer or None, optional (default=None)] The maximum depth of the tree. If None, then nodes are expanded until all leaves are pure or until all leaves contain less than min_samples_split samples.

min_samples_split [int, float, optional (default=2)] The minimum number of samples required to split an internal node:

- If int, then consider `min_samples_split` as the minimum number.
- If float, then `min_samples_split` is a fraction and `ceil(min_samples_split * n_samples)` are the minimum number of samples for each split.

Changed in version 0.18: Added float values for fractions.

min_samples_leaf [int, float, optional (default=1)] The minimum number of samples required to be at a leaf node. A split point at any depth will only be considered if it leaves at least

min_samples_leaf training samples in each of the left and right branches. This may have the effect of smoothing the model, especially in regression.

- If int, then consider min_samples_leaf as the minimum number.
- If float, then min_samples_leaf is a fraction and ceil(min_samples_leaf * n_samples) are the minimum number of samples for each node.

Changed in version 0.18: Added float values for fractions.

min_weight_fraction_leaf [float, optional (default=0.)] The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when sample_weight is not provided.

max_features [int, float, string or None, optional (default="auto")] The number of features to consider when looking for the best split:

- If int, then consider max_features features at each split.
- If float, then max_features is a fraction and int(max_features * n_features) features are considered at each split.
- If "auto", then max_features=sqrt(n_features).
- If "sqrt", then max_features=sqrt(n_features).
- If "log2", then max_features=log2(n_features).
- If None, then max_features=n_features.

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than max_features features.

max_leaf_nodes [int or None, optional (default=None)] Grow trees with max_leaf_nodes in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

min_impurity_decrease [float, optional (default=0.)] A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

```
N_t / N * (impurity - N_t_R / N_t * right_impurity
                    - N_t_L / N_t * left_impurity)
```

where N is the total number of samples, N_t is the number of samples at the current node, N_t_L is the number of samples in the left child, and N_t_R is the number of samples in the right child.

N, N_t, N_t_R and N_t_L all refer to the weighted sum, if sample_weight is passed.

New in version 0.19.

min_impurity_split [float, (default=1e-7)] Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: min_impurity_split has been deprecated in favor of min_impurity_decrease in 0.19. The default value of min_impurity_split will change from 1e-7 to 0 in 0.23 and it will be removed in 0.25. Use min_impurity_decrease instead.

bootstrap [boolean, optional (default=False)] Whether bootstrap samples are used when building trees. If False, the whole dataset is used to build each tree.

oob_score [bool, optional (default=False)] Whether to use out-of-bag samples to estimate the generalization accuracy.

n_jobs [int or None, optional (default=None)] The number of jobs to run in parallel. *fit*, *predict*, *decision_path* and *apply* are all parallelized over the trees. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

random_state [int, RandomState instance or None, optional (default=None)] Controls 3 sources of randomness:

- the bootstrapping of the samples used when building trees (if `bootstrap=True`)
- the sampling of the features to consider when looking for the best split at each node (if `max_features < n_features`)
- the draw of the splits for each of the `max_features`

See *Glossary* for details.

verbose [int, optional (default=0)] Controls the verbosity when fitting and predicting.

warm_start [bool, optional (default=False)] When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just fit a whole new forest. See *the Glossary*.

class_weight [dict, list of dicts, "balanced", "balanced_subsample" or None, optional (default=None)] Weights associated with classes in the form `{class_label: weight}`. If not given, all classes are supposed to have weight one. For multi-output problems, a list of dicts can be provided in the same order as the columns of y.

Note that for multioutput (including multilabel) weights should be defined for each class of every column in its own dict. For example, for four-class multilabel classification weights should be [{0: 1, 1: 1}, {0: 1, 1: 5}, {0: 1, 1: 1}, {0: 1, 1: 1}] instead of [{1:1}, {2:5}, {3:1}, {4:1}].

The "balanced" mode uses the values of y to automatically adjust weights inversely proportional to class frequencies in the input data as `n_samples / (n_classes * np.bincount(y))`

The "balanced_subsample" mode is the same as "balanced" except that weights are computed based on the bootstrap sample for every tree grown.

For multi-output, the weights of each column of y will be multiplied.

Note that these weights will be multiplied with sample_weight (passed through the fit method) if sample_weight is specified.

ccp_alpha [non-negative float, optional (default=0.0)] Complexity parameter used for Minimal Cost-Complexity Pruning. The subtree with the largest cost complexity that is smaller than `ccp_alpha` will be chosen. By default, no pruning is performed. See *Minimal Cost-Complexity Pruning* for details.

New in version 0.22.

max_samples [int or float, default=None] If bootstrap is True, the number of samples to draw from X to train each base estimator.

- If None (default), then draw `X.shape[0]` samples.
- If int, then draw `max_samples` samples.
- If float, then draw `max_samples * X.shape[0]` samples. Thus, `max_samples` should be in the interval `(0, 1)`.

New in version 0.22.

Attributes

base_estimator_ [ExtraTreeClassifier] The child estimator template used to create the collection of fitted sub-estimators.

estimators_ [list of DecisionTreeClassifier] The collection of fitted sub-estimators.

classes_ [array of shape (n_classes,) or a list of such arrays] The classes labels (single output problem), or a list of arrays of class labels (multi-output problem).

n_classes_ [int or list] The number of classes (single output problem), or a list containing the number of classes for each output (multi-output problem).

feature_importances_ [ndarray of shape (n_features,)] Return the feature importances (the higher, the more important the feature).

n_features_ [int] The number of features when `fit` is performed.

n_outputs_ [int] The number of outputs when `fit` is performed.

oob_score_ [float] Score of the training dataset obtained using an out-of-bag estimate. This attribute exists only when `oob_score` is True.

oob_decision_function_ [array of shape (n_samples, n_classes)] Decision function computed with out-of-bag estimate on the training set. If n_estimators is small it might be possible that a data point was never left out during the bootstrap. In this case, `oob_decision_function_` might contain NaN. This attribute exists only when `oob_score` is True.

See also:

sklearn.tree.ExtraTreeClassifier Base classifier for this ensemble.

RandomForestClassifier Ensemble Classifier based on trees with optimal splits.

Notes

The default values for the parameters controlling the size of the trees (e.g. `max_depth`, `min_samples_leaf`, etc.) lead to fully grown and unpruned trees which can potentially be very large on some data sets. To reduce memory consumption, the complexity and size of the trees should be controlled by setting those parameter values.

Examples

```
>>> from sklearn.ensemble import ExtraTreesClassifier
>>> from sklearn.datasets import make_classification
>>> X, y = make_classification(n_features=4, random_state=0)
>>> clf = ExtraTreesClassifier(n_estimators=100, random_state=0)
>>> clf.fit(X, y)
ExtraTreesClassifier(random_state=0)
>>> clf.predict([[0, 0, 0, 0]])
array([1])
```

Methods

apply(self, X)	Apply trees in the forest to X, return leaf indices.
decision_path(self, X)	Return the decision path in the forest.
fit(self, X, y[, sample_weight])	Build a forest of trees from the training set (X, y).
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict class for X.
predict_log_proba(self, X)	Predict class log-probabilities for X.
predict_proba(self, X)	Predict class probabilities for X.
score(self, X, y[, sample_weight])	Return the mean accuracy on the given test data and labels.
set_params(self, **params)	Set the parameters of this estimator.

__init__(*self*, *n_estimators=100*, *criterion='gini'*, *max_depth=None*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_features='auto'*, *max_leaf_nodes=None*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *bootstrap=False*, *oob_score=False*, *n_jobs=None*, *random_state=None*, *verbose=0*, *warm_start=False*, *class_weight=None*, *ccp_alpha=0.0*, *max_samples=None*)

Initialize self. See help(type(self)) for accurate signature.

apply(*self*, *X*)

Apply trees in the forest to X, return leaf indices.

Parameters

X [{array-like or sparse matrix} of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

X_leaves [array_like, shape = [n_samples, n_estimators]] For each datapoint x in X and for each tree in the forest, return the index of the leaf x ends up in.

decision_path(*self*, *X*)

Return the decision path in the forest.

New in version 0.18.

Parameters

X [{array-like or sparse matrix} of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

indicator [sparse csr array, shape = [n_samples, n_nodes]] Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes.

n_nodes_ptr [array of size (n_estimators + 1,)] The columns from indicator[n_nodes_ptr[i]:n_nodes_ptr[i+1]] gives the indicator value for the i-th estimator.

property feature_importances_

Return the feature importances (the higher, the more important the feature).

Returns

feature_importances_ [array, shape = [n_features]] The values of this array sum to 1, unless all trees are single node trees consisting of only the root node, in which case it will be an array of zeros.

fit (*self*, *X*, *y*, *sample_weight=None*)

Build a forest of trees from the training set (X, y).

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The training input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csc_matrix`.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] The target values (class labels in classification, real numbers in regression).

sample_weight [array-like of shape (n_samples,), default=None] Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

Returns

self [object]

get_params (*self*, *deep=True*)

Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict (*self*, *X*)

Predict class for X.

The predicted class of an input sample is a vote by the trees in the forest, weighted by their probability estimates. That is, the predicted class is the one with highest mean probability estimate across the trees.

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] The predicted classes.

predict_log_proba (*self*, *X*)

Predict class log-probabilities for X.

The predicted class log-probabilities of an input sample is computed as the log of the mean predicted class probabilities of the trees in the forest.

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

p [array of shape (n_samples, n_classes), or a list of n_outputs] such arrays if n_outputs > 1. The class probabilities of the input samples. The order of the classes corresponds to that in the attribute *classes_*.

predict_proba(*self*, *X*)

Predict class probabilities for X.

The predicted class probabilities of an input sample are computed as the mean predicted class probabilities of the trees in the forest. The class probability of a single tree is the fraction of samples of the same class in a leaf.

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

p [array of shape (n_samples, n_classes), or a list of n_outputs] such arrays if n_outputs > 1. The class probabilities of the input samples. The order of the classes corresponds to that in the attribute *classes_*.

score(*self*, *X*, *y*, *sample_weight=None*)

Return the mean accuracy on the given test data and labels.

In multi-label classification, this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True labels for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] Mean accuracy of self.predict(X) wrt. y.

set_params(*self*, ***params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

Examples using `sklearn.ensemble.ExtraTreesClassifier`

- *Pixel importances with a parallel forest of trees*
- *Feature importances with forests of trees*
- *Hashing feature transformation using Totally Random Trees*
- *Plot the decision surfaces of ensembles of trees on the iris dataset*

`sklearn.ensemble.ExtraTreesRegressor`

class sklearn.ensemble.**ExtraTreesRegressor**(*n_estimators=100*, *criterion='mse'*, *max_depth=None*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_features='auto'*, *max_leaf_nodes=None*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *bootstrap=False*, *oob_score=False*, *n_jobs=None*, *random_state=None*, *verbose=0*, *warm_start=False*, *ccp_alpha=0.0*, *max_samples=None*)

An extra-trees regressor.

This class implements a meta estimator that fits a number of randomized decision trees (a.k.a. extra-trees) on various sub-samples of the dataset and uses averaging to improve the predictive accuracy and control over-fitting.

Read more in the *User Guide*.

Parameters

n_estimators [integer, optional (default=10)] The number of trees in the forest.

Changed in version 0.22: The default value of `n_estimators` changed from 10 to 100 in 0.22.

criterion [string, optional (default="mse")] The function to measure the quality of a split. Supported criteria are "mse" for the mean squared error, which is equal to variance reduction as feature selection criterion, and "mae" for the mean absolute error.

New in version 0.18: Mean Absolute Error (MAE) criterion.

max_depth [integer or None, optional (default=None)] The maximum depth of the tree. If None, then nodes are expanded until all leaves are pure or until all leaves contain less than min_samples_split samples.

min_samples_split [int, float, optional (default=2)] The minimum number of samples required to split an internal node:

- If int, then consider `min_samples_split` as the minimum number.
- If float, then `min_samples_split` is a fraction and `ceil(min_samples_split * n_samples)` are the minimum number of samples for each split.

Changed in version 0.18: Added float values for fractions.

min_samples_leaf [int, float, optional (default=1)] The minimum number of samples required to be at a leaf node. A split point at any depth will only be considered if it leaves at least `min_samples_leaf` training samples in each of the left and right branches. This may have the effect of smoothing the model, especially in regression.

- If int, then consider `min_samples_leaf` as the minimum number.
- If float, then `min_samples_leaf` is a fraction and `ceil(min_samples_leaf * n_samples)` are the minimum number of samples for each node.

Changed in version 0.18: Added float values for fractions.

min_weight_fraction_leaf [float, optional (default=0.)] The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when sample_weight is not provided.

max_features [int, float, string or None, optional (default="auto")] The number of features to consider when looking for the best split:

- If int, then consider `max_features` features at each split.
- If float, then `max_features` is a fraction and `int(max_features * n_features)` features are considered at each split.
- If "auto", then `max_features=n_features`.
- If "sqrt", then `max_features=sqrt(n_features)`.
- If "log2", then `max_features=log2(n_features)`.
- If None, then `max_features=n_features`.

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than `max_features` features.

max_leaf_nodes [int or None, optional (default=None)] Grow trees with `max_leaf_nodes` in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

min_impurity_decrease [float, optional (default=0.)] A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

```
N_t / N * (impurity - N_t_R / N_t * right_impurity
                    - N_t_L / N_t * left_impurity)
```

where `N` is the total number of samples, `N_t` is the number of samples at the current node, `N_t_L` is the number of samples in the left child, and `N_t_R` is the number of samples in the right child.

`N`, `N_t`, `N_t_R` and `N_t_L` all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

min_impurity_split [float, (default=1e-7)] Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19. The default value of `min_impurity_split` will change from 1e-7 to 0 in 0.23 and it will be removed in 0.25. Use `min_impurity_decrease` instead.

bootstrap [boolean, optional (default=False)] Whether bootstrap samples are used when building trees. If False, the whole dataset is used to build each tree.

oob_score [bool, optional (default=False)] Whether to use out-of-bag samples to estimate the R^2 on unseen data.

n_jobs [int or None, optional (default=None)] The number of jobs to run in parallel. *fit*, *predict*, *decision_path* and *apply* are all parallelized over the trees. `None` means 1 unless in a `joblib.parallel_backend` context. `-1` means using all processors. See *Glossary* for more details.

random_state [int, RandomState instance or None, optional (default=None)] Controls 3 sources of randomness:

- the bootstrapping of the samples used when building trees (if `bootstrap=True`)
- the sampling of the features to consider when looking for the best split at each node (if `max_features < n_features`)
- the draw of the splits for each of the `max_features`

See *Glossary* for details.

verbose [int, optional (default=0)] Controls the verbosity when fitting and predicting.

warm_start [bool, optional (default=False)] When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just fit a whole new forest. See *the Glossary*.

ccp_alpha [non-negative float, optional (default=0.0)] Complexity parameter used for Minimal Cost-Complexity Pruning. The subtree with the largest cost complexity that is smaller than `ccp_alpha` will be chosen. By default, no pruning is performed. See *Minimal Cost-Complexity Pruning* for details.

New in version 0.22.

max_samples [int or float, default=None] If bootstrap is True, the number of samples to draw from X to train each base estimator.

- If None (default), then draw `X.shape[0]` samples.
- If int, then draw `max_samples` samples.
- If float, then draw `max_samples * X.shape[0]` samples. Thus, `max_samples` should be in the interval `(0, 1)`.

New in version 0.22.

Attributes

base_estimator_ [ExtraTreeRegressor] The child estimator template used to create the collection of fitted sub-estimators.

estimators_ [list of DecisionTreeRegressor] The collection of fitted sub-estimators.

feature_importances_ [ndarray of shape (n_features,)] Return the feature importances (the higher, the more important the feature).

n_features_ [int] The number of features.

n_outputs_ [int] The number of outputs.

oob_score_ [float] Score of the training dataset obtained using an out-of-bag estimate. This attribute exists only when `oob_score` is True.

oob_prediction_ [ndarray of shape (n_samples,)] Prediction computed with out-of-bag estimate on the training set. This attribute exists only when `oob_score` is True.

Initialize self. See help(type(self)) for accurate signature.

apply(*self*, *X*)

Apply trees in the forest to X, return leaf indices.

Parameters

X [{array-like or sparse matrix} of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

X_leaves [array_like, shape = [n_samples, n_estimators]] For each datapoint x in X and for each tree in the forest, return the index of the leaf x ends up in.

decision_path(*self*, *X*)

Return the decision path in the forest.

New in version 0.18.

Parameters

X [{array-like or sparse matrix} of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

indicator [sparse csr array, shape = [n_samples, n_nodes]] Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes.

n_nodes_ptr [array of size (n_estimators + 1,)] The columns from indicator[n_nodes_ptr[i]:n_nodes_ptr[i+1]] gives the indicator value for the i-th estimator.

property feature_importances_

Return the feature importances (the higher, the more important the feature).

Returns

feature_importances_ [array, shape = [n_features]] The values of this array sum to 1, unless all trees are single node trees consisting of only the root node, in which case it will be an array of zeros.

fit (*self*, *X*, *y*, *sample_weight=None*)

Build a forest of trees from the training set (X, y).

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The training input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csc_matrix`.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] The target values (class labels in classification, real numbers in regression).

sample_weight [array-like of shape (n_samples,), default=None] Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

Returns

self [object]

get_params (*self*, *deep=True*)

Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict (*self*, *X*)

Predict regression target for X.

The predicted regression target of an input sample is computed as the mean predicted regression targets of the trees in the forest.

Parameters

X [array-like or sparse matrix of shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

Returns

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] The predicted values.

score (*self*, *X*, *y*, *sample_weight=None*)

Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params (*self*, ***params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

Examples using `sklearn.ensemble.ExtraTreesRegressor`

- *Face completion with a multi-output estimators*
- *Imputing missing values with variants of IterativeImputer*

sklearn.ensemble.GradientBoostingClassifier

class sklearn.ensemble.**GradientBoostingClassifier**(*loss='deviance'*, *learning_rate=0.1*, *n_estimators=100*, *subsample=1.0*, *criterion='friedman_mse'*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_depth=3*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *init=None*, *random_state=None*, *max_features=None*, *verbose=0*, *max_leaf_nodes=None*, *warm_start=False*, *presort='deprecated'*, *validation_fraction=0.1*, *n_iter_no_change=None*, *tol=0.0001*, *ccp_alpha=0.0*)

Gradient Boosting for classification.

GB builds an additive model in a forward stage-wise fashion; it allows for the optimization of arbitrary differentiable loss functions. In each stage `n_classes_` regression trees are fit on the negative gradient of the binomial or multinomial deviance loss function. Binary classification is a special case where only a single regression tree is induced.

Read more in the *User Guide*.

Parameters

loss [{'deviance', 'exponential'}, optional (default='deviance')] loss function to be optimized. 'deviance' refers to deviance (= logistic regression) for classification with probabilistic outputs. For loss 'exponential' gradient boosting recovers the AdaBoost algorithm.

learning_rate [float, optional (default=0.1)] learning rate shrinks the contribution of each tree by `learning_rate`. There is a trade-off between learning_rate and n_estimators.

n_estimators [int (default=100)] The number of boosting stages to perform. Gradient boosting is fairly robust to over-fitting so a large number usually results in better performance.

subsample [float, optional (default=1.0)] The fraction of samples to be used for fitting the individual base learners. If smaller than 1.0 this results in Stochastic Gradient Boosting. `subsample` interacts with the parameter `n_estimators`. Choosing `subsample < 1.0` leads to a reduction of variance and an increase in bias.

criterion [string, optional (default="friedman_mse")] The function to measure the quality of a split. Supported criteria are "friedman_mse" for the mean squared error with improvement score by Friedman, "mse" for mean squared error, and "mae" for the mean absolute error. The default value of "friedman_mse" is generally the best as it can provide a better approximation in some cases.

New in version 0.18.

min_samples_split [int, float, optional (default=2)] The minimum number of samples required to split an internal node:

- If int, then consider `min_samples_split` as the minimum number.

- If float, then `min_samples_split` is a fraction and `ceil(min_samples_split * n_samples)` are the minimum number of samples for each split.

Changed in version 0.18: Added float values for fractions.

min_samples_leaf [int, float, optional (default=1)] The minimum number of samples required to be at a leaf node. A split point at any depth will only be considered if it leaves at least `min_samples_leaf` training samples in each of the left and right branches. This may have the effect of smoothing the model, especially in regression.

- If int, then consider `min_samples_leaf` as the minimum number.
- If float, then `min_samples_leaf` is a fraction and `ceil(min_samples_leaf * n_samples)` are the minimum number of samples for each node.

Changed in version 0.18: Added float values for fractions.

min_weight_fraction_leaf [float, optional (default=0.)] The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when sample_weight is not provided.

max_depth [integer, optional (default=3)] maximum depth of the individual regression estimators. The maximum depth limits the number of nodes in the tree. Tune this parameter for best performance; the best value depends on the interaction of the input variables.

min_impurity_decrease [float, optional (default=0.)] A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

```
N_t / N * (impurity - N_t_R / N_t * right_impurity
                    - N_t_L / N_t * left_impurity)
```

where `N` is the total number of samples, `N_t` is the number of samples at the current node, `N_t_L` is the number of samples in the left child, and `N_t_R` is the number of samples in the right child.

`N`, `N_t`, `N_t_R` and `N_t_L` all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

min_impurity_split [float, (default=1e-7)] Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19. The default value of `min_impurity_split` will change from 1e-7 to 0 in 0.23 and it will be removed in 0.25. Use `min_impurity_decrease` instead.

init [estimator or 'zero', optional (default=None)] An estimator object that is used to compute the initial predictions. `init` has to provide *fit* and *predict_proba*. If 'zero', the initial raw predictions are set to zero. By default, a `DummyEstimator` predicting the classes priors is used.

random_state [int, RandomState instance or None, optional (default=None)] If int, random_state is the seed used by the random number generator; If RandomState instance, random_state is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`.

max_features [int, float, string or None, optional (default=None)] The number of features to consider when looking for the best split:

- If int, then consider `max_features` features at each split.

- If float, then `max_features` is a fraction and `int(max_features * n_features)` features are considered at each split.
- If "auto", then `max_features=sqrt(n_features)`.
- If "sqrt", then `max_features=sqrt(n_features)`.
- If "log2", then `max_features=log2(n_features)`.
- If None, then `max_features=n_features`.

Choosing `max_features < n_features` leads to a reduction of variance and an increase in bias.

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than `max_features` features.

verbose [int, default: 0] Enable verbose output. If 1 then it prints progress and performance once in a while (the more trees the lower the frequency). If greater than 1 then it prints progress and performance for every tree.

max_leaf_nodes [int or None, optional (default=None)] Grow trees with `max_leaf_nodes` in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

warm_start [bool, default: False] When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just erase the previous solution. See *the Glossary*.

presort [deprecated, default='deprecated'] This parameter is deprecated and will be removed in v0.24.

Deprecated since version 0.22.

validation_fraction [float, optional, default 0.1] The proportion of training data to set aside as validation set for early stopping. Must be between 0 and 1. Only used if `n_iter_no_change` is set to an integer.

New in version 0.20.

n_iter_no_change [int, default None] `n_iter_no_change` is used to decide if early stopping will be used to terminate training when validation score is not improving. By default it is set to None to disable early stopping. If set to a number, it will set aside `validation_fraction` size of the training data as validation and terminate training when validation score is not improving in all of the previous `n_iter_no_change` numbers of iterations. The split is stratified.

New in version 0.20.

tol [float, optional, default 1e-4] Tolerance for the early stopping. When the loss is not improving by at least tol for `n_iter_no_change` iterations (if set to a number), the training stops.

New in version 0.20.

ccp_alpha [non-negative float, optional (default=0.0)] Complexity parameter used for Minimal Cost-Complexity Pruning. The subtree with the largest cost complexity that is smaller than `ccp_alpha` will be chosen. By default, no pruning is performed. See *Minimal Cost-Complexity Pruning* for details.

New in version 0.22.

Attributes

n_estimators_ [int] The number of estimators as selected by early stopping (if `n_iter_no_change` is specified). Otherwise it is set to `n_estimators`.

New in version 0.20.

feature_importances_ [array, shape (n_features,)] Return the feature importances (the higher, the more important the feature).

oob_improvement_ [array, shape (n_estimators,)] The improvement in loss (= deviance) on the out-of-bag samples relative to the previous iteration. `oob_improvement_[0]` is the improvement in loss of the first stage over the `init` estimator. Only available if `subsample < 1.0`

train_score_ [array, shape (n_estimators,)] The i-th score `train_score_[i]` is the deviance (= loss) of the model at iteration `i` on the in-bag sample. If `subsample == 1` this is the deviance on the training data.

loss_ [LossFunction] The concrete `LossFunction` object.

init_ [estimator] The estimator that provides the initial predictions. Set via the `init` argument or `loss.init_estimator`.

estimators_ [ndarray of DecisionTreeRegressor,shape (n_estimators, `loss_.K`)] The collection of fitted sub-estimators. `loss_.K` is 1 for binary classification, otherwise n_classes.

classes_ [array of shape (n_classes,)] The classes labels.

sklearn.tree.DecisionTreeClassifier, ***RandomForestClassifier***

AdaBoostClassifier

Notes

The features are always randomly permuted at each split. Therefore, the best found split may vary, even with the same training data and `max_features=n_features`, if the improvement of the criterion is identical for several splits enumerated during the search of the best split. To obtain a deterministic behaviour during fitting, `random_state` has to be fixed.

Methods

apply(self, X)	Apply trees in the ensemble to X, return leaf indices.
decision_function(self, X)	Compute the decision function of `X`.
fit(self, X, y[, sample_weight, monitor])	Fit the gradient boosting model.

Continued on next page

Table 19 – continued from previous page

get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict class for X.
predict_log_proba(self, X)	Predict class log-probabilities for X.
predict_proba(self, X)	Predict class probabilities for X.
score(self, X, y[, sample_weight])	Return the mean accuracy on the given test data and labels.
set_params(self, **params)	Set the parameters of this estimator.
staged_decision_function(self, X)	Compute decision function of X for each iteration.
staged_predict(self, X)	Predict class at each stage for X.
staged_predict_proba(self, X)	Predict class probabilities at each stage for X.

__init__ (*self*, *loss='deviance'*, *learning_rate=0.1*, *n_estimators=100*, *subsample=1.0*, *criterion='friedman_mse'*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_depth=3*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *init=None*, *random_state=None*, *max_features=None*, *verbose=0*, *max_leaf_nodes=None*, *warm_start=False*, *presort='deprecated'*, *validation_fraction=0.1*, *n_iter_no_change=None*, *tol=0.0001*, *ccp_alpha=0.0*)

Initialize self. See help(type(self)) for accurate signature.

apply (*self*, *X*)

Apply trees in the ensemble to X, return leaf indices.

New in version 0.17.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted to a sparse `csr_matrix`.

Returns

X_leaves [array-like, shape (n_samples, n_estimators, n_classes)] For each datapoint x in X and for each tree in the ensemble, return the index of the leaf x ends up in each estimator. In the case of binary classification n_classes is 1.

decision_function (*self*, *X*)

Compute the decision function of `X`.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

Returns

score [array, shape (n_samples, n_classes) or (n_samples,)] The decision function of the input samples, which corresponds to the raw values predicted from the trees of the ensemble . The order of the classes corresponds to that in the attribute *classes_*. Regression and binary classification produce an array of shape [n_samples].

property feature_importances_

Return the feature importances (the higher, the more important the feature).

Returns

feature_importances_ [array, shape (n_features,)] The values of this array sum to 1, unless all trees are single node trees consisting of only the root node, in which case it will be an array of zeros.

fit (*self*, *X*, *y*, *sample_weight=None*, *monitor=None*)
Fit the gradient boosting model.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

y [array-like, shape (n_samples,)] Target values (strings or integers in classification, real numbers in regression) For classification, labels must correspond to classes.

sample_weight [array-like, shape (n_samples,) or None] Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

monitor [callable, optional] The monitor is called after each iteration with the current iteration, a reference to the estimator and the local variables of `_fit_stages` as keyword arguments `callable(i, self, locals())`. If the callable returns `True` the fitting procedure is stopped. The monitor can be used for various things such as computing held-out estimates, early stopping, model introspect, and snapshoting.

Returns

self [object]

get_params (*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict (*self*, *X*)
Predict class for X.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

Returns

y [array, shape (n_samples,)] The predicted values.

predict_log_proba (*self*, *X*)
Predict class log-probabilities for X.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

Returns

p [array, shape (n_samples, n_classes)] The class log-probabilities of the input samples. The order of the classes corresponds to that in the attribute *classes_*.

Raises

AttributeError If the `loss` does not support probabilities.

predict_proba(*self*, *X*)

Predict class probabilities for X.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

Returns

p [array, shape (n_samples, n_classes)] The class probabilities of the input samples. The order of the classes corresponds to that in the attribute *classes_*.

Raises

AttributeError If the `loss` does not support probabilities.

score(*self*, *X*, *y*, *sample_weight=None*)

Return the mean accuracy on the given test data and labels.

In multi-label classification, this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True labels for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] Mean accuracy of self.predict(X) wrt. y.

set_params(*self*, ***params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

staged_decision_function(*self*, *X*)

Compute decision function of `X` for each iteration.

This method allows monitoring (i.e. determine error on testing set) after each stage.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

Returns

score [generator of array, shape (n_samples, k)] The decision function of the input samples, which corresponds to the raw values predicted from the trees of the ensemble . The classes corresponds to that in the attribute *classes_*. Regression and binary classification are special cases with `k == 1`, otherwise `k==n_classes`.

staged_predict (*self*, *X*)

Predict class at each stage for X.

This method allows monitoring (i.e. determine error on testing set) after each stage.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

Returns

y [generator of array of shape (n_samples,)] The predicted value of the input samples.

staged_predict_proba (*self*, *X*)

Predict class probabilities at each stage for X.

This method allows monitoring (i.e. determine error on testing set) after each stage.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

Returns

y [generator of array of shape (n_samples,)] The predicted value of the input samples.

Examples using `sklearn.ensemble.GradientBoostingClassifier`

- *Gradient Boosting regularization*
- *Early stopping of Gradient Boosting*

- *Feature discretization*

sklearn.ensemble.GradientBoostingRegressor

class sklearn.ensemble.**GradientBoostingRegressor**(*loss='ls'*, *learning_rate=0.1*, *n_estimators=100*, *subsample=1.0*, *criterion='friedman_mse'*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_depth=3*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *init=None*, *random_state=None*, *max_features=None*, *alpha=0.9*, *verbose=0*, *max_leaf_nodes=None*, *warm_start=False*, *presort='deprecated'*, *validation_fraction=0.1*, *n_iter_no_change=None*, *tol=0.0001*, *ccp_alpha=0.0*)

Gradient Boosting for regression.

GB builds an additive model in a forward stage-wise fashion; it allows for the optimization of arbitrary differentiable loss functions. In each stage a regression tree is fit on the negative gradient of the given loss function.

Read more in the *User Guide*.

Parameters

loss [{'ls', 'lad', 'huber', 'quantile'}, optional (default='ls')] loss function to be optimized. 'ls' refers to least squares regression. 'lad' (least absolute deviation) is a highly robust loss function solely based on order information of the input variables. 'huber' is a combination of the two. 'quantile' allows quantile regression (use `alpha` to specify the quantile).

learning_rate [float, optional (default=0.1)] learning rate shrinks the contribution of each tree by `learning_rate`. There is a trade-off between learning_rate and n_estimators.

n_estimators [int (default=100)] The number of boosting stages to perform. Gradient boosting is fairly robust to over-fitting so a large number usually results in better performance.

subsample [float, optional (default=1.0)] The fraction of samples to be used for fitting the individual base learners. If smaller than 1.0 this results in Stochastic Gradient Boosting. `subsample` interacts with the parameter `n_estimators`. Choosing `subsample < 1.0` leads to a reduction of variance and an increase in bias.

criterion [string, optional (default="friedman_mse")] The function to measure the quality of a split. Supported criteria are "friedman_mse" for the mean squared error with improvement score by Friedman, "mse" for mean squared error, and "mae" for the mean absolute error. The default value of "friedman_mse" is generally the best as it can provide a better approximation in some cases.

New in version 0.18.

min_samples_split [int, float, optional (default=2)] The minimum number of samples required to split an internal node:

- If int, then consider `min_samples_split` as the minimum number.
- If float, then `min_samples_split` is a fraction and `ceil(min_samples_split * n_samples)` are the minimum number of samples for each split.

Changed in version 0.18: Added float values for fractions.

min_samples_leaf [int, float, optional (default=1)] The minimum number of samples required to be at a leaf node. A split point at any depth will only be considered if it leaves at least `min_samples_leaf` training samples in each of the left and right branches. This may have the effect of smoothing the model, especially in regression.

- If int, then consider `min_samples_leaf` as the minimum number.
- If float, then `min_samples_leaf` is a fraction and `ceil(min_samples_leaf * n_samples)` are the minimum number of samples for each node.

Changed in version 0.18: Added float values for fractions.

min_weight_fraction_leaf [float, optional (default=0.)] The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when sample_weight is not provided.

max_depth [integer, optional (default=3)] maximum depth of the individual regression estimators. The maximum depth limits the number of nodes in the tree. Tune this parameter for best performance; the best value depends on the interaction of the input variables.

min_impurity_decrease [float, optional (default=0.)] A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

```
N_t / N * (impurity - N_t_R / N_t * right_impurity
                    - N_t_L / N_t * left_impurity)
```

where `N` is the total number of samples, `N_t` is the number of samples at the current node, `N_t_L` is the number of samples in the left child, and `N_t_R` is the number of samples in the right child.

`N`, `N_t`, `N_t_R` and `N_t_L` all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

min_impurity_split [float, (default=1e-7)] Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19. The default value of `min_impurity_split` will change from 1e-7 to 0 in 0.23 and it will be removed in 0.25. Use `min_impurity_decrease` instead.

init [estimator or 'zero', optional (default=None)] An estimator object that is used to compute the initial predictions. `init` has to provide *fit* and *predict*. If 'zero', the initial raw predictions are set to zero. By default a `DummyEstimator` is used, predicting either the average target value (for loss='ls'), or a quantile for the other losses.

random_state [int, RandomState instance or None, optional (default=None)] If int, random_state is the seed used by the random number generator; If RandomState instance, random_state is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`.

max_features [int, float, string or None, optional (default=None)] The number of features to consider when looking for the best split:

- If int, then consider `max_features` features at each split.
- If float, then `max_features` is a fraction and `int(max_features * n_features)` features are considered at each split.

- If "auto", then `max_features=n_features`.
- If "sqrt", then `max_features=sqrt(n_features)`.
- If "log2", then `max_features=log2(n_features)`.
- If None, then `max_features=n_features`.

Choosing `max_features < n_features` leads to a reduction of variance and an increase in bias.

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than `max_features` features.

alpha [float (default=0.9)] The alpha-quantile of the huber loss function and the quantile loss function. Only if `loss='huber'` or `loss='quantile'`.

verbose [int, default: 0] Enable verbose output. If 1 then it prints progress and performance once in a while (the more trees the lower the frequency). If greater than 1 then it prints progress and performance for every tree.

max_leaf_nodes [int or None, optional (default=None)] Grow trees with `max_leaf_nodes` in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

warm_start [bool, default: False] When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just erase the previous solution. See *the Glossary*.

presort [deprecated, default='deprecated'] This parameter is deprecated and will be removed in v0.24.

Deprecated since version 0.22.

validation_fraction [float, optional, default 0.1] The proportion of training data to set aside as validation set for early stopping. Must be between 0 and 1. Only used if `n_iter_no_change` is set to an integer.

New in version 0.20.

n_iter_no_change [int, default None] `n_iter_no_change` is used to decide if early stopping will be used to terminate training when validation score is not improving. By default it is set to None to disable early stopping. If set to a number, it will set aside `validation_fraction` size of the training data as validation and terminate training when validation score is not improving in all of the previous `n_iter_no_change` numbers of iterations.

New in version 0.20.

tol [float, optional, default 1e-4] Tolerance for the early stopping. When the loss is not improving by at least tol for `n_iter_no_change` iterations (if set to a number), the training stops.

New in version 0.20.

ccp_alpha [non-negative float, optional (default=0.0)] Complexity parameter used for Minimal Cost-Complexity Pruning. The subtree with the largest cost complexity that is smaller than `ccp_alpha` will be chosen. By default, no pruning is performed. See *Minimal Cost-Complexity Pruning* for details.

New in version 0.22.

Attributes

*feature_importances_* [array, shape (n_features,)] Return the feature importances (the higher, the more important the feature).

oob_improvement_ [array, shape (n_estimators,)] The improvement in loss (= deviance) on the out-of-bag samples relative to the previous iteration. `oob_improvement_[0]` is the improvement in loss of the first stage over the `init` estimator. Only available if `subsample < 1.0`

train_score_ [array, shape (n_estimators,)] The i-th score `train_score_[i]` is the deviance (= loss) of the model at iteration `i` on the in-bag sample. If `subsample == 1` this is the deviance on the training data.

loss_ [LossFunction] The concrete `LossFunction` object.

init_ [estimator] The estimator that provides the initial predictions. Set via the `init` argument or `loss.init_estimator`.

estimators_ [array of DecisionTreeRegressor, shape (n_estimators, 1)] The collection of fitted sub-estimators.

sklearn.ensemble.HistGradientBoostingRegressor

sklearn.tree.DecisionTreeRegressor, *RandomForestRegressor*

Notes

The features are always randomly permuted at each split. Therefore, the best found split may vary, even with the same training data and `max_features=n_features`, if the improvement of the criterion is identical for several splits enumerated during the search of the best split. To obtain a deterministic behaviour during fitting, `random_state` has to be fixed.

Methods

apply(self, X)	Apply trees in the ensemble to X, return leaf indices.
fit(self, X, y[, sample_weight, monitor])	Fit the gradient boosting model.
get_params(self[, deep])	Get parameters for this estimator.
predict(self, X)	Predict regression target for X.
score(self, X, y[, sample_weight])	Return the coefficient of determination R^2 of the prediction.
set_params(self, **params)	Set the parameters of this estimator.
staged_predict(self, X)	Predict regression target at each stage for X.

__init__ (*self*, *loss='ls'*, *learning_rate=0.1*, *n_estimators=100*, *subsample=1.0*, *criterion='friedman_mse'*, *min_samples_split=2*, *min_samples_leaf=1*, *min_weight_fraction_leaf=0.0*, *max_depth=3*, *min_impurity_decrease=0.0*, *min_impurity_split=None*, *init=None*, *random_state=None*, *max_features=None*, *alpha=0.9*, *verbose=0*, *max_leaf_nodes=None*, *warm_start=False*, *presort='deprecated'*, *validation_fraction=0.1*, *n_iter_no_change=None*, *tol=0.0001*, *ccp_alpha=0.0*)
Initialize self. See help(type(self)) for accurate signature.

apply (*self*, *X*)
Apply trees in the ensemble to X, return leaf indices.

New in version 0.17.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted to a sparse `csr_matrix`.

Returns

X_leaves [array-like, shape (n_samples, n_estimators)] For each datapoint x in X and for each tree in the ensemble, return the index of the leaf x ends up in each estimator.

property feature_importances_

Return the feature importances (the higher, the more important the feature).

Returns

feature_importances_ [array, shape (n_features,)] The values of this array sum to 1, unless all trees are single node trees consisting of only the root node, in which case it will be an array of zeros.

fit (*self*, *X*, *y*, *sample_weight=None*, *monitor=None*)
Fit the gradient boosting model.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

y [array-like, shape (n_samples,)] Target values (strings or integers in classification, real numbers in regression) For classification, labels must correspond to classes.

sample_weight [array-like, shape (n_samples,) or None] Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

monitor [callable, optional] The monitor is called after each iteration with the current iteration, a reference to the estimator and the local variables of `_fit_stages` as keyword arguments `callable(i, self, locals())`. If the callable returns `True` the fitting procedure is stopped. The monitor can be used for various things such as computing held-out estimates, early stopping, model introspect, and snapshoting.

Returns

self [object]

get_params(*self*, *deep=True*)
Get parameters for this estimator.

Parameters

deep [bool, default=True] If True, will return the parameters for this estimator and contained subobjects that are estimators.

Returns

params [mapping of string to any] Parameter names mapped to their values.

predict(*self*, *X*)
Predict regression target for X.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

Returns

y [array, shape (n_samples,)] The predicted values.

score(*self*, *X*, *y*, *sample_weight=None*)
Return the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as (1 - u/v), where u is the residual sum of squares ((y_true - y_pred) ** 2).sum() and v is the total sum of squares ((y_true - y_true.mean()) ** 2).sum(). The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

Parameters

X [array-like of shape (n_samples, n_features)] Test samples. For some estimators this may be a precomputed kernel matrix or a list of generic objects instead, shape = (n_samples, n_samples_fitted), where n_samples_fitted is the number of samples used in the fitting for the estimator.

y [array-like of shape (n_samples,) or (n_samples, n_outputs)] True values for X.

sample_weight [array-like of shape (n_samples,), default=None] Sample weights.

Returns

score [float] R^2 of self.predict(X) wrt. y.

Notes

The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with *r2_score*. This will influence the `score` method of all the multioutput regressors (except for *MultiOutputRegressor*). To specify the default value manually and avoid the warning, please either call *r2_score* directly or make a custom scorer with *make_scorer* (the built-in scorer `'r2'` uses `multioutput='uniform_average'`).

set_params(*self*, ***params*)
Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

Parameters

****params** [dict] Estimator parameters.

Returns

self [object] Estimator instance.

staged_predict (*self*, *X*)

Predict regression target at each stage for X.

This method allows monitoring (i.e. determine error on testing set) after each stage.

Parameters

X [{array-like, sparse matrix}, shape (n_samples, n_features)] The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

Returns

y [generator of array of shape (n_samples,)] The predicted value of the input samples.

4.3.3 Metrics and scoring: quantifying the quality of predictions

There are 3 different APIs for evaluating the quality of a model's predictions:

- **Estimator score method**: Estimators have a `score` method providing a default evaluation criterion for the problem they are designed to solve. This is not discussed on this page, but in each estimator's documentation.
- **Scoring parameter**: Model-evaluation tools using *cross-validation* (such as *model_selection.cross_val_score* and *model_selection.GridSearchCV*) rely on an internal *scoring* strategy. This is discussed in the section *The scoring parameter: defining model evaluation rules*.
- **Metric functions**: The `metrics` module implements functions assessing prediction error for specific purposes. These metrics are detailed in sections on *Classification metrics*, *Multilabel ranking metrics*, *Regression metrics* and *Clustering metrics*.

Finally, *Dummy estimators* are useful to get a baseline value of those metrics for random predictions.

See also:

For "pairwise" metrics, between *samples* and not estimators or predictions, see the *Pairwise metrics, Affinities and Kernels* section.

The `scoring` parameter: defining model evaluation rules

Model selection and evaluation using tools, such as *model_selection.GridSearchCV* and *model_selection.cross_val_score*, take a `scoring` parameter that controls what metric they apply to the estimators evaluated.

Common cases: predefined values

For the most common use cases, you can designate a scorer object with the `scoring` parameter; the table below shows all possible values. All scorer objects follow the convention that **higher return values are better than lower return values**. Thus metrics which measure the distance between the model and the data, like *metrics.mean_squared_error*, are available as neg_mean_squared_error which return the negated value of the metric.

Scoring	Function	Comment
Classification		
'accuracy'	*metrics.accuracy_score*	
'balanced_accuracy'	*metrics.balanced_accuracy_score*	
'average_precision'	*metrics.average_precision_score*	
'neg_brier_score'	*metrics.brier_score_loss*	
'f1'	*metrics.f1_score*	for binary targets
'f1_micro'	*metrics.f1_score*	micro-averaged
'f1_macro'	*metrics.f1_score*	macro-averaged
'f1_weighted'	*metrics.f1_score*	weighted average
'f1_samples'	*metrics.f1_score*	by multilabel sample
'neg_log_loss'	*metrics.log_loss*	requires `predict_proba` support
'precision' etc.	*metrics.precision_score*	suffixes apply as with 'f1'
'recall' etc.	*metrics.recall_score*	suffixes apply as with 'f1'
'jaccard' etc.	*metrics.jaccard_score*	suffixes apply as with 'f1'
'roc_auc'	*metrics.roc_auc_score*	
'roc_auc_ovr'	*metrics.roc_auc_score*	
'roc_auc_ovo'	*metrics.roc_auc_score*	
'roc_auc_ovr_weighted'	*metrics.roc_auc_score*	
'roc_auc_ovo_weighted'	*metrics.roc_auc_score*	
Clustering		
'adjusted_mutual_info_score'	*metrics.adjusted_mutual_info_score*	
'adjusted_rand_score'	*metrics.adjusted_rand_score*	
'completeness_score'	*metrics.completeness_score*	
'fowlkes_mallows_score'	*metrics.fowlkes_mallows_score*	
'homogeneity_score'	*metrics.homogeneity_score*	
'mutual_info_score'	*metrics.mutual_info_score*	
'normalized_mutual_info_score'	*metrics.normalized_mutual_info_score*	
'v_measure_score'	*metrics.v_measure_score*	
Regression		
'explained_variance'	*metrics.explained_variance_score*	
'max_error'	*metrics.max_error*	
'neg_mean_absolute_error'	*metrics.mean_absolute_error*	
'neg_mean_squared_error'	*metrics.mean_squared_error*	
'neg_root_mean_squared_error'	*metrics.mean_squared_error*	
'neg_mean_squared_log_error'	*metrics.mean_squared_log_error*	
'neg_median_absolute_error'	*metrics.median_absolute_error*	
'r2'	*metrics.r2_score*	
'neg_mean_poisson_deviance'	*metrics.mean_poisson_deviance*	
'neg_mean_gamma_deviance'	*metrics.mean_gamma_deviance*	

Usage examples:

```
>>> from sklearn import svm, datasets
```

(continues on next page)

(continued from previous page)

```
>>> from sklearn.model_selection import cross_val_score
>>> X, y = datasets.load_iris(return_X_y=True)
>>> clf = svm.SVC(random_state=0)
>>> cross_val_score(clf, X, y, cv=5, scoring='recall_macro')
array([0.96..., 0.96..., 0.96..., 0.93..., 1.        ])
>>> model = svm.SVC()
>>> cross_val_score(model, X, y, cv=5, scoring='wrong_choice')
Traceback (most recent call last):
ValueError: 'wrong_choice' is not a valid scoring value. Use sorted(sklearn.metrics.
↪SCORERS.keys()) to get valid options.
```

Note: The values listed by the ValueError exception correspond to the functions measuring prediction accuracy described in the following sections. The scorer objects for those functions are stored in the dictionary `sklearn.metrics.SCORERS`.

Defining your scoring strategy from metric functions

The module *sklearn.metrics* also exposes a set of simple functions measuring a prediction error given ground truth and prediction:

- functions ending with `_score` return a value to maximize, the higher the better.
- functions ending with `_error` or `_loss` return a value to minimize, the lower the better. When converting into a scorer object using *make_scorer*, set the `greater_is_better` parameter to False (True by default; see the parameter description below).

Metrics available for various machine learning tasks are detailed in sections below.

Many metrics are not given names to be used as `scoring` values, sometimes because they require additional parameters, such as *fbeta_score*. In such cases, you need to generate an appropriate scoring object. The simplest way to generate a callable object for scoring is by using *make_scorer*. That function converts metrics into callables that can be used for model evaluation.

One typical use case is to wrap an existing metric function from the library with non-default values for its parameters, such as the `beta` parameter for the *fbeta_score* function:

```
>>> from sklearn.metrics import fbeta_score, make_scorer
>>> ftwo_scorer = make_scorer(fbeta_score, beta=2)
>>> from sklearn.model_selection import GridSearchCV
>>> from sklearn.svm import LinearSVC
>>> grid = GridSearchCV(LinearSVC(), param_grid={'C': [1, 10]},
...                     scoring=ftwo_scorer, cv=5)
```

The second use case is to build a completely custom scorer object from a simple python function using *make_scorer*, which can take several parameters:

- the python function you want to use (`my_custom_loss_func` in the example below)
- whether the python function returns a score (`greater_is_better=True`, the default) or a loss (`greater_is_better=False`). If a loss, the output of the python function is negated by the scorer object, conforming to the cross validation convention that scorers return higher values for better models.
- for classification metrics only: whether the python function you provided requires continuous decision certainties (`needs_threshold=True`). The default value is False.
- any additional parameters, such as `beta` or `labels` in *f1_score*.

Here is an example of building custom scorers, and of using the `greater_is_better` parameter:

```
>>> import numpy as np
>>> def my_custom_loss_func(y_true, y_pred):
...     diff = np.abs(y_true - y_pred).max()
...     return np.log1p(diff)
...
>>> # score will negate the return value of my_custom_loss_func,
>>> # which will be np.log(2), 0.693, given the values for X
>>> # and y defined below.
>>> score = make_scorer(my_custom_loss_func, greater_is_better=False)
>>> X = [[1], [1]]
>>> y = [0, 1]
>>> from sklearn.dummy import DummyClassifier
>>> clf = DummyClassifier(strategy='most_frequent', random_state=0)
>>> clf = clf.fit(X, y)
>>> my_custom_loss_func(clf.predict(X), y)
0.69...
>>> score(clf, X, y)
-0.69...
```

Implementing your own scoring object

You can generate even more flexible model scorers by constructing your own scoring object from scratch, without using the *make_scorer* factory. For a callable to be a scorer, it needs to meet the protocol specified by the following two rules:

- It can be called with parameters `(estimator, X, y)`, where `estimator` is the model that should be evaluated, `X` is validation data, and `y` is the ground truth target for `X` (in the supervised case) or `None` (in the unsupervised case).
- It returns a floating point number that quantifies the `estimator` prediction quality on `X`, with reference to `y`. Again, by convention higher numbers are better, so if your scorer returns loss, that value should be negated.

Note: Using custom scorers in functions where n_jobs > 1

While defining the custom scoring function alongside the calling function should work out of the box with the default joblib backend (loky), importing it from another module will be a more robust approach and work independently of the joblib backend.

For example, to use `n_jobs` greater than 1 in the example below, `custom_scoring_function` function is saved in a user-created module (`custom_scorer_module.py`) and imported:

```
>>> from custom_scorer_module import custom_scoring_function
>>> cross_val_score(model,
...  X_train,
...  y_train,
...  scoring=make_scorer(custom_scoring_function, greater_is_better=False),
...  cv=5,
...  n_jobs=-1)
```

Using multiple metric evaluation

Scikit-learn also permits evaluation of multiple metrics in `GridSearchCV`, `RandomizedSearchCV` and `cross_validate`.

There are two ways to specify multiple scoring metrics for the `scoring` parameter:

- **As an iterable of string metrics::**

```
>>> scoring = ['accuracy', 'precision']
```

- **As a `dict` mapping the scorer name to the scoring function::**

```
>>> from sklearn.metrics import accuracy_score
>>> from sklearn.metrics import make_scorer
>>> scoring = {'accuracy': make_scorer(accuracy_score),
...            'prec': 'precision'}
```

Note that the dict values can either be scorer functions or one of the predefined metric strings.

Currently only those scorer functions that return a single score can be passed inside the dict. Scorer functions that return multiple values are not permitted and will require a wrapper to return a single metric:

```
>>> from sklearn.model_selection import cross_validate
>>> from sklearn.metrics import confusion_matrix
>>> # A sample toy binary classification dataset
>>> X, y = datasets.make_classification(n_classes=2, random_state=0)
>>> svm = LinearSVC(random_state=0)
>>> def tn(y_true, y_pred): return confusion_matrix(y_true, y_pred)[0, 0]
>>> def fp(y_true, y_pred): return confusion_matrix(y_true, y_pred)[0, 1]
>>> def fn(y_true, y_pred): return confusion_matrix(y_true, y_pred)[1, 0]
>>> def tp(y_true, y_pred): return confusion_matrix(y_true, y_pred)[1, 1]
>>> scoring = {'tp': make_scorer(tp), 'tn': make_scorer(tn),
...            'fp': make_scorer(fp), 'fn': make_scorer(fn)}
>>> cv_results = cross_validate(svm.fit(X, y), X, y, cv=5, scoring=scoring)
>>> # Getting the test set true positive scores
>>> print(cv_results['test_tp'])
[10  9  8  7  8]
>>> # Getting the test set false negative scores
>>> print(cv_results['test_fn'])
[0 1 2 3 2]
```

Classification metrics

The *sklearn.metrics* module implements several loss, score, and utility functions to measure classification performance. Some metrics might require probability estimates of the positive class, confidence values, or binary decisions values. Most implementations allow each sample to provide a weighted contribution to the overall score, through the `sample_weight` parameter.

Some of these are restricted to the binary classification case:

precision_recall_curve(y_true, probas_pred)	Compute precision-recall pairs for different probability thresholds
roc_curve(y_true, y_score[, pos_label, ...])	Compute Receiver operating characteristic (ROC)

Others also work in the multiclass case:

balanced_accuracy_score(y_true, y_pred[, ...])	Compute the balanced accuracy
cohen_kappa_score(y1, y2[, labels, weights, ...])	Cohen's kappa: a statistic that measures inter-annotator agreement.
confusion_matrix(y_true, y_pred[, labels, ...])	Compute confusion matrix to evaluate the accuracy of a classification.
hinge_loss(y_true, pred_decision[, labels, ...])	Average hinge loss (non-regularized)
matthews_corrcoef(y_true, y_pred[, ...])	Compute the Matthews correlation coefficient (MCC)
roc_auc_score(y_true, y_score[, average, ...])	Compute Area Under the Receiver Operating Characteristic Curve (ROC AUC) from prediction scores.

Some also work in the multilabel case:

accuracy_score(y_true, y_pred[, normalize, ...])	Accuracy classification score.
classification_report(y_true, y_pred[, ...])	Build a text report showing the main classification metrics
f1_score(y_true, y_pred[, labels, ...])	Compute the F1 score, also known as balanced F-score or F-measure
fbeta_score(y_true, y_pred, beta[, labels, ...])	Compute the F-beta score
hamming_loss(y_true, y_pred[, labels, ...])	Compute the average Hamming loss.
jaccard_score(y_true, y_pred[, labels, ...])	Jaccard similarity coefficient score
log_loss(y_true, y_pred[, eps, normalize, ...])	Log loss, aka logistic loss or cross-entropy loss.
multilabel_confusion_matrix(y_true, y_pred)	Compute a confusion matrix for each class or sample
precision_recall_fscore_support(y_true, y_pred)	Compute precision, recall, F-measure and support for each class
precision_score(y_true, y_pred[, labels, ...])	Compute the precision
recall_score(y_true, y_pred[, labels, ...])	Compute the recall
roc_auc_score(y_true, y_score[, average, ...])	Compute Area Under the Receiver Operating Characteristic Curve (ROC AUC) from prediction scores.
zero_one_loss(y_true, y_pred[, normalize, ...])	Zero-one classification loss.

And some work with binary and multilabel (but not multiclass) problems:

average_precision_score(y_true, y_score[, ...])	Compute average precision (AP) from prediction scores

In the following sub-sections, we will describe each of those functions, preceded by some notes on common API and metric definition.

From binary to multiclass and multilabel

Some metrics are essentially defined for binary classification tasks (e.g. f1_score, roc_auc_score). In these cases, by default only the positive label is evaluated, assuming by default that the positive class is labelled 1 (though this may be configurable through the pos_label parameter).

In extending a binary metric to multiclass or multilabel problems, the data is treated as a collection of binary problems, one for each class. There are then a number of ways to average binary metric calculations across the set of classes, each of which may be useful in some scenario. Where available, you should select among these using the average parameter.

- `"macro"` simply calculates the mean of the binary metrics, giving equal weight to each class. In problems where infrequent classes are nonetheless important, macro-averaging may be a means of highlighting their performance. On the other hand, the assumption that all classes are equally important is often untrue, such that macro-averaging will over-emphasize the typically low performance on an infrequent class.
- `"weighted"` accounts for class imbalance by computing the average of binary metrics in which each class's score is weighted by its presence in the true data sample.
- `"micro"` gives each sample-class pair an equal contribution to the overall metric (except as a result of sample-weight). Rather than summing the metric per class, this sums the dividends and divisors that make up the per-class metrics to calculate an overall quotient. Micro-averaging may be preferred in multilabel settings, including multiclass classification where a majority class is to be ignored.
- `"samples"` applies only to multilabel problems. It does not calculate a per-class measure, instead calculating the metric over the true and predicted classes for each sample in the evaluation data, and returning their (`sample_weight`-weighted) average.
- Selecting `average=None` will return an array with the score for each class.

While multiclass data is provided to the metric, like binary targets, as an array of class labels, multilabel data is specified as an indicator matrix, in which cell `[i, j]` has value 1 if sample `i` has label `j` and value 0 otherwise.

Accuracy score

The *accuracy_score* function computes the accuracy, either the fraction (default) or the count (normalize=False) of correct predictions.

In multilabel classification, the function returns the subset accuracy. If the entire set of predicted labels for a sample strictly match with the true set of labels, then the subset accuracy is 1.0; otherwise it is 0.0.

If $\hat{y}_i$ is the predicted value of the i-th sample and y_i is the corresponding true value, then the fraction of correct predictions over n_{samples} is defined as

$$\texttt{accuracy}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} 1(\hat{y}_i = y_i)$$

where $1(x)$ is the indicator function.

```
>>> import numpy as np
>>> from sklearn.metrics import accuracy_score
>>> y_pred = [0, 2, 1, 3]
>>> y_true = [0, 1, 2, 3]
>>> accuracy_score(y_true, y_pred)
0.5
>>> accuracy_score(y_true, y_pred, normalize=False)
2
```

In the multilabel case with binary label indicators:

```
>>> accuracy_score(np.array([[0, 1], [1, 1]]), np.ones((2, 2)))
0.5
```

Example:

- See *Test with permutations the significance of a classification score* for an example of accuracy score usage using permutations of the dataset.

Balanced accuracy score

The `balanced_accuracy_score` function computes the balanced accuracy, which avoids inflated performance estimates on imbalanced datasets. It is the macro-average of recall scores per class or, equivalently, raw accuracy where each sample is weighted according to the inverse prevalence of its true class. Thus for balanced datasets, the score is equal to accuracy.

In the binary case, balanced accuracy is equal to the arithmetic mean of sensitivity (true positive rate) and specificity (true negative rate), or the area under the ROC curve with binary predictions rather than scores.

If the classifier performs equally well on either class, this term reduces to the conventional accuracy (i.e., the number of correct predictions divided by the total number of predictions).

In contrast, if the conventional accuracy is above chance only because the classifier takes advantage of an imbalanced test set, then the balanced accuracy, as appropriate, will drop to $\frac{1}{n\_classes}$.

The score ranges from 0 to 1, or when `adjusted=True` is used, it rescaled to the range $\frac{1}{1-n\_classes}$ to 1, inclusive, with performance at random scoring 0.

If y_i is the true value of the i-th sample, and w_i is the corresponding sample weight, then we adjust the sample weight to:

$$\hat{w}_i = \frac{w_i}{\sum_j 1(y_j = y_i) w_j}$$

where $1(x)$ is the indicator function. Given predicted $\hat{y}_i$ for sample i, balanced accuracy is defined as:

$$\texttt{balanced-accuracy}(y, \hat{y}, w) = \frac{1}{\sum \hat{w}_i} \sum_i 1(\hat{y}_i = y_i) \hat{w}_i$$

With `adjusted=True`, balanced accuracy reports the relative increase from $\texttt{balanced-accuracy}(y, \mathbf{0}, w) = \frac{1}{n\_classes}$. In the binary case, this is also known as *Youden's J statistic*, or *informedness*.

Note: The multiclass definition here seems the most reasonable extension of the metric used in binary classification, though there is no certain consensus in the literature:

- Our definition: [Mosley2013], [Kelleher2015] and [Guyon2015], where [Guyon2015] adopt the adjusted version to ensure that random predictions have a score of 0 and perfect predictions have a score of 1..
- Class balanced accuracy as described in [Mosley2013]: the minimum between the precision and the recall for each class is computed. Those values are then averaged over the total number of classes to get the balanced accuracy.
- Balanced Accuracy as described in [Urbanowicz2015]: the average of sensitivity and specificity is computed for each class and then averaged over total number of classes.

References:

Cohen's kappa

The function `cohen_kappa_score` computes Cohen's kappa statistic. This measure is intended to compare labelings by different human annotators, not a classifier versus a ground truth.

The kappa score (see docstring) is a number between -1 and 1. Scores above .8 are generally considered good agreement; zero or lower means no agreement (practically random labels).

Kappa scores can be computed for binary or multiclass problems, but not for multilabel problems (except by manually computing a per-label score) and not for more than two annotators.

```
>>> from sklearn.metrics import cohen_kappa_score
>>> y_true = [2, 0, 2, 2, 0, 1]
>>> y_pred = [0, 0, 2, 2, 0, 2]
>>> cohen_kappa_score(y_true, y_pred)
0.4285714285714286
```

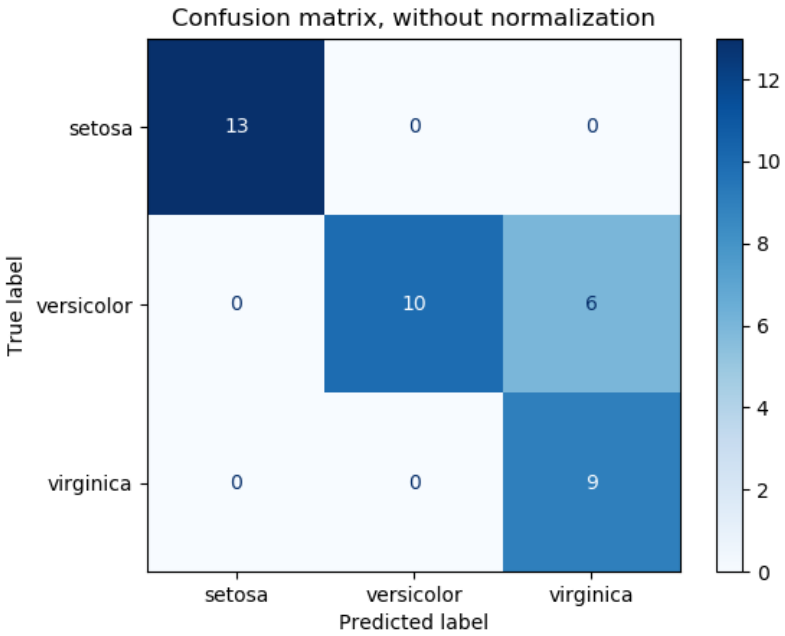
Confusion matrix

The *confusion_matrix* function evaluates classification accuracy by computing the confusion matrix with each row corresponding to the true class <https://en.wikipedia.org/wiki/Confusion_matrix>‘_. (Wikipedia and other references may use different convention for axes.)

By definition, entry i, j in a confusion matrix is the number of observations actually in group i, but predicted to be in group j. Here is an example:

```
>>> from sklearn.metrics import confusion_matrix
>>> y_true = [2, 0, 2, 2, 0, 1]
>>> y_pred = [0, 0, 2, 2, 0, 2]
>>> confusion_matrix(y_true, y_pred)
array([[2, 0, 0],
       [0, 0, 1],
       [1, 0, 2]])
```

plot_confusion_matrix can be used to visually represent a confusion matrix as shown in the *Confusion matrix* example, which creates the following figure:



The parameter `normalize` allows to report ratios instead of counts. The confusion matrix can be normalized in 3 different ways: `'pred'`, `'true'`, and `'all'` which will divide the counts by the sum of each columns, rows, or the entire matrix, respectively.

```
>>> y_true = [0, 0, 0, 1, 1, 1, 1, 1]
>>> y_pred = [0, 1, 0, 1, 0, 1, 0, 1]
>>> confusion_matrix(y_true, y_pred, normalize='all')
array([[0.25 , 0.125],
       [0.25 , 0.375]])
```

For binary problems, we can get counts of true negatives, false positives, false negatives and true positives as follows:

```
>>> y_true = [0, 0, 0, 1, 1, 1, 1, 1]
>>> y_pred = [0, 1, 0, 1, 0, 1, 0, 1]
>>> tn, fp, fn, tp = confusion_matrix(y_true, y_pred).ravel()
>>> tn, fp, fn, tp
(2, 1, 2, 3)
```

Example:

- See *Confusion matrix* for an example of using a confusion matrix to evaluate classifier output quality.
- See *Recognizing hand-written digits* for an example of using a confusion matrix to classify hand-written digits.
- See *Classification of text documents using sparse features* for an example of using a confusion matrix to classify text documents.

Classification report

The `classification_report` function builds a text report showing the main classification metrics. Here is a small example with custom `target_names` and inferred labels:

```
>>> from sklearn.metrics import classification_report
>>> y_true = [0, 1, 2, 2, 0]
>>> y_pred = [0, 0, 2, 1, 0]
>>> target_names = ['class 0', 'class 1', 'class 2']
>>> print(classification_report(y_true, y_pred, target_names=target_names))
              precision    recall  f1-score   support

     class 0       0.67      1.00      0.80         2
     class 1       0.00      0.00      0.00         1
     class 2       1.00      0.50      0.67         2

    accuracy                           0.60         5
   macro avg       0.56      0.50      0.49         5
weighted avg       0.67      0.60      0.59         5
```

Example:

- See *Recognizing hand-written digits* for an example of classification report usage for hand-written digits.
- See *Classification of text documents using sparse features* for an example of classification report usage for text documents.
- See *Parameter estimation using grid search with cross-validation* for an example of classification report usage for grid search with nested cross-validation.

Hamming loss

The *hamming_loss* computes the average Hamming loss or Hamming distance between two sets of samples.

If $\hat{y}_j$ is the predicted value for the j-th label of a given sample, y_j is the corresponding true value, and n_{labels} is the number of classes or labels, then the Hamming loss $L_{Hamming}$ between two samples is defined as:

$$L_{Hamming}(y, \hat{y}) = \frac{1}{n_{\text{labels}}} \sum_{j=0}^{n_{\text{labels}}-1} 1(\hat{y}_j \neq y_j)$$

where $1(x)$ is the indicator function.

```
>>> from sklearn.metrics import hamming_loss
>>> y_pred = [1, 2, 3, 4]
>>> y_true = [2, 2, 3, 4]
>>> hamming_loss(y_true, y_pred)
0.25
```

In the multilabel case with binary label indicators:

```
>>> hamming_loss(np.array([[0, 1], [1, 1]]), np.zeros((2, 2)))
0.75
```

Note: In multiclass classification, the Hamming loss corresponds to the Hamming distance between `y_true` and `y_pred` which is similar to the *Zero one loss* function. However, while zero-one loss penalizes prediction sets that do not strictly match true sets, the Hamming loss penalizes individual labels. Thus the Hamming loss, upper bounded by the zero-one loss, is always between zero and one, inclusive; and predicting a proper subset or superset of the true labels will give a Hamming loss between zero and one, exclusive.

Precision, recall and F-measures

Intuitively, precision is the ability of the classifier not to label as positive a sample that is negative, and recall is the ability of the classifier to find all the positive samples.

The F-measure (F_β and F_1 measures) can be interpreted as a weighted harmonic mean of the precision and recall. A F_β measure reaches its best value at 1 and its worst score at 0. With $\beta = 1$, F_β and F_1 are equivalent, and the recall and the precision are equally important.

The *precision_recall_curve* computes a precision-recall curve from the ground truth label and a score given by the classifier by varying a decision threshold.

The *average_precision_score* function computes the average precision (AP) from prediction scores. The value is between 0 and 1 and higher is better. AP is defined as

$$\text{AP} = \sum_n (R_n - R_{n-1}) P_n$$

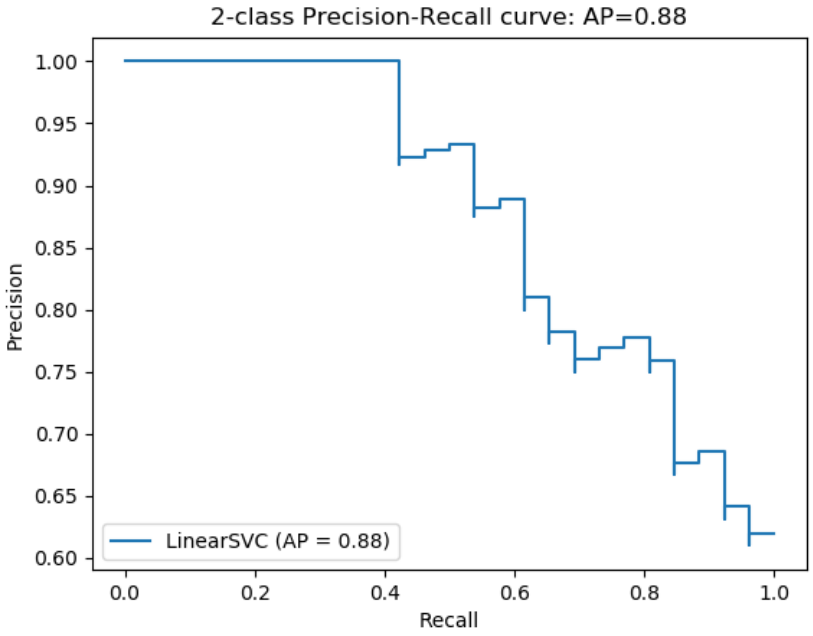
where P_n and R_n are the precision and recall at the nth threshold. With random predictions, the AP is the fraction of positive samples.

References [Manning2008] and [Everingham2010] present alternative variants of AP that interpolate the precision-recall curve. Currently, *average_precision_score* does not implement any interpolated variant. References [Davis2006] and [Flach2015] describe why a linear interpolation of points on the precision-recall curve provides an overly-optimistic measure of classifier performance. This linear interpolation is used when computing area under the curve with the trapezoidal rule in *auc*.

Several functions allow you to analyze the precision, recall and F-measures score:

average_precision_score(y_true, y_score[, ...])	Compute average precision (AP) from prediction scores
f1_score(y_true, y_pred[, labels, ...])	Compute the F1 score, also known as balanced F-score or F-measure
fbeta_score(y_true, y_pred, beta[, labels, ...])	Compute the F-beta score
precision_recall_curve(y_true, probas_pred)	Compute precision-recall pairs for different probability thresholds
precision_recall_fscore_support(y_true, y_pred)	Compute precision, recall, F-measure and support for each class
precision_score(y_true, y_pred[, labels, ...])	Compute the precision
recall_score(y_true, y_pred[, labels, ...])	Compute the recall

Note that the precision_recall_curve function is restricted to the binary case. The average_precision_score function works only in binary classification and multilabel indicator format. The plot_precision_recall_curve function plots the precision recall as follows.



Examples:

- See *Classification of text documents using sparse features* for an example of f1_score usage to classify text documents.
- See *Parameter estimation using grid search with cross-validation* for an example of precision_score and recall_score usage to estimate parameters using grid search with nested cross-validation.
- See *Precision-Recall* for an example of precision_recall_curve usage to evaluate classifier output quality.

References:

Binary classification

In a binary classification task, the terms ''positive'' and ''negative'' refer to the classifier's prediction, and the terms ''true'' and ''false'' refer to whether that prediction corresponds to the external judgment (sometimes known as the ''observation''). Given these definitions, we can formulate the following table:

	Actual class (observation)	
Predicted class (expectation)	tp (true positive) Correct result	fp (false positive) Unexpected result
	fn (false negative) Missing result	tn (true negative) Correct absence of result

In this context, we can define the notions of precision, recall and F-measure:

$$\text{precision} = \frac{tp}{tp + fp},$$

$$\text{recall} = \frac{tp}{tp + fn},$$

$$F_\beta = (1 + \beta^2)\frac{\text{precision} \times \text{recall}}{\beta^2 \text{precision} + \text{recall}}.$$

Here are some small examples in binary classification:

```
>>> from sklearn import metrics
>>> y_pred = [0, 1, 0, 0]
>>> y_true = [0, 1, 0, 1]
>>> metrics.precision_score(y_true, y_pred)
1.0
>>> metrics.recall_score(y_true, y_pred)
0.5
>>> metrics.f1_score(y_true, y_pred)
0.66...
>>> metrics.fbeta_score(y_true, y_pred, beta=0.5)
0.83...
>>> metrics.fbeta_score(y_true, y_pred, beta=1)
0.66...
>>> metrics.fbeta_score(y_true, y_pred, beta=2)
0.55...
>>> metrics.precision_recall_fscore_support(y_true, y_pred, beta=0.5)
(array([0.66..., 1.        ]), array([1. , 0.5]), array([0.71..., 0.83...]), array([2,
↪ 2]))

>>> import numpy as np
>>> from sklearn.metrics import precision_recall_curve
>>> from sklearn.metrics import average_precision_score
>>> y_true = np.array([0, 0, 1, 1])
>>> y_scores = np.array([0.1, 0.4, 0.35, 0.8])
>>> precision, recall, threshold = precision_recall_curve(y_true, y_scores)
>>> precision
array([0.66..., 0.5       , 1.        , 1.        ])
>>> recall
array([1. , 0.5, 0.5, 0. ])
```

(continues on next page)

(continued from previous page)

```
>>> threshold
array([0.35, 0.4 , 0.8 ])
>>> average_precision_score(y_true, y_scores)
0.83...
```

Multiclass and multilabel classification

In multiclass and multilabel classification task, the notions of precision, recall, and F-measures can be applied to each label independently. There are a few ways to combine results across labels, specified by the `average` argument to the *average_precision_score* (multilabel only), *f1_score*, *fbeta_score*, *precision_recall_fscore_support*, *precision_score* and *recall_score* functions, as described *above*. Note that if all labels are included, "micro"-averaging in a multiclass setting will produce precision, recall and F that are all identical to accuracy. Also note that "weighted" averaging may produce an F-score that is not between precision and recall.

To make this more explicit, consider the following notation:

- y the set of *predicted* $(sample, label)$ pairs
- $\hat{y}$ the set of *true* $(sample, label)$ pairs
- L the set of labels
- S the set of samples
- y_s the subset of y with sample s, i.e. $y_s := \{(s', l) \in y | s' = s\}$
- y_l the subset of y with label l
- similarly, $\hat{y}_s$ and $\hat{y}_l$ are subsets of $\hat{y}$
- $P(A, B) := \frac{|A \cap B|}{|A|}$ for some sets A and B
- $R(A, B) := \frac{|A \cap B|}{|B|}$ (Conventions vary on handling $B = \emptyset$; this implementation uses $R(A, B) := 0$, and similar for P.)
- $F_\beta(A, B) := \left(1 + \beta^2\right) \frac{P(A,B) \times R(A,B)}{\beta^2 P(A,B) + R(A,B)}$

Then the metrics are defined as:

average	Precision	Recall	F_beta
"micro"	$P(y, \hat{y})$	$R(y, \hat{y})$	$F_\beta(y, \hat{y})$
"samples"	$\frac{1}{\lvert S \rvert} \sum_{s \in S} P(y_s, \hat{y}_s)$	$\frac{1}{\lvert S \rvert} \sum_{s \in S} R(y_s, \hat{y}_s)$	$\frac{1}{\lvert S \rvert} \sum_{s \in S} F_\beta(y_s, \hat{y}_s)$
"macro"	$\frac{1}{\lvert L \rvert} \sum_{l \in L} P(y_l, \hat{y}_l)$	$\frac{1}{\lvert L \rvert} \sum_{l \in L} R(y_l, \hat{y}_l)$	$\frac{1}{\lvert L \rvert} \sum_{l \in L} F_\beta(y_l, \hat{y}_l)$
"weighted"	$\frac{1}{\sum_{l \in L} \lvert \hat{y}_l \rvert} \sum_{l \in L} \lvert \hat{y}_l \rvert P(y_l, \hat{y}_l)$	$\frac{1}{\sum_{l \in L} \lvert \hat{y}_l \rvert} \sum_{l \in L} \lvert \hat{y}_l \rvert R(y_l, \hat{y}_l)$	$\frac{1}{\sum_{l \in L} \lvert \hat{y}_l \rvert} \sum_{l \in L} \lvert \hat{y}_l \rvert F_\beta(y_l, \hat{y}_l)$
None	$\langle P(y_l, \hat{y}_l) \vert l \in L \rangle$	$\langle R(y_l, \hat{y}_l) \vert l \in L \rangle$	$\langle F_\beta(y_l, \hat{y}_l) \vert l \in L \rangle$

```
>>> from sklearn import metrics
>>> y_true = [0, 1, 2, 0, 1, 2]
>>> y_pred = [0, 2, 1, 0, 0, 1]
>>> metrics.precision_score(y_true, y_pred, average='macro')
0.22...
>>> metrics.recall_score(y_true, y_pred, average='micro')
0.33...
>>> metrics.f1_score(y_true, y_pred, average='weighted')
```

(continues on next page)

(continued from previous page)

```
0.26...
>>> metrics.fbeta_score(y_true, y_pred, average='macro', beta=0.5)
0.23...
>>> metrics.precision_recall_fscore_support(y_true, y_pred, beta=0.5, average=None)
(array([0.66..., 0.        , 0.        ]), array([1., 0., 0.]), array([0.71..., 0.
↪    , 0.        ]), array([2, 2, 2]...))
```

For multiclass classification with a "negative class", it is possible to exclude some labels:

```
>>> metrics.recall_score(y_true, y_pred, labels=[1, 2], average='micro')
... # excluding 0, no labels were correctly recalled
0.0
```

Similarly, labels not present in the data sample may be accounted for in macro-averaging.

```
>>> metrics.precision_score(y_true, y_pred, labels=[0, 1, 2, 3], average='macro')
0.166...
```

Jaccard similarity coefficient score

The *jaccard_score* function computes the average of Jaccard similarity coefficients, also called the Jaccard index, between pairs of label sets.

The Jaccard similarity coefficient of the i-th samples, with a ground truth label set y_i and predicted label set $\hat{y}_i$, is defined as

$$J(y_i, \hat{y}_i) = \frac{|y_i \cap \hat{y}_i|}{|y_i \cup \hat{y}_i|}.$$

jaccard_score works like *precision_recall_fscore_support* as a naively set-wise measure applying natively to binary targets, and extended to apply to multilabel and multiclass through the use of `average` (see *above*).

In the binary case:

```
>>> import numpy as np
>>> from sklearn.metrics import jaccard_score
>>> y_true = np.array([[0, 1, 1],
...                    [1, 1, 0]])
>>> y_pred = np.array([[1, 1, 1],
...                    [1, 0, 0]])
>>> jaccard_score(y_true[0], y_pred[0])
0.6666...
```

In the multilabel case with binary label indicators:

```
>>> jaccard_score(y_true, y_pred, average='samples')
0.5833...
>>> jaccard_score(y_true, y_pred, average='macro')
0.6666...
>>> jaccard_score(y_true, y_pred, average=None)
array([0.5, 0.5, 1. ])
```

Multiclass problems are binarized and treated like the corresponding multilabel problem:

```
>>> y_pred = [0, 2, 1, 2]
>>> y_true = [0, 1, 2, 2]
>>> jaccard_score(y_true, y_pred, average=None)
array([1. , 0. , 0.33...])
>>> jaccard_score(y_true, y_pred, average='macro')
0.44...
>>> jaccard_score(y_true, y_pred, average='micro')
0.33...
```

Hinge loss

The *hinge_loss* function computes the average distance between the model and the data using hinge loss, a one-sided metric that considers only prediction errors. (Hinge loss is used in maximal margin classifiers such as support vector machines.)

If the labels are encoded with +1 and -1, y: is the true value, and w is the predicted decisions as output by `decision_function`, then the hinge loss is defined as:

$$L_{\text{Hinge}}(y, w) = \max\{1 - wy, 0\} = |1 - wy|_+$$

If there are more than two labels, *hinge_loss* uses a multiclass variant due to Crammer & Singer. Here is the paper describing it.

If y_w is the predicted decision for true label and y_t is the maximum of the predicted decisions for all other labels, where predicted decisions are output by decision function, then multiclass hinge loss is defined by:

$$L_{\text{Hinge}}(y_w, y_t) = \max\{1 + y_t - y_w, 0\}$$

Here a small example demonstrating the use of the *hinge_loss* function with a svm classifier in a binary class problem:

```
>>> from sklearn import svm
>>> from sklearn.metrics import hinge_loss
>>> X = [[0], [1]]
>>> y = [-1, 1]
>>> est = svm.LinearSVC(random_state=0)
>>> est.fit(X, y)
LinearSVC(random_state=0)
>>> pred_decision = est.decision_function([[-2], [3], [0.5]])
>>> pred_decision
array([-2.18...,  2.36...,  0.09...])
>>> hinge_loss([-1, 1, 1], pred_decision)
0.3...
```

Here is an example demonstrating the use of the *hinge_loss* function with a svm classifier in a multiclass problem:

```
>>> X = np.array([[0], [1], [2], [3]])
>>> Y = np.array([0, 1, 2, 3])
>>> labels = np.array([0, 1, 2, 3])
>>> est = svm.LinearSVC()
>>> est.fit(X, Y)
LinearSVC()
>>> pred_decision = est.decision_function([[-1], [2], [3]])
>>> y_true = [0, 2, 3]
>>> hinge_loss(y_true, pred_decision, labels)
0.56...
```

Log loss

Log loss, also called logistic regression loss or cross-entropy loss, is defined on probability estimates. It is commonly used in (multinomial) logistic regression and neural networks, as well as in some variants of expectation-maximization, and can be used to evaluate the probability outputs (`predict_proba`) of a classifier instead of its discrete predictions.

For binary classification with a true label $y \in \{0, 1\}$ and a probability estimate $p = \Pr(y = 1)$, the log loss per sample is the negative log-likelihood of the classifier given the true label:

$$L_{\log}(y, p) = -\log \Pr(y|p) = -(y \log(p) + (1 - y) \log(1 - p))$$

This extends to the multiclass case as follows. Let the true labels for a set of samples be encoded as a 1-of-K binary indicator matrix Y, i.e., $y_{i,k} = 1$ if sample i has label k taken from a set of K labels. Let P be a matrix of probability estimates, with $p_{i,k} = \Pr(t_{i,k} = 1)$. Then the log loss of the whole set is

$$L_{\log}(Y, P) = -\log \Pr(Y|P) = -\frac{1}{N} \sum_{i=0}^{N-1} \sum_{k=0}^{K-1} y_{i,k} \log p_{i,k}$$

To see how this generalizes the binary log loss given above, note that in the binary case, $p_{i,0} = 1 - p_{i,1}$ and $y_{i,0} = 1 - y_{i,1}$, so expanding the inner sum over $y_{i,k} \in \{0, 1\}$ gives the binary log loss.

The *log_loss* function computes log loss given a list of ground-truth labels and a probability matrix, as returned by an estimator's `predict_proba` method.

```
>>> from sklearn.metrics import log_loss
>>> y_true = [0, 0, 1, 1]
>>> y_pred = [[.9, .1], [.8, .2], [.3, .7], [.01, .99]]
>>> log_loss(y_true, y_pred)
0.1738...
```

The first `[.9, .1]` in `y_pred` denotes 90% probability that the first sample has label 0. The log loss is non-negative.

Matthews correlation coefficient

The *matthews_corrcoef* function computes the Matthew's correlation coefficient (MCC) for binary classes. Quoting Wikipedia:

> "The Matthews correlation coefficient is used in machine learning as a measure of the quality of binary (two-class) classifications. It takes into account true and false positives and negatives and is generally regarded as a balanced measure which can be used even if the classes are of very different sizes. The MCC is in essence a correlation coefficient value between -1 and +1. A coefficient of +1 represents a perfect prediction, 0 an average random prediction and -1 an inverse prediction. The statistic is also known as the phi coefficient."

In the binary (two-class) case, tp, tn, fp and fn are respectively the number of true positives, true negatives, false positives and false negatives, the MCC is defined as

$$MCC = \frac{tp \times tn - fp \times fn}{\sqrt{(tp + fp)(tp + fn)(tn + fp)(tn + fn)}}.$$

In the multiclass case, the Matthews correlation coefficient can be defined in terms of a *confusion_matrix* C for K classes. To simplify the definition consider the following intermediate variables:

- $t_k = \sum_i^K C_{ik}$ the number of times class k truly occurred,
- $p_k = \sum_i^K C_{ki}$ the number of times class k was predicted,

- $c = \sum_k^K C_{kk}$ the total number of samples correctly predicted,
- $s = \sum_i^K \sum_j^K C_{ij}$ the total number of samples.

Then the multiclass MCC is defined as:

$$MCC = \frac{c \times s - \sum_k^K p_k \times t_k}{\sqrt{(s^2 - \sum_k^K p_k^2) \times (s^2 - \sum_k^K t_k^2)}}$$

When there are more than two labels, the value of the MCC will no longer range between -1 and +1. Instead the minimum value will be somewhere between -1 and 0 depending on the number and distribution of ground true labels. The maximum value is always +1.

Here is a small example illustrating the usage of the *matthews_corrcoef* function:

```
>>> from sklearn.metrics import matthews_corrcoef
>>> y_true = [+1, +1, +1, -1]
>>> y_pred = [+1, -1, +1, +1]
>>> matthews_corrcoef(y_true, y_pred)
-0.33...
```

Multi-label confusion matrix

The *multilabel_confusion_matrix* function computes class-wise (default) or sample-wise (samplewise=True) multilabel confusion matrix to evaluate the accuracy of a classification. multilabel_confusion_matrix also treats multiclass data as if it were multilabel, as this is a transformation commonly applied to evaluate multiclass problems with binary classification metrics (such as precision, recall, etc.).

When calculating class-wise multilabel confusion matrix C, the count of true negatives for class i is $C_{i,0,0}$, false negatives is $C_{i,1,0}$, true positives is $C_{i,1,1}$ and false positives is $C_{i,0,1}$.

Here is an example demonstrating the use of the *multilabel_confusion_matrix* function with *multilabel indicator matrix* input:

```
>>> import numpy as np
>>> from sklearn.metrics import multilabel_confusion_matrix
>>> y_true = np.array([[1, 0, 1],
...                    [0, 1, 0]])
>>> y_pred = np.array([[1, 0, 0],
...                    [0, 1, 1]])
>>> multilabel_confusion_matrix(y_true, y_pred)
array([[[1, 0],
        [0, 1]],

       [[1, 0],
        [0, 1]],

       [[0, 1],
        [1, 0]]])
```

Or a confusion matrix can be constructed for each sample's labels:

```
>>> multilabel_confusion_matrix(y_true, y_pred, samplewise=True)
array([[[1, 0],
        [1, 1]],
<BLANKLINE>
       [[1, 1],
        [0, 1]]])
```

Here is an example demonstrating the use of the *multilabel_confusion_matrix* function with *multiclass* input:

```
>>> y_true = ["cat", "ant", "cat", "cat", "ant", "bird"]
>>> y_pred = ["ant", "ant", "cat", "cat", "ant", "cat"]
>>> multilabel_confusion_matrix(y_true, y_pred,
...                             labels=["ant", "bird", "cat"])
array([[[3, 1],
        [0, 2]],

       [[5, 0],
        [1, 0]],

       [[2, 1],
        [1, 2]]])
```

Here are some examples demonstrating the use of the *multilabel_confusion_matrix* function to calculate recall (or sensitivity), specificity, fall out and miss rate for each class in a problem with multilabel indicator matrix input.

Calculating recall (also called the true positive rate or the sensitivity) for each class:

```
>>> y_true = np.array([[0, 0, 1],
...                    [0, 1, 0],
...                    [1, 1, 0]])
>>> y_pred = np.array([[0, 1, 0],
...                    [0, 0, 1],
...                    [1, 1, 0]])
>>> mcm = multilabel_confusion_matrix(y_true, y_pred)
>>> tn = mcm[:, 0, 0]
>>> tp = mcm[:, 1, 1]
>>> fn = mcm[:, 1, 0]
>>> fp = mcm[:, 0, 1]
>>> tp / (tp + fn)
array([1. , 0.5, 0. ])
```

Calculating specificity (also called the true negative rate) for each class:

```
>>> tn / (tn + fp)
array([1. , 0. , 0.5])
```

Calculating fall out (also called the false positive rate) for each class:

```
>>> fp / (fp + tn)
array([0. , 1. , 0.5])
```

Calculating miss rate (also called the false negative rate) for each class:

```
>>> fn / (fn + tp)
array([0. , 0.5, 1. ])
```

Receiver operating characteristic (ROC)

The function *roc_curve* computes the receiver operating characteristic curve, or ROC curve. Quoting Wikipedia :

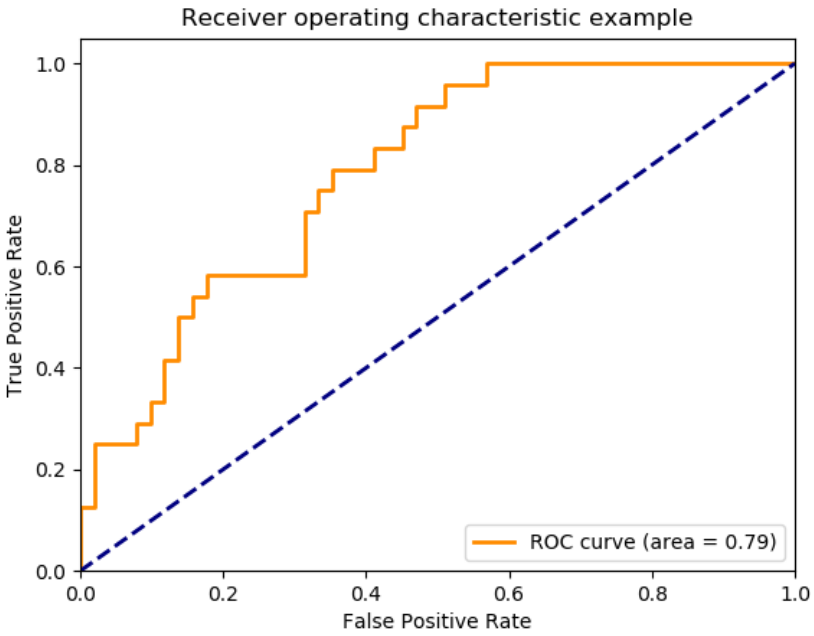
> "A receiver operating characteristic (ROC), or simply ROC curve, is a graphical plot which illustrates the performance of a binary classifier system as its discrimination threshold is varied. It is created by

plotting the fraction of true positives out of the positives (TPR = true positive rate) vs. the fraction of false positives out of the negatives (FPR = false positive rate), at various threshold settings. TPR is also known as sensitivity, and FPR is one minus the specificity or true negative rate."

This function requires the true binary value and the target scores, which can either be probability estimates of the positive class, confidence values, or binary decisions. Here is a small example of how to use the *roc_curve* function:

```
>>> import numpy as np
>>> from sklearn.metrics import roc_curve
>>> y = np.array([1, 1, 2, 2])
>>> scores = np.array([0.1, 0.4, 0.35, 0.8])
>>> fpr, tpr, thresholds = roc_curve(y, scores, pos_label=2)
>>> fpr
array([0. , 0. , 0.5, 0.5, 1. ])
>>> tpr
array([0. , 0.5, 0.5, 1. , 1. ])
>>> thresholds
array([1.8 , 0.8 , 0.4 , 0.35, 0.1 ])
```

This figure shows an example of such an ROC curve:



The *roc_auc_score* function computes the area under the receiver operating characteristic (ROC) curve, which is also denoted by AUC or AUROC. By computing the area under the roc curve, the curve information is summarized in one number. For more information see the Wikipedia article on AUC.

```
>>> import numpy as np
>>> from sklearn.metrics import roc_auc_score
>>> y_true = np.array([0, 0, 1, 1])
>>> y_scores = np.array([0.1, 0.4, 0.35, 0.8])
>>> roc_auc_score(y_true, y_scores)
0.75
```

In multi-label classification, the *roc_auc_score* function is extended by averaging over the labels as *above*.

Compared to metrics such as the subset accuracy, the Hamming loss, or the F1 score, ROC doesn't require optimizing

a threshold for each label.

The *roc_auc_score* function can also be used in multi-class classification. Two averaging strategies are currently supported: the one-vs-one algorithm computes the average of the pairwise ROC AUC scores, and the one-vs-rest algorithm computes the average of the ROC AUC scores for each class against all other classes. In both cases, the predicted labels are provided in an array with values from 0 to `n_classes`, and the scores correspond to the probability estimates that a sample belongs to a particular class. The OvO and OvR algorithms support weighting uniformly (`average='macro'`) and by prevalence (`average='weighted'`).

One-vs-one Algorithm: Computes the average AUC of all possible pairwise combinations of classes. [HT2001] defines a multiclass AUC metric weighted uniformly:

$$\frac{2}{c(c-1)}\sum_{j=1}^{c}\sum_{k>j}^{c}(\text{AUC}(j|k)+\text{AUC}(k|j))$$

where c is the number of classes and $\text{AUC}(j|k)$ is the AUC with class j as the positive class and class k as the negative class. In general, $\text{AUC}(j|k) \neq \text{AUC}(k|j))$ in the multiclass case. This algorithm is used by setting the keyword argument `multiclass` to `'ovo'` and `average` to `'macro'`.

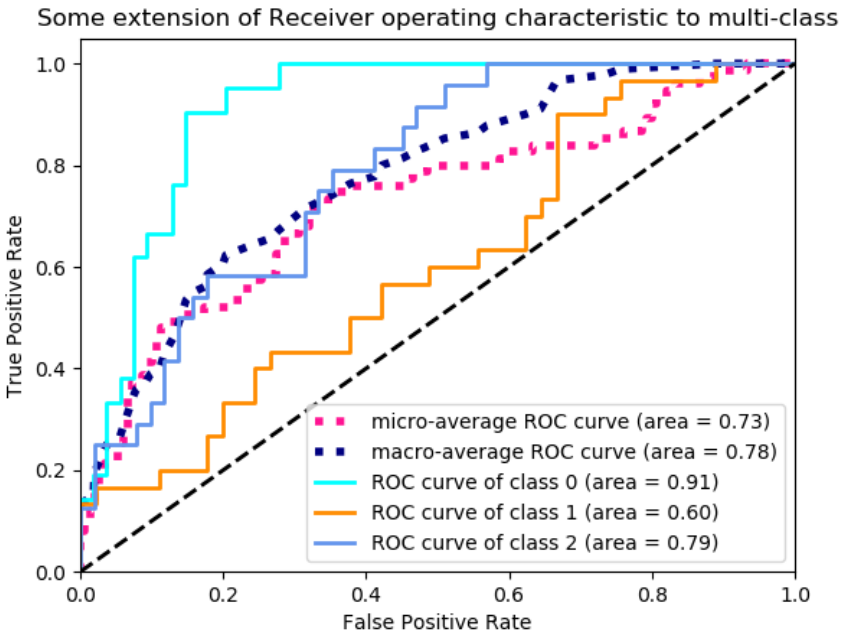
The [HT2001] multiclass AUC metric can be extended to be weighted by the prevalence:

$$\frac{2}{c(c-1)}\sum_{j=1}^{c}\sum_{k>j}^{c}p(j\cup k)(\text{AUC}(j|k)+\text{AUC}(k|j))$$

where c is the number of classes. This algorithm is used by setting the keyword argument `multiclass` to `'ovo'` and `average` to `'weighted'`. The `'weighted'` option returns a prevalence-weighted average as described in [FC2009].

One-vs-rest Algorithm: Computes the AUC of each class against the rest [PD2000]. The algorithm is functionally the same as the multilabel case. To enable this algorithm set the keyword argument `multiclass` to `'ovr'`. Like OvO, OvR supports two types of averaging: `'macro'` [F2006] and `'weighted'` [F2001].

In applications where a high false positive rate is not tolerable the parameter `max_fpr` of *roc_auc_score* can be used to summarize the ROC curve up to the given limit.



Examples:

- See *Receiver Operating Characteristic (ROC)* for an example of using ROC to evaluate the quality of the output of a classifier.
- See *Receiver Operating Characteristic (ROC) with cross validation* for an example of using ROC to evaluate classifier output quality, using cross-validation.
- See *Species distribution modeling* for an example of using ROC to model species distribution.

Zero one loss

The `zero_one_loss` function computes the sum or the average of the 0-1 classification loss (L_{0-1}) over n_{samples}. By default, the function normalizes over the sample. To get the sum of the L_{0-1}, set `normalize` to `False`.

In multilabel classification, the `zero_one_loss` scores a subset as one if its labels strictly match the predictions, and as a zero if there are any errors. By default, the function returns the percentage of imperfectly predicted subsets. To get the count of such subsets instead, set `normalize` to `False`

If $\hat{y}_i$ is the predicted value of the i-th sample and y_i is the corresponding true value, then the 0-1 loss L_{0-1} is defined as:

$$L_{0-1}(y_i, \hat{y}_i) = 1(\hat{y}_i \neq y_i)$$

where $1(x)$ is the indicator function.

```
>>> from sklearn.metrics import zero_one_loss
>>> y_pred = [1, 2, 3, 4]
>>> y_true = [2, 2, 3, 4]
>>> zero_one_loss(y_true, y_pred)
0.25
>>> zero_one_loss(y_true, y_pred, normalize=False)
1
```

In the multilabel case with binary label indicators, where the first label set [0,1] has an error:

```
>>> zero_one_loss(np.array([[0, 1], [1, 1]]), np.ones((2, 2)))
0.5

>>> zero_one_loss(np.array([[0, 1], [1, 1]]), np.ones((2, 2)),  normalize=False)
1
```

Example:

- See *Recursive feature elimination with cross-validation* for an example of zero one loss usage to perform recursive feature elimination with cross-validation.

Brier score loss

The *brier_score_loss* function computes the Brier score for binary classes. Quoting Wikipedia:

> "The Brier score is a proper score function that measures the accuracy of probabilistic predictions. It is applicable to tasks in which predictions must assign probabilities to a set of mutually exclusive discrete outcomes."

This function returns a score of the mean square difference between the actual outcome and the predicted probability of the possible outcome. The actual outcome has to be 1 or 0 (true or false), while the predicted probability of the actual outcome can be a value between 0 and 1.

The brier score loss is also between 0 to 1 and the lower the score (the mean square difference is smaller), the more accurate the prediction is. It can be thought of as a measure of the "calibration" of a set of probabilistic predictions.

$$BS = \frac{1}{N}\sum_{t=1}^{N}(f_t - o_t)^2$$

where : N is the total number of predictions, f_t is the predicted probability of the actual outcome o_t.

Here is a small example of usage of this function::

```
>>> import numpy as np
>>> from sklearn.metrics import brier_score_loss
>>> y_true = np.array([0, 1, 1, 0])
>>> y_true_categorical = np.array(["spam", "ham", "ham", "spam"])
>>> y_prob = np.array([0.1, 0.9, 0.8, 0.4])
>>> y_pred = np.array([0, 1, 1, 0])
>>> brier_score_loss(y_true, y_prob)
0.055
>>> brier_score_loss(y_true, 1 - y_prob, pos_label=0)
0.055
>>> brier_score_loss(y_true_categorical, y_prob, pos_label="ham")
0.055
>>> brier_score_loss(y_true, y_prob > 0.5)
0.0
```

Example:

- See *Probability calibration of classifiers* for an example of Brier score loss usage to perform probability calibration of classifiers.

Multilabel ranking metrics

In multilabel learning, each sample can have any number of ground truth labels associated with it. The goal is to give high scores and better rank to the ground truth labels.

Coverage error

The *coverage_error* function computes the average number of labels that have to be included in the final prediction such that all true labels are predicted. This is useful if you want to know how many top-scored-labels you have to predict in average without missing any true one. The best value of this metrics is thus the average number of true labels.

Note: Our implementation's score is 1 greater than the one given in Tsoumakas et al., 2010. This extends it to handle the degenerate case in which an instance has 0 true labels.

Formally, given a binary indicator matrix of the ground truth labels $y \in \{0,1\}^{n_{\text{samples}} \times n_{\text{labels}}}$ and the score associated with each label $\hat{f} \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$, the coverage is defined as

$$coverage(y, \hat{f}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \max_{j:y_{ij}=1} \text{rank}_{ij}$$

with $\text{rank}_{ij} = \left|\left\{k : \hat{f}_{ik} \geq \hat{f}_{ij}\right\}\right|$. Given the rank definition, ties in `y_scores` are broken by giving the maximal rank that would have been assigned to all tied values.

Here is a small example of usage of this function:

```
>>> import numpy as np
>>> from sklearn.metrics import coverage_error
>>> y_true = np.array([[1, 0, 0], [0, 0, 1]])
>>> y_score = np.array([[0.75, 0.5, 1], [1, 0.2, 0.1]])
>>> coverage_error(y_true, y_score)
2.5
```

Label ranking average precision

The *label_ranking_average_precision_score* function implements label ranking average precision (LRAP). This metric is linked to the *average_precision_score* function, but is based on the notion of label ranking instead of precision and recall.

Label ranking average precision (LRAP) averages over the samples the answer to the following question: for each ground truth label, what fraction of higher-ranked labels were true labels? This performance measure will be higher if you are able to give better rank to the labels associated with each sample. The obtained score is always strictly greater than 0, and the best value is 1. If there is exactly one relevant label per sample, label ranking average precision is equivalent to the mean reciprocal rank.

Formally, given a binary indicator matrix of the ground truth labels $y \in \{0,1\}^{n_{\text{samples}} \times n_{\text{labels}}}$ and the score associated with each label $\hat{f} \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$, the average precision is defined as

$$LRAP(y, \hat{f}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \frac{1}{||y_i||_0} \sum_{j:y_{ij}=1} \frac{|\mathcal{L}_{ij}|}{\text{rank}_{ij}}$$

where $\mathcal{L}_{ij} = \left\{k : y_{ik} = 1, \hat{f}_{ik} \geq \hat{f}_{ij}\right\}$, $\text{rank}_{ij} = \left|\left\{k : \hat{f}_{ik} \geq \hat{f}_{ij}\right\}\right|$, $|\cdot|$ computes the cardinality of the set (i.e., the number of elements in the set), and $||\cdot||_0$ is the ℓ_0 "norm" (which computes the number of nonzero elements in a vector).

Here is a small example of usage of this function:

```
>>> import numpy as np
>>> from sklearn.metrics import label_ranking_average_precision_score
>>> y_true = np.array([[1, 0, 0], [0, 0, 1]])
>>> y_score = np.array([[0.75, 0.5, 1], [1, 0.2, 0.1]])
>>> label_ranking_average_precision_score(y_true, y_score)
0.416...
```

Ranking loss

The *label_ranking_loss* function computes the ranking loss which averages over the samples the number of label pairs that are incorrectly ordered, i.e. true labels have a lower score than false labels, weighted by the inverse of the number of ordered pairs of false and true labels. The lowest achievable ranking loss is zero.

Formally, given a binary indicator matrix of the ground truth labels $y \in \{0, 1\}^{n_{\text{samples}} \times n_{\text{labels}}}$ and the score associated with each label $\hat{f} \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$, the ranking loss is defined as

$$ranking\_loss(y, \hat{f}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \frac{1}{||y_i||_0(n_{\text{labels}} - ||y_i||_0)} \left|\left\{(k, l) : \hat{f}_{ik} \leq \hat{f}_{il}, y_{ik} = 1, y_{il} = 0\right\}\right|$$

where $|\cdot|$ computes the cardinality of the set (i.e., the number of elements in the set) and $||\cdot||_0$ is the ℓ_0 "norm" (which computes the number of nonzero elements in a vector).

Here is a small example of usage of this function:

```
>>> import numpy as np
>>> from sklearn.metrics import label_ranking_loss
>>> y_true = np.array([[1, 0, 0], [0, 0, 1]])
>>> y_score = np.array([[0.75, 0.5, 1], [1, 0.2, 0.1]])
>>> label_ranking_loss(y_true, y_score)
0.75...
>>> # With the following prediction, we have perfect and minimal loss
>>> y_score = np.array([[1.0, 0.1, 0.2], [0.1, 0.2, 0.9]])
>>> label_ranking_loss(y_true, y_score)
0.0
```

Normalized Discounted Cumulative Gain

Discounted Cumulative Gain (DCG) and Normalized Discounted Cumulative Gain (NDCG) are ranking metrics; they compare a predicted order to ground-truth scores, such as the relevance of answers to a query.

from the Wikipedia page for Discounted Cumulative Gain:

"Discounted cumulative gain (DCG) is a measure of ranking quality. In information retrieval, it is often used to measure effectiveness of web search engine algorithms or related applications. Using a graded relevance scale of documents in a search-engine result set, DCG measures the usefulness, or gain, of a document based on its position in the result list. The gain is accumulated from the top of the result list to the bottom, with the gain of each result discounted at lower ranks"

DCG orders the true targets (e.g. relevance of query answers) in the predicted order, then multiplies them by a logarithmic decay and sums the result. The sum can be truncated after the first K results, in which case we call it DCG@K. NDCG, or NDCG@K is DCG divided by the DCG obtained by a perfect prediction, so that it is always between 0 and 1. Usually, NDCG is preferred to DCG.

Compared with the ranking loss, NDCG can take into account relevance scores, rather than a ground-truth ranking. So if the ground-truth consists only of an ordering, the ranking loss should be preferred; if the ground-truth consists of actual usefulness scores (e.g. 0 for irrelevant, 1 for relevant, 2 for very relevant), NDCG can be used.

For one sample, given the vector of continuous ground-truth values for each target $y \in \mathbb{R}^M$, where M is the number of outputs, and the prediction $\hat{y}$, which induces the ranking function f, the DCG score is

$$\sum_{r=1}^{\min(K,M)} \frac{y_{f(r)}}{\log(1+r)}$$

and the NDCG score is the DCG score divided by the DCG score obtained for y.

Regression metrics

The *sklearn.metrics* module implements several loss, score, and utility functions to measure regression performance. Some of those have been enhanced to handle the multioutput case: *mean_squared_error*, *mean_absolute_error*, *explained_variance_score* and *r2_score*.

These functions have an `multioutput` keyword argument which specifies the way the scores or losses for each individual target should be averaged. The default is `'uniform_average'`, which specifies a uniformly weighted mean over outputs. If an `ndarray` of shape `(n_outputs,)` is passed, then its entries are interpreted as weights and an according weighted average is returned. If `multioutput` is `'raw_values'` is specified, then all unaltered individual scores or losses will be returned in an array of shape `(n_outputs,)`.

The *r2_score* and *explained_variance_score* accept an additional value `'variance_weighted'` for the `multioutput` parameter. This option leads to a weighting of each individual score by the variance of the corresponding target variable. This setting quantifies the globally captured unscaled variance. If the target variables are of different scale, then this score puts more importance on well explaining the higher variance variables. `multioutput='variance_weighted'` is the default value for *r2_score* for backward compatibility. This will be changed to `uniform_average` in the future.

Explained variance score

The *explained_variance_score* computes the explained variance regression score.

If $\hat{y}$ is the estimated target output, y the corresponding (correct) target output, and Var is Variance, the square of the standard deviation, then the explained variance is estimated as follow:

$$explained\_variance(y, \hat{y}) = 1 - \frac{Var\{y - \hat{y}\}}{Var\{y\}}$$

The best possible score is 1.0, lower values are worse.

Here is a small example of usage of the *explained_variance_score* function:

```
>>> from sklearn.metrics import explained_variance_score
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> explained_variance_score(y_true, y_pred)
0.957...
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> explained_variance_score(y_true, y_pred, multioutput='raw_values')
array([0.967..., 1.        ])
>>> explained_variance_score(y_true, y_pred, multioutput=[0.3, 0.7])
0.990...
```

Max error

The *max_error* function computes the maximum residual error , a metric that captures the worst case error between the predicted value and the true value. In a perfectly fitted single output regression model, `max_error` would be `0` on the training set and though this would be highly unlikely in the real world, this metric shows the extent of error that the model had when it was fitted.

If $\hat{y}_i$ is the predicted value of the i-th sample, and y_i is the corresponding true value, then the max error is defined as

$$\text{Max Error}(y, \hat{y}) = max(|y_i - \hat{y}_i|)$$

Here is a small example of usage of the *max_error* function:

```
>>> from sklearn.metrics import max_error
>>> y_true = [3, 2, 7, 1]
>>> y_pred = [9, 2, 7, 1]
>>> max_error(y_true, y_pred)
6
```

The *max_error* does not support multioutput.

Mean absolute error

The *mean_absolute_error* function computes mean absolute error, a risk metric corresponding to the expected value of the absolute error loss or $l1$-norm loss.

If $\hat{y}_i$ is the predicted value of the i-th sample, and y_i is the corresponding true value, then the mean absolute error (MAE) estimated over n_{samples} is defined as

$$\text{MAE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} |y_i - \hat{y}_i| .$$

Here is a small example of usage of the *mean_absolute_error* function:

```
>>> from sklearn.metrics import mean_absolute_error
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> mean_absolute_error(y_true, y_pred)
0.5
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> mean_absolute_error(y_true, y_pred)
0.75
>>> mean_absolute_error(y_true, y_pred, multioutput='raw_values')
array([0.5, 1. ])
>>> mean_absolute_error(y_true, y_pred, multioutput=[0.3, 0.7])
0.85...
```

Mean squared error

The *mean_squared_error* function computes mean square error, a risk metric corresponding to the expected value of the squared (quadratic) error or loss.

If $\hat{y}_i$ is the predicted value of the i-th sample, and y_i is the corresponding true value, then the mean squared error (MSE) estimated over n_{samples} is defined as

$$\text{MSE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} (y_i - \hat{y}_i)^2.$$

Here is a small example of usage of the *mean_squared_error* function:

```
>>> from sklearn.metrics import mean_squared_error
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> mean_squared_error(y_true, y_pred)
0.375
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> mean_squared_error(y_true, y_pred)
0.7083...
```

Examples:

- See *Gradient Boosting regression* for an example of mean squared error usage to evaluate gradient boosting regression.

Mean squared logarithmic error

The *mean_squared_log_error* function computes a risk metric corresponding to the expected value of the squared logarithmic (quadratic) error or loss.

If $\hat{y}_i$ is the predicted value of the i-th sample, and y_i is the corresponding true value, then the mean squared logarithmic error (MSLE) estimated over n_{samples} is defined as

$$\text{MSLE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} (\log_e(1 + y_i) - \log_e(1 + \hat{y}_i))^2.$$

Where $\log_e(x)$ means the natural logarithm of x. This metric is best to use when targets having exponential growth, such as population counts, average sales of a commodity over a span of years etc. Note that this metric penalizes an under-predicted estimate greater than an over-predicted estimate.

Here is a small example of usage of the *mean_squared_log_error* function:

```
>>> from sklearn.metrics import mean_squared_log_error
>>> y_true = [3, 5, 2.5, 7]
>>> y_pred = [2.5, 5, 4, 8]
>>> mean_squared_log_error(y_true, y_pred)
0.039...
>>> y_true = [[0.5, 1], [1, 2], [7, 6]]
>>> y_pred = [[0.5, 2], [1, 2.5], [8, 8]]
>>> mean_squared_log_error(y_true, y_pred)
0.044...
```

Median absolute error

The *median_absolute_error* is particularly interesting because it is robust to outliers. The loss is calculated by taking the median of all absolute differences between the target and the prediction.

If $\hat{y}_i$ is the predicted value of the i-th sample and y_i is the corresponding true value, then the median absolute error (MedAE) estimated over n_{samples} is defined as

$$\text{MedAE}(y, \hat{y}) = \text{median}(\mid y_1 - \hat{y}_1 \mid, \ldots, \mid y_n - \hat{y}_n \mid).$$

The *median_absolute_error* does not support multioutput.

Here is a small example of usage of the *median_absolute_error* function:

```
>>> from sklearn.metrics import median_absolute_error
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> median_absolute_error(y_true, y_pred)
0.5
```

R^2 score, the coefficient of determination

The *r2_score* function computes the coefficient of determination, usually denoted as R^2.

It represents the proportion of variance (of y) that has been explained by the independent variables in the model. It provides an indication of goodness of fit and therefore a measure of how well unseen samples are likely to be predicted by the model, through the proportion of explained variance.

As such variance is dataset dependent, R^2 may not be meaningfully comparable across different datasets. Best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

If $\hat{y}_i$ is the predicted value of the i-th sample and y_i is the corresponding true value for total n samples, the estimated R^2 is defined as:

$$R^2(y, \hat{y}) = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2}$$

where $\bar{y} = \frac{1}{n}\sum_{i=1}^{n} y_i$ and $\sum_{i=1}^{n}(y_i - \hat{y}_i)^2 = \sum_{i=1}^{n} \epsilon_i^2$.

Note that *r2_score* calculates unadjusted R^2 without correcting for bias in sample variance of y.

Here is a small example of usage of the *r2_score* function:

```
>>> from sklearn.metrics import r2_score
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> r2_score(y_true, y_pred)
0.948...
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> r2_score(y_true, y_pred, multioutput='variance_weighted')
0.938...
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> r2_score(y_true, y_pred, multioutput='uniform_average')
0.936...
>>> r2_score(y_true, y_pred, multioutput='raw_values')
array([0.965..., 0.908...])
>>> r2_score(y_true, y_pred, multioutput=[0.3, 0.7])
0.925...
```

Example:

- See *Lasso and Elastic Net for Sparse Signals* for an example of R^2 score usage to evaluate Lasso and Elastic Net on sparse signals.

Mean Poisson, Gamma, and Tweedie deviances

The *mean_tweedie_deviance* function computes the mean Tweedie deviance error with a `power` parameter (p). This is a metric that elicits predicted expectation values of regression targets.

Following special cases exist,

- when `power=0` it is equivalent to *mean_squared_error*.
- when `power=1` it is equivalent to *mean_poisson_deviance*.
- when `power=2` it is equivalent to *mean_gamma_deviance*.

If $\hat{y}_i$ is the predicted value of the i-th sample, and y_i is the corresponding true value, then the mean Tweedie deviance error (D) for power p, estimated over n_{samples} is defined as

$$\mathrm{D}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \begin{cases} (y_i - \hat{y}_i)^2, & \text{for } p = 0 \text{ (Normal)} \\ 2(y_i \log(y/\hat{y}_i) + \hat{y}_i - y_i), & \text{for} p = 1 \text{ (Poisson)} \\ 2(\log(\hat{y}_i/y_i) + y_i/\hat{y}_i - 1), & \text{for} p = 2 \text{ (Gamma)} \\ 2\left(\frac{\max(y_i,0)^{2-p}}{(1-p)(2-p)} - \frac{y\,\hat{y}_i^{1-p}}{1-p} + \frac{\hat{y}_i^{2-p}}{2-p}\right), & \text{otherwise} \end{cases}$$

Tweedie deviance is a homogeneous function of degree `2-power`. Thus, Gamma distribution with `power=2` means that simultaneously scaling `y_true` and `y_pred` has no effect on the deviance. For Poisson distribution `power=1` the deviance scales linearly, and for Normal distribution (`power=0`), quadratically. In general, the higher `power` the less weight is given to extreme deviations between true and predicted targets.

For instance, let's compare the two predictions 1.0 and 100 that are both 50% of their corresponding true value.

The mean squared error (`power=0`) is very sensitive to the prediction difference of the second point,:

```
>>> from sklearn.metrics import mean_tweedie_deviance
>>> mean_tweedie_deviance([1.0], [1.5], power=0)
0.25
>>> mean_tweedie_deviance([100.], [150.], power=0)
2500.0
```

If we increase `power` to 1,:

```
>>> mean_tweedie_deviance([1.0], [1.5], power=1)
0.18...
>>> mean_tweedie_deviance([100.], [150.], power=1)
18.9...
```

the difference in errors decreases. Finally, by setting, `power=2`:

```
>>> mean_tweedie_deviance([1.0], [1.5], power=2)
0.14...
>>> mean_tweedie_deviance([100.], [150.], power=2)
0.14...
```

we would get identical errors. The deviance when `power=2` is thus only sensitive to relative errors.

Clustering metrics

The *`sklearn.metrics`* module implements several loss, score, and utility functions. For more information see the *Clustering performance evaluation* section for instance clustering, and *Biclustering evaluation* for biclustering.

Dummy estimators

When doing supervised learning, a simple sanity check consists of comparing one's estimator against simple rules of thumb. *`DummyClassifier`* implements several such simple strategies for classification:

- `stratified` generates random predictions by respecting the training set class distribution.
- `most_frequent` always predicts the most frequent label in the training set.
- `prior` always predicts the class that maximizes the class prior (like `most_frequent`) and `predict_proba` returns the class prior.
- `uniform` generates predictions uniformly at random.
- **`constant` always predicts a constant label that is provided by the user.** A major motivation of this method is F1-scoring, when the positive class is in the minority.

Note that with all these strategies, the `predict` method completely ignores the input data!

To illustrate *`DummyClassifier`*, first let's create an imbalanced dataset:

```
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split
>>> X, y = load_iris(return_X_y=True)
>>> y[y != 1] = -1
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
```

Next, let's compare the accuracy of `SVC` and `most_frequent`:

```
>>> from sklearn.dummy import DummyClassifier
>>> from sklearn.svm import SVC
>>> clf = SVC(kernel='linear', C=1).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.63...
>>> clf = DummyClassifier(strategy='most_frequent', random_state=0)
>>> clf.fit(X_train, y_train)
DummyClassifier(random_state=0, strategy='most_frequent')
>>> clf.score(X_test, y_test)
0.57...
```

We see that SVC doesn't do much better than a dummy classifier. Now, let's change the kernel:

```
>>> clf = SVC(kernel='rbf', C=1).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.94...
```

We see that the accuracy was boosted to almost 100%. A cross validation strategy is recommended for a better estimate of the accuracy, if it is not too CPU costly. For more information see the *Cross-validation: evaluating estimator performance* section. Moreover if you want to optimize over the parameter space, it is highly recommended to use an appropriate methodology; see the *Tuning the hyper-parameters of an estimator* section for details.

More generally, when the accuracy of a classifier is too close to random, it probably means that something went wrong: features are not helpful, a hyperparameter is not correctly tuned, the classifier is suffering from class imbalance, etc...

DummyRegressor also implements four simple rules of thumb for regression:

- `mean` always predicts the mean of the training targets.
- `median` always predicts the median of the training targets.
- `quantile` always predicts a user provided quantile of the training targets.
- `constant` always predicts a constant value that is provided by the user.

In all these strategies, the `predict` method completely ignores the input data.

4.3.4 Model persistence

After training a scikit-learn model, it is desirable to have a way to persist the model for future use without having to retrain. The following section gives you an example of how to persist a model with pickle. We'll also review a few security and maintainability issues when working with pickle serialization.

An alternative to pickling is to export the model to another format using one of the model export tools listed under *Related Projects*. Unlike pickling, once exported you cannot recover the full Scikit-learn estimator object, but you can deploy the model for prediction, usually by using tools supporting open model interchange formats such as ONNX or PMML.

Persistence example

It is possible to save a model in scikit-learn by using Python's built-in persistence model, namely pickle:

```
>>> from sklearn import svm
>>> from sklearn import datasets
>>> clf = svm.SVC()
>>> X, y= datasets.load_iris(return_X_y=True)
>>> clf.fit(X, y)
```

(continues on next page)

(continued from previous page)

```
SVC()

>>> import pickle
>>> s = pickle.dumps(clf)
>>> clf2 = pickle.loads(s)
>>> clf2.predict(X[0:1])
array([0])
>>> y[0]
0
```

In the specific case of scikit-learn, it may be better to use joblib's replacement of pickle (`dump` & `load`), which is more efficient on objects that carry large numpy arrays internally as is often the case for fitted scikit-learn estimators, but can only pickle to the disk and not to a string:

```
>>> from joblib import dump, load
>>> dump(clf, 'filename.joblib')
```

Later you can load back the pickled model (possibly in another Python process) with:

```
>>> clf = load('filename.joblib')
```

Note: `dump` and `load` functions also accept file-like object instead of filenames. More information on data persistence with Joblib is available here.

Security & maintainability limitations

pickle (and joblib by extension), has some issues regarding maintainability and security. Because of this,

- Never unpickle untrusted data as it could lead to malicious code being executed upon loading.
- While models saved using one version of scikit-learn might load in other versions, this is entirely unsupported and inadvisable. It should also be kept in mind that operations performed on such data could give different and unexpected results.

In order to rebuild a similar model with future versions of scikit-learn, additional metadata should be saved along the pickled model:

- The training data, e.g. a reference to an immutable snapshot
- The python source code used to generate the model
- The versions of scikit-learn and its dependencies
- The cross validation score obtained on the training data

This should make it possible to check that the cross-validation score is in the same range as before.

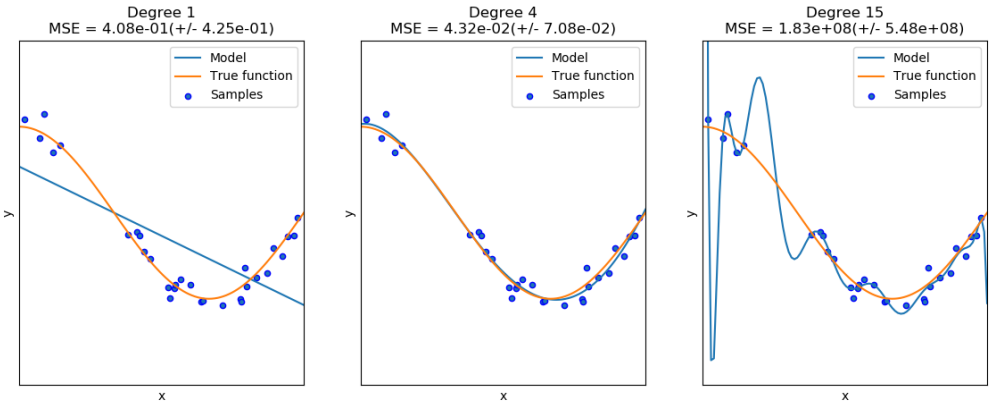
Since a model internal representation may be different on two different architectures, dumping a model on one architecture and loading it on another architecture is not supported.

If you want to know more about these issues and explore other possible serialization methods, please refer to this talk by Alex Gaynor.

4.3.5 Validation curves: plotting scores to evaluate models

Every estimator has its advantages and drawbacks. Its generalization error can be decomposed in terms of bias, variance and noise. The **bias** of an estimator is its average error for different training sets. The **variance** of an estimator indicates how sensitive it is to varying training sets. Noise is a property of the data.

In the following plot, we see a function $f(x) = \cos(\frac{3}{2}\pi x)$ and some noisy samples from that function. We use three different estimators to fit the function: linear regression with polynomial features of degree 1, 4 and 15. We see that the first estimator can at best provide only a poor fit to the samples and the true function because it is too simple (high bias), the second estimator approximates it almost perfectly and the last estimator approximates the training data perfectly but does not fit the true function very well, i.e. it is very sensitive to varying training data (high variance).



Bias and variance are inherent properties of estimators and we usually have to select learning algorithms and hyperparameters so that both bias and variance are as low as possible (see Bias-variance dilemma). Another way to reduce the variance of a model is to use more training data. However, you should only collect more training data if the true function is too complex to be approximated by an estimator with a lower variance.

In the simple one-dimensional problem that we have seen in the example it is easy to see whether the estimator suffers from bias or variance. However, in high-dimensional spaces, models can become very difficult to visualize. For this reason, it is often helpful to use the tools described below.

Examples:

- *Underfitting vs. Overfitting*
- *Plotting Validation Curves*
- *Plotting Learning Curves*

Validation curve

To validate a model we need a scoring function (see *Metrics and scoring: quantifying the quality of predictions*), for example accuracy for classifiers. The proper way of choosing multiple hyperparameters of an estimator are of course grid search or similar methods (see *Tuning the hyper-parameters of an estimator*) that select the hyperparameter with the maximum score on a validation set or multiple validation sets. Note that if we optimized the hyperparameters based on a validation score the validation score is biased and not a good estimate of the generalization any longer. To get a proper estimate of the generalization we have to compute the score on another test set.

However, it is sometimes helpful to plot the influence of a single hyperparameter on the training score and the validation score to find out whether the estimator is overfitting or underfitting for some hyperparameter values.

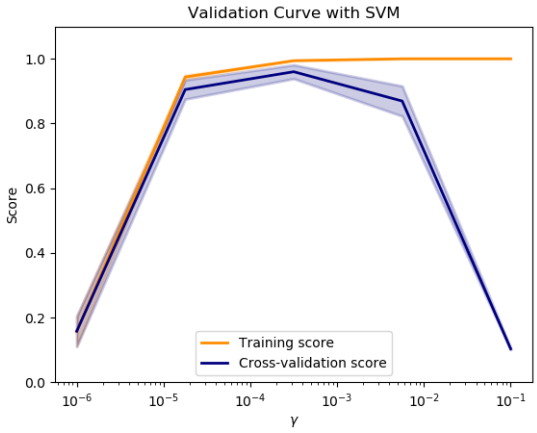
The function *validation_curve* can help in this case:

```
>>> import numpy as np
>>> from sklearn.model_selection import validation_curve
>>> from sklearn.datasets import load_iris
>>> from sklearn.linear_model import Ridge

>>> np.random.seed(0)
>>> X, y = load_iris(return_X_y=True)
>>> indices = np.arange(y.shape[0])
>>> np.random.shuffle(indices)
>>> X, y = X[indices], y[indices]

>>> train_scores, valid_scores = validation_curve(Ridge(), X, y, "alpha",
...                                               np.logspace(-7, 3, 3),
...                                               cv=5)
>>> train_scores
array([[0.93..., 0.94..., 0.92..., 0.91..., 0.92...],
       [0.93..., 0.94..., 0.92..., 0.91..., 0.92...],
       [0.51..., 0.52..., 0.49..., 0.47..., 0.49...]])
>>> valid_scores
array([[0.90..., 0.84..., 0.94..., 0.96..., 0.93...],
       [0.90..., 0.84..., 0.94..., 0.96..., 0.93...],
       [0.46..., 0.25..., 0.50..., 0.49..., 0.52...]])
```

If the training score and the validation score are both low, the estimator will be underfitting. If the training score is high and the validation score is low, the estimator is overfitting and otherwise it is working very well. A low training score and a high validation score is usually not possible. All three cases can be found in the plot below where we vary the parameter γ of an SVM on the digits dataset.



Learning curve

A learning curve shows the validation and training score of an estimator for varying numbers of training samples. It is a tool to find out how much we benefit from adding more training data and whether the estimator suffers more from a variance error or a bias error. Consider the following example where we plot the learning curve of a naive Bayes classifier and an SVM.

For the naive Bayes, both the validation score and the training score converge to a value that is quite low with increasing size of the training set. Thus, we will probably not benefit much from more training data.

In contrast, for small amounts of data, the training score of the SVM is much greater than the validation score. Adding more training samples will most likely increase generalization.

We can use the function *learning_curve* to generate the values that are required to plot such a learning curve (number of samples that have been used, the average scores on the training sets and the average scores on the validation sets):

```
>>> from sklearn.model_selection import learning_curve
>>> from sklearn.svm import SVC

>>> train_sizes, train_scores, valid_scores = learning_curve(
...     SVC(kernel='linear'), X, y, train_sizes=[50, 80, 110], cv=5)
>>> train_sizes
array([ 50, 80, 110])
>>> train_scores
array([[0.98..., 0.98 , 0.98..., 0.98..., 0.98...],
       [0.98..., 1.   , 0.98..., 0.98..., 0.98...],
       [0.98..., 1.   , 0.98..., 0.98..., 0.99...]])
>>> valid_scores
array([[1. ,  0.93...,  1. ,  1. ,  0.96...],
       [1. ,  0.96...,  1. ,  1. ,  0.96...],
       [1. ,  0.96...,  1. ,  1. ,  0.96...]])
```

4.4 Inspection

Predictive performance is often the main goal of developing machine learning models. Yet summarising performance with an evaluation metric is often insufficient: it assumes that the evaluation metric and test dataset perfectly reflect the target domain, which is rarely true. In certain domains, a model needs a certain level of interpretability before it can be deployed. A model that is exhibiting performance issues needs to be debugged for one to understand the model's underlying issue. The *sklearn.inspection* module provides tools to help understand the predictions from a model and what affects them. This can be used to evaluate assumptions and biases of a model, design a better model, or to diagnose issues with model performance.

4.4.1 Partial dependence plots

Partial dependence plots (PDP) show the dependence between the target response[1] and a set of 'target' features, marginalizing over the values of all other features (the 'complement' features). Intuitively, we can interpret the partial dependence as the expected target response as a function of the 'target' features.

Due to the limits of human perception the size of the target feature set must be small (usually, one or two) thus the target features are usually chosen among the most important features.

The figure below shows four one-way and one two-way partial dependence plots for the California housing dataset, with a *GradientBoostingRegressor*:

One-way PDPs tell us about the interaction between the target response and the target feature (e.g. linear, non-linear). The upper left plot in the above figure shows the effect of the median income in a district on the median house price; we can clearly see a linear relationship among them. Note that PDPs assume that the target features are independent from the complement features, and this assumption is often violated in practice.

PDPs with two target features show the interactions among the two features. For example, the two-variable PDP in the above figure shows the dependence of median house price on joint values of house age and average occupants per

[1] For classification, the target response may be the probability of a class (the positive class for binary classification), or the decision function.

household. We can clearly see an interaction between the two features: for an average occupancy greater than two, the house price is nearly independent of the house age, whereas for values less than 2 there is a strong dependence on age.

The *sklearn.inspection* module provides a convenience function *plot_partial_dependence* to create one-way and two-way partial dependence plots. In the below example we show how to create a grid of partial dependence plots: two one-way PDPs for the features `0` and `1` and a two-way PDP between the two features:

```
>>> from sklearn.datasets import make_hastie_10_2
>>> from sklearn.ensemble import GradientBoostingClassifier
>>> from sklearn.inspection import plot_partial_dependence

>>> X, y = make_hastie_10_2(random_state=0)
>>> clf = GradientBoostingClassifier(n_estimators=100, learning_rate=1.0,
...     max_depth=1, random_state=0).fit(X, y)
>>> features = [0, 1, (0, 1)]
>>> plot_partial_dependence(clf, X, features)
```

You can access the newly created figure and Axes objects using `plt.gcf()` and `plt.gca()`.

For multi-class classification, you need to set the class label for which the PDPs should be created via the `target` argument:

```
>>> from sklearn.datasets import load_iris
>>> iris = load_iris()
>>> mc_clf = GradientBoostingClassifier(n_estimators=10,
...     max_depth=1).fit(iris.data, iris.target)
>>> features = [3, 2, (3, 2)]
>>> plot_partial_dependence(mc_clf, X, features, target=0)
```

The same parameter `target` is used to specify the target in multi-output regression settings.

If you need the raw values of the partial dependence function rather than the plots, you can use the *sklearn.inspection.partial_dependence* function:

```
>>> from sklearn.inspection import partial_dependence

>>> pdp, axes = partial_dependence(clf, X, [0])
>>> pdp
array([[ 2.466...,  2.466..., ...
>>> axes
[array([-1.624..., -1.592..., ...
```

The values at which the partial dependence should be evaluated are directly generated from `X`. For 2-way partial dependence, a 2D-grid of values is generated. The `values` field returned by *`sklearn.inspection.partial_dependence`* gives the actual values used in the grid for each target feature. They also correspond to the axis of the plots.

For each value of the 'target' features in the `grid` the partial dependence function needs to marginalize the predictions of the estimator over all possible values of the 'complement' features. With the `'brute'` method, this is done by replacing every target feature value of `X` by those in the grid, and computing the average prediction.

In decision trees this can be evaluated efficiently without reference to the training data (`'recursion'` method). For each grid point a weighted tree traversal is performed: if a split node involves a 'target' feature, the corresponding left or right branch is followed, otherwise both branches are followed, each branch is weighted by the fraction of training samples that entered that branch. Finally, the partial dependence is given by a weighted average of all visited leaves. Note that with the `'recursion'` method, `X` is only used to generate the grid, not to compute the averaged predictions. The averaged predictions will always be computed on the data with which the trees were trained.

Examples:

- *Partial Dependence Plots*

4.4.2 Permutation feature importance

Permutation feature importance is a model inspection technique that can be used for any *fitted estimator* when the data is rectangular. This is especially useful for non-linear or opaque *estimators*. The permutation feature importance is defined to be the decrease in a model score when a single feature value is randomly shuffled[1]. This procedure breaks the relationship between the feature and the target, thus the drop in the model score is indicative of how much the model depends on the feature. This technique benefits from being model agnostic and can be calculated many times with different permutations of the feature.

The *`permutation_importance`* function calculates the feature importance of *estimators* for a given dataset. The `n_repeats` parameter sets the number of times a feature is randomly shuffled and returns a sample of feature importances. Permutation importances can either be computed on the training set or an held-out testing or validation set. Using a held-out set makes it possible to highlight which features contribute the most to the generalization power of the inspected model. Features that are important on the training set but not on the held-out set might cause the model to overfit.

[1] L. Breiman, "Random Forests", Machine Learning, 45(1), 5-32, 2001. https://doi.org/10.1023/A:1010933404324

Note that features that are deemed non-important for some model with a low predictive performance could be highly predictive for a model that generalizes better. The conclusions should always be drawn in the context of the specific model under inspection and cannot be automatically generalized to the intrinsic predictive value of the features by them-selves. Therefore it is always important to evaluate the predictive power of a model using a held-out set (or better with cross-validation) prior to computing importances.

Relation to impurity-based importance in trees

Tree based models provides a different measure of feature importances based on the mean decrease in impurity (MDI, the splitting criterion). This gives importance to features that may not be predictive on unseen data. The permutation feature importance avoids this issue, since it can be applied to unseen data. Furthermore, impurity-based feature importance for trees are strongly biased and favor high cardinality features (typically numerical features). Permutation-based feature importances do not exhibit such a bias. Additionally, the permutation feature importance may use an arbitrary metric on the tree's predictions. These two methods of obtaining feature importance are explored in: *Permutation Importance vs Random Forest Feature Importance (MDI)*.

Strongly correlated features

When two features are correlated and one of the features is permuted, the model will still have access to the feature through its correlated feature. This will result in a lower importance for both features, where they might *actually* be important. One way to handle this is to cluster features that are correlated and only keep one feature from each cluster. This use case is explored in: *Permutation Importance with Multicollinear or Correlated Features*.

Examples:

- *Permutation Importance vs Random Forest Feature Importance (MDI)*
- *Permutation Importance with Multicollinear or Correlated Features*

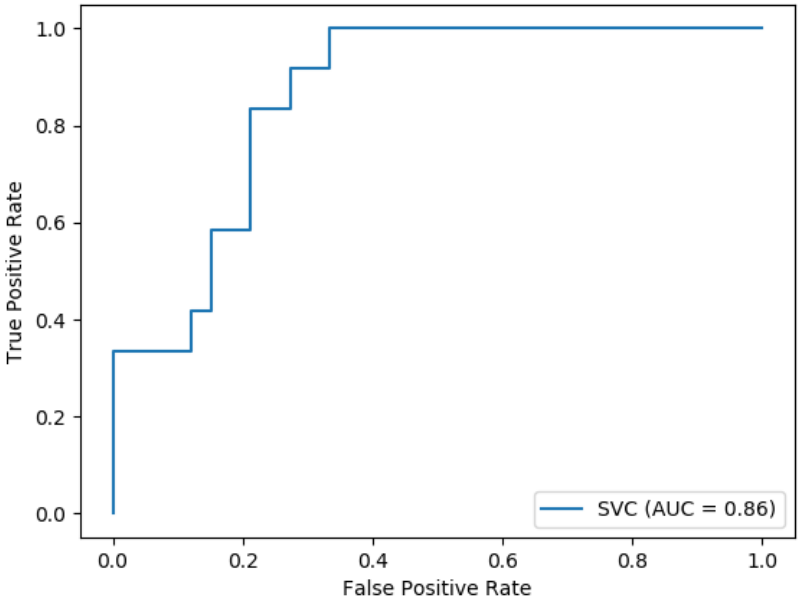
4.5 Visualizations

Scikit-learn defines a simple API for creating visualizations for machine learning. The key feature of this API is to allow for quick plotting and visual adjustments without recalculation. In the following example, we plot a ROC curve for a fitted support vector machine:

```
from sklearn.model_selection import train_test_split
from sklearn.svm import SVC
from sklearn.metrics import plot_roc_curve
from sklearn.datasets import load_wine

X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=42)
svc = SVC(random_state=42)
svc.fit(X_train, y_train)

svc_disp = plot_roc_curve(svc, X_test, y_test)
```



The returned `svc_disp` object allows us to continue using the already computed ROC curve for SVC in future plots. In this case, the `svc_disp` is a *`RocCurveDisplay`* that stores the computed values as attributes called `roc_auc`, `fpr`, and `tpr`. Next, we train a random forest classifier and plot the previously computed roc curve again by using the `plot` method of the `Display` object.

```
import matplotlib.pyplot as plt
from sklearn.ensemble import RandomForestClassifier

rfc = RandomForestClassifier(random_state=42)
rfc.fit(X_train, y_train)

ax = plt.gca()
rfc_disp = plot_roc_curve(rfc, X_test, y_test, ax=ax, alpha=0.8)
svc_disp.plot(ax=ax, alpha=0.8)
```

Notice that we pass `alpha=0.8` to the plot functions to adjust the alpha values of the curves.

4.6 Dataset transformations

scikit-learn provides a library of transformers, which may clean (see *Preprocessing data*), reduce (see *Unsupervised dimensionality reduction*), expand (see *Kernel Approximation*) or generate (see *Feature extraction*) feature representations.

Like other estimators, these are represented by classes with a `fit` method, which learns model parameters (e.g. mean and standard deviation for normalization) from a training set, and a `transform` method which applies this transformation model to unseen data. `fit_transform` may be more convenient and efficient for modelling and transforming the training data simultaneously.

Combining such transformers, either in parallel or series is covered in *Pipelines and composite estimators*. *Pairwise metrics, Affinities and Kernels* covers transforming feature spaces into affinity matrices, while *Transforming the prediction target (y)* considers transformations of the target space (e.g. categorical labels) for use in scikit-learn.

4.6.1 Pipelines and composite estimators

All estimators in a pipeline, except the last one, must be transformers (i.e. must have a *transform* method). The last estimator may be any type (transformer, classifier, etc.).

Usage

Construction

The *Pipeline* is built using a list of `(key, value)` pairs, where the `key` is a string containing the name you want to give this step and `value` is an estimator object:

```
>>> from sklearn.pipeline import Pipeline
>>> from sklearn.svm import SVC
>>> from sklearn.decomposition import PCA
>>> estimators = [('reduce_dim', PCA()), ('clf', SVC())]
>>> pipe = Pipeline(estimators)
>>> pipe
Pipeline(steps=[('reduce_dim', PCA()), ('clf', SVC())])
```

The utility function *make_pipeline* is a shorthand for constructing pipelines; it takes a variable number of estimators and returns a pipeline, filling in the names automatically:

```
>>> from sklearn.pipeline import make_pipeline
>>> from sklearn.naive_bayes import MultinomialNB
>>> from sklearn.preprocessing import Binarizer
>>> make_pipeline(Binarizer(), MultinomialNB())
Pipeline(steps=[('binarizer', Binarizer()), ('multinomialnb', MultinomialNB())])
```

Accessing steps

The estimators of a pipeline are stored as a list in the `steps` attribute, but can be accessed by index or name by indexing (with `[idx]`) the Pipeline:

```
>>> pipe.steps[0]
('reduce_dim', PCA())
>>> pipe[0]
PCA()
>>> pipe['reduce_dim']
PCA()
```

Pipeline's `named_steps` attribute allows accessing steps by name with tab completion in interactive environments:

```
>>> pipe.named_steps.reduce_dim is pipe['reduce_dim']
True
```

A sub-pipeline can also be extracted using the slicing notation commonly used for Python Sequences such as lists or strings (although only a step of 1 is permitted). This is convenient for performing only some of the transformations (or their inverse):

```
>>> pipe[:1]
Pipeline(steps=[('reduce_dim', PCA())])
>>> pipe[-1:]
Pipeline(steps=[('clf', SVC())])
```

Nested parameters

Parameters of the estimators in the pipeline can be accessed using the `<estimator>__<parameter>` syntax:

```
>>> pipe.set_params(clf__C=10)
Pipeline(steps=[('reduce_dim', PCA()), ('clf', SVC(C=10))])
```

This is particularly important for doing grid searches:

```
>>> from sklearn.model_selection import GridSearchCV
>>> param_grid = dict(reduce_dim__n_components=[2, 5, 10],
...                   clf__C=[0.1, 10, 100])
>>> grid_search = GridSearchCV(pipe, param_grid=param_grid)
```

Individual steps may also be replaced as parameters, and non-final steps may be ignored by setting them to `'passthrough'`:

```
>>> from sklearn.linear_model import LogisticRegression
>>> param_grid = dict(reduce_dim=['passthrough', PCA(5), PCA(10)],
...                   clf=[SVC(), LogisticRegression()],
...                   clf__C=[0.1, 10, 100])
>>> grid_search = GridSearchCV(pipe, param_grid=param_grid)
```

The estimators of the pipeline can be retrieved by index:

```
>>> pipe[0]
PCA()
```

or by name:

```
>>> pipe['reduce_dim']
PCA()
```

Examples:

- *Pipeline Anova SVM*
- *Sample pipeline for text feature extraction and evaluation*
- *Pipelining: chaining a PCA and a logistic regression*
- *Explicit feature map approximation for RBF kernels*
- *SVM-Anova: SVM with univariate feature selection*
- *Selecting dimensionality reduction with Pipeline and GridSearchCV*

See also:

- *Composite estimators and parameter spaces*

Notes

Calling `fit` on the pipeline is the same as calling `fit` on each estimator in turn, `transform` the input and pass it on to the next step. The pipeline has all the methods that the last estimator in the pipeline has, i.e. if the last estimator is a classifier, the *Pipeline* can be used as a classifier. If the last estimator is a transformer, again, so is the pipeline.

Caching transformers: avoid repeated computation

Fitting transformers may be computationally expensive. With its `memory` parameter set, *Pipeline* will cache each transformer after calling `fit`. This feature is used to avoid computing the fit transformers within a pipeline if the parameters and input data are identical. A typical example is the case of a grid search in which the transformers can be fitted only once and reused for each configuration.

The parameter `memory` is needed in order to cache the transformers. `memory` can be either a string containing the directory where to cache the transformers or a joblib.Memory object:

```
>>> from tempfile import mkdtemp
>>> from shutil import rmtree
>>> from sklearn.decomposition import PCA
>>> from sklearn.svm import SVC
>>> from sklearn.pipeline import Pipeline
>>> estimators = [('reduce_dim', PCA()), ('clf', SVC())]
>>> cachedir = mkdtemp()
>>> pipe = Pipeline(estimators, memory=cachedir)
>>> pipe
Pipeline(memory=...,
         steps=[('reduce_dim', PCA()), ('clf', SVC())])
>>> # Clear the cache directory when you don't need it anymore
>>> rmtree(cachedir)
```

Warning: Side effect of caching transformers

Using a *Pipeline* without cache enabled, it is possible to inspect the original instance such as:

```
>>> from sklearn.datasets import load_digits
>>> X_digits, y_digits = load_digits(return_X_y=True)
>>> pca1 = PCA()
>>> svm1 = SVC()
>>> pipe = Pipeline([('reduce_dim', pca1), ('clf', svm1)])
>>> pipe.fit(X_digits, y_digits)
Pipeline(steps=[('reduce_dim', PCA()), ('clf', SVC())])
>>> # The pca instance can be inspected directly
>>> print(pca1.components_)
    [[-1.77484909e-19  ... 4.07058917e-18]]
```

Enabling caching triggers a clone of the transformers before fitting. Therefore, the transformer instance given to the pipeline cannot be inspected directly. In following example, accessing the `PCA` instance `pca2` will raise an `AttributeError` since `pca2` will be an unfitted transformer. Instead, use the attribute `named_steps` to inspect estimators within the pipeline:

```
>>> cachedir = mkdtemp()
>>> pca2 = PCA()
>>> svm2 = SVC()
>>> cached_pipe = Pipeline([('reduce_dim', pca2), ('clf', svm2)],
...                        memory=cachedir)
>>> cached_pipe.fit(X_digits, y_digits)
Pipeline(memory=...,
         steps=[('reduce_dim', PCA()), ('clf', SVC())])
>>> print(cached_pipe.named_steps['reduce_dim'].components_)
    [[-1.77484909e-19  ... 4.07058917e-18]]
>>> # Remove the cache directory
>>> rmtree(cachedir)
```

Transforming target in regression

`TransformedTargetRegressor` transforms the targets `y` before fitting a regression model. The predictions are mapped back to the original space via an inverse transform. It takes as an argument the regressor that will be used for prediction, and the transformer that will be applied to the target variable:

```
>>> import numpy as np
>>> from sklearn.datasets import load_boston
>>> from sklearn.compose import TransformedTargetRegressor
>>> from sklearn.preprocessing import QuantileTransformer
>>> from sklearn.linear_model import LinearRegression
>>> from sklearn.model_selection import train_test_split
>>> X, y = load_boston(return_X_y=True)
>>> transformer = QuantileTransformer(output_distribution='normal')
>>> regressor = LinearRegression()
>>> regr = TransformedTargetRegressor(regressor=regressor,
...                                   transformer=transformer)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
>>> regr.fit(X_train, y_train)
TransformedTargetRegressor(...)
>>> print('R2 score: {0:.2f}'.format(regr.score(X_test, y_test)))
R2 score: 0.67
>>> raw_target_regr = LinearRegression().fit(X_train, y_train)
>>> print('R2 score: {0:.2f}'.format(raw_target_regr.score(X_test, y_test)))
R2 score: 0.64
```

For simple transformations, instead of a Transformer object, a pair of functions can be passed, defining the transformation and its inverse mapping:

```
>>> def func(x):
...     return np.log(x)
>>> def inverse_func(x):
...     return np.exp(x)
```

Subsequently, the object is created as:

```
>>> regr = TransformedTargetRegressor(regressor=regressor,
...                                   func=func,
...                                   inverse_func=inverse_func)
>>> regr.fit(X_train, y_train)
TransformedTargetRegressor(...)
>>> print('R2 score: {0:.2f}'.format(regr.score(X_test, y_test)))
R2 score: 0.65
```

By default, the provided functions are checked at each fit to be the inverse of each other. However, it is possible to bypass this checking by setting `check_inverse` to `False`:

```
>>> def inverse_func(x):
...     return x
>>> regr = TransformedTargetRegressor(regressor=regressor,
...                                   func=func,
...                                   inverse_func=inverse_func,
...                                   check_inverse=False)
>>> regr.fit(X_train, y_train)
TransformedTargetRegressor(...)
>>> print('R2 score: {0:.2f}'.format(regr.score(X_test, y_test)))
R2 score: -4.50
```

Note: The transformation can be triggered by setting either `transformer` or the pair of functions `func` and `inverse_func`. However, setting both options will raise an error.

Examples:

- *Effect of transforming the targets in regression model*

FeatureUnion: composite feature spaces

FeatureUnion combines several transformer objects into a new transformer that combines their output. A *FeatureUnion* takes a list of transformer objects. During fitting, each of these is fit to the data independently. The transformers are applied in parallel, and the feature matrices they output are concatenated side-by-side into a larger matrix.

When you want to apply different transformations to each field of the data, see the related class *sklearn.compose.ColumnTransformer* (see *user guide*).

FeatureUnion serves the same purposes as *Pipeline* - convenience and joint parameter estimation and validation.

FeatureUnion and *Pipeline* can be combined to create complex models.

(A *FeatureUnion* has no way of checking whether two transformers might produce identical features. It only produces a union when the feature sets are disjoint, and making sure they are the caller's responsibility.)

Usage

A *FeatureUnion* is built using a list of `(key, value)` pairs, where the `key` is the name you want to give to a given transformation (an arbitrary string; it only serves as an identifier) and `value` is an estimator object:

```
>>> from sklearn.pipeline import FeatureUnion
>>> from sklearn.decomposition import PCA
>>> from sklearn.decomposition import KernelPCA
>>> estimators = [('linear_pca', PCA()), ('kernel_pca', KernelPCA())]
>>> combined = FeatureUnion(estimators)
>>> combined
FeatureUnion(transformer_list=[('linear_pca', PCA()),
                               ('kernel_pca', KernelPCA())])
```

Like pipelines, feature unions have a shorthand constructor called *make_union* that does not require explicit naming of the components.

Like `Pipeline`, individual steps may be replaced using `set_params`, and ignored by setting to `'drop'`:

```
>>> combined.set_params(kernel_pca='drop')
FeatureUnion(transformer_list=[('linear_pca', PCA()),
                               ('kernel_pca', 'drop')])
```

Examples:

- *Concatenating multiple feature extraction methods*

ColumnTransformer for heterogeneous data

Warning: The *compose.ColumnTransformer* class is experimental and the API is subject to change.

Many datasets contain features of different types, say text, floats, and dates, where each type of feature requires separate preprocessing or feature extraction steps. Often it is easiest to preprocess data before applying scikit-learn methods, for example using pandas. Processing your data before passing it to scikit-learn might be problematic for one of the following reasons:

1. Incorporating statistics from test data into the preprocessors makes cross-validation scores unreliable (known as *data leakage*), for example in the case of scalers or imputing missing values.
2. You may want to include the parameters of the preprocessors in a *parameter search*.

The *ColumnTransformer* helps performing different transformations for different columns of the data, within a *Pipeline* that is safe from data leakage and that can be parametrized. *ColumnTransformer* works on arrays, sparse matrices, and pandas DataFrames.

To each column, a different transformation can be applied, such as preprocessing or a specific feature extraction method:

```
>>> import pandas as pd
>>> X = pd.DataFrame(
...     {'city': ['London', 'London', 'Paris', 'Sallisaw'],
...      'title': ["His Last Bow", "How Watson Learned the Trick",
...                "A Moveable Feast", "The Grapes of Wrath"],
...      'expert_rating': [5, 3, 4, 5],
...      'user_rating': [4, 5, 4, 3]})
```

For this data, we might want to encode the `'city'` column as a categorical variable using *preprocessing.OneHotEncoder* but apply a *feature_extraction.text.CountVectorizer* to the `'title'` column.

As we might use multiple feature extraction methods on the same column, we give each transformer a unique name, say `'city_category'` and `'title_bow'`. By default, the remaining rating columns are ignored (`remainder='drop'`):

```
>>> from sklearn.compose import ColumnTransformer
>>> from sklearn.feature_extraction.text import CountVectorizer
>>> from sklearn.preprocessing import OneHotEncoder
>>> column_trans = ColumnTransformer(
...     [('city_category', OneHotEncoder(dtype='int'),['city']),
...      ('title_bow', CountVectorizer(), 'title')],
...     remainder='drop')

>>> column_trans.fit(X)
ColumnTransformer(transformers=[('city_category', OneHotEncoder(dtype='int'),
                                 ['city']),
                                ('title_bow', CountVectorizer(), 'title')])

>>> column_trans.get_feature_names()
['city_category__x0_London', 'city_category__x0_Paris', 'city_category__x0_Sallisaw',
'title_bow__bow', 'title_bow__feast', 'title_bow__grapes', 'title_bow__his',
'title_bow__how', 'title_bow__last', 'title_bow__learned', 'title_bow__moveable',
'title_bow__of', 'title_bow__the', 'title_bow__trick', 'title_bow__watson',
'title_bow__wrath']

>>> column_trans.transform(X).toarray()
array([[1, 0, 0, 1, 0, 0, 1, 0, 1, 0, 0, 0, 0, 0, 0, 0],
       [1, 0, 0, 0, 0, 0, 0, 1, 0, 1, 0, 0, 1, 1, 1, 0],
       [0, 1, 0, 0, 1, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0],
       [0, 0, 1, 0, 0, 1, 0, 0, 0, 0, 0, 1, 1, 0, 0, 1]]...)
```

In the above example, the *CountVectorizer* expects a 1D array as input and therefore the columns were specified as a string (`'title'`). However, *preprocessing.OneHotEncoder* as most of other transformers expects 2D data, therefore in that case you need to specify the column as a list of strings (`['city']`).

Apart from a scalar or a single item list, the column selection can be specified as a list of multiple items, an integer array, a slice, a boolean mask, or with a *make_column_selector*. The *make_column_selector* is used to select columns based on data type or column name:

```
>>> from sklearn.preprocessing import StandardScaler
>>> from sklearn.compose import make_column_selector
>>> ct = ColumnTransformer([
...       ('scale', StandardScaler(),
...       make_column_selector(dtype_include=np.number)),
...       ('onehot',
...       OneHotEncoder(),
...       make_column_selector(pattern='city', dtype_include=object))])
>>> ct.fit_transform(X)
array([[ 0.904...,  0.      ,  1. ,  0. ,  0. ],
       [-1.507...,  1.414...,  1. ,  0. ,  0. ],
       [-0.301...,  0.      ,  0. ,  1. ,  0. ],
       [ 0.904..., -1.414...,  0. ,  0. ,  1. ]])
```

Strings can reference columns if the input is a DataFrame, integers are always interpreted as the positional columns.

We can keep the remaining rating columns by setting `remainder='passthrough'`. The values are appended to the end of the transformation:

```
>>> column_trans = ColumnTransformer(
...     [('city_category', OneHotEncoder(dtype='int'),['city']),
...      ('title_bow', CountVectorizer(), 'title')],
...     remainder='passthrough')

>>> column_trans.fit_transform(X)
array([[1, 0, 0, 1, 0, 0, 1, 0, 1, 0, 0, 0, 0, 0, 0, 0, 5, 4],
       [1, 0, 0, 0, 0, 0, 0, 1, 0, 1, 0, 0, 1, 1, 1, 0, 3, 5],
       [0, 1, 0, 0, 1, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0, 4, 4],
       [0, 0, 1, 0, 0, 1, 0, 0, 0, 0, 0, 1, 1, 0, 0, 1, 5, 3]]...)
```

The `remainder` parameter can be set to an estimator to transform the remaining rating columns. The transformed values are appended to the end of the transformation:

```
>>> from sklearn.preprocessing import MinMaxScaler
>>> column_trans = ColumnTransformer(
...     [('city_category', OneHotEncoder(), ['city']),
...      ('title_bow', CountVectorizer(), 'title')],
...     remainder=MinMaxScaler())

>>> column_trans.fit_transform(X)[:, -2:]
array([[1. , 0.5],
       [0. , 1. ],
       [0.5, 0.5],
       [1. , 0. ]])
```

The *make_column_transformer* function is available to more easily create a *ColumnTransformer* object. Specifically, the names will be given automatically. The equivalent for the above example would be:

```
>>> from sklearn.compose import make_column_transformer
>>> column_trans = make_column_transformer(
...     (OneHotEncoder(), ['city']),
...     (CountVectorizer(), 'title'),
...     remainder=MinMaxScaler())
>>> column_trans
ColumnTransformer(remainder=MinMaxScaler(),
                  transformers=[('onehotencoder', OneHotEncoder(), ['city']),
                                ('countvectorizer', CountVectorizer(),
                                 'title')])
```

Examples:

- *Column Transformer with Heterogeneous Data Sources*
- *Column Transformer with Mixed Types*

4.6.2 Feature extraction

The *sklearn.feature_extraction* module can be used to extract features in a format supported by machine learning algorithms from datasets consisting of formats such as text and image.

Note: Feature extraction is very different from *Feature selection*: the former consists in transforming arbitrary data, such as text or images, into numerical features usable for machine learning. The latter is a machine learning technique

applied on these features.

Loading features from dicts

The class *DictVectorizer* can be used to convert feature arrays represented as lists of standard Python `dict` objects to the NumPy/SciPy representation used by scikit-learn estimators.

While not particularly fast to process, Python's `dict` has the advantages of being convenient to use, being sparse (absent features need not be stored) and storing feature names in addition to values.

DictVectorizer implements what is called one-of-K or "one-hot" coding for categorical (aka nominal, discrete) features. Categorical features are "attribute-value" pairs where the value is restricted to a list of discrete of possibilities without ordering (e.g. topic identifiers, types of objects, tags, names...).

In the following, "city" is a categorical attribute while "temperature" is a traditional numerical feature:

```
>>> measurements = [
...     {'city': 'Dubai', 'temperature': 33.},
...     {'city': 'London', 'temperature': 12.},
...     {'city': 'San Francisco', 'temperature': 18.},
... ]

>>> from sklearn.feature_extraction import DictVectorizer
>>> vec = DictVectorizer()

>>> vec.fit_transform(measurements).toarray()
array([[ 1.,  0.,  0., 33.],
       [ 0.,  1.,  0., 12.],
       [ 0.,  0.,  1., 18.]])

>>> vec.get_feature_names()
['city=Dubai', 'city=London', 'city=San Francisco', 'temperature']
```

DictVectorizer is also a useful representation transformation for training sequence classifiers in Natural Language Processing models that typically work by extracting feature windows around a particular word of interest.

For example, suppose that we have a first algorithm that extracts Part of Speech (PoS) tags that we want to use as complementary tags for training a sequence classifier (e.g. a chunker). The following dict could be such a window of features extracted around the word 'sat' in the sentence 'The cat sat on the mat.':

```
>>> pos_window = [
...     {
...         'word-2': 'the',
...         'pos-2': 'DT',
...         'word-1': 'cat',
...         'pos-1': 'NN',
...         'word+1': 'on',
...         'pos+1': 'PP',
...     },
...     # in a real application one would extract many such dictionaries
... ]
```

This description can be vectorized into a sparse two-dimensional matrix suitable for feeding into a classifier (maybe after being piped into a *text.TfidfTransformer* for normalization):

```
>>> vec = DictVectorizer()
>>> pos_vectorized = vec.fit_transform(pos_window)
>>> pos_vectorized
<1x6 sparse matrix of type '<... 'numpy.float64'>'
    with 6 stored elements in Compressed Sparse ... format>
>>> pos_vectorized.toarray()
array([[1., 1., 1., 1., 1., 1.]])
>>> vec.get_feature_names()
['pos+1=PP', 'pos-1=NN', 'pos-2=DT', 'word+1=on', 'word-1=cat', 'word-2=the']
```

As you can imagine, if one extracts such a context around each individual word of a corpus of documents the resulting matrix will be very wide (many one-hot-features) with most of them being valued to zero most of the time. So as to make the resulting data structure able to fit in memory the `DictVectorizer` class uses a `scipy.sparse` matrix by default instead of a `numpy.ndarray`.

Feature hashing

The class *`FeatureHasher`* is a high-speed, low-memory vectorizer that uses a technique known as feature hashing, or the "hashing trick". Instead of building a hash table of the features encountered in training, as the vectorizers do, instances of *`FeatureHasher`* apply a hash function to the features to determine their column index in sample matrices directly. The result is increased speed and reduced memory usage, at the expense of inspectability; the hasher does not remember what the input features looked like and has no `inverse_transform` method.

Since the hash function might cause collisions between (unrelated) features, a signed hash function is used and the sign of the hash value determines the sign of the value stored in the output matrix for a feature. This way, collisions are likely to cancel out rather than accumulate error, and the expected mean of any output feature's value is zero. This mechanism is enabled by default with `alternate_sign=True` and is particularly useful for small hash table sizes (`n_features < 10000`). For large hash table sizes, it can be disabled, to allow the output to be passed to estimators like *`sklearn.naive_bayes.MultinomialNB`* or *`sklearn.feature_selection.chi2`* feature selectors that expect non-negative inputs.

`FeatureHasher` accepts either mappings (like Python's `dict` and its variants in the `collections` module), `(feature, value)` pairs, or strings, depending on the constructor parameter `input_type`. Mapping are treated as lists of `(feature, value)` pairs, while single strings have an implicit value of 1, so `['feat1', 'feat2', 'feat3']` is interpreted as `[('feat1', 1), ('feat2', 1), ('feat3', 1)]`. If a single feature occurs multiple times in a sample, the associated values will be summed (so `('feat', 2)` and `('feat', 3.5)` become `('feat', 5.5)`). The output from *`FeatureHasher`* is always a `scipy.sparse` matrix in the CSR format.

Feature hashing can be employed in document classification, but unlike *`text.CountVectorizer`*, *`FeatureHasher`* does not do word splitting or any other preprocessing except Unicode-to-UTF-8 encoding; see *Vectorizing a large text corpus with the hashing trick*, below, for a combined tokenizer/hasher.

As an example, consider a word-level natural language processing task that needs features extracted from `(token, part_of_speech)` pairs. One could use a Python generator function to extract features:

```
def token_features(token, part_of_speech):
    if token.isdigit():
        yield "numeric"
    else:
        yield "token={}".format(token.lower())
        yield "token,pos={},{}".format(token, part_of_speech)
    if token[0].isupper():
        yield "uppercase_initial"
    if token.isupper():
        yield "all_uppercase"
    yield "pos={}".format(part_of_speech)
```

Then, the `raw_X` to be fed to `FeatureHasher.transform` can be constructed using:

```
raw_X = (token_features(tok, pos_tagger(tok)) for tok in corpus)
```

and fed to a hasher with:

```
hasher = FeatureHasher(input_type='string')
X = hasher.transform(raw_X)
```

to get a `scipy.sparse` matrix `X`.

Note the use of a generator comprehension, which introduces laziness into the feature extraction: tokens are only processed on demand from the hasher.

Implementation details

FeatureHasher uses the signed 32-bit variant of MurmurHash3. As a result (and because of limitations in `scipy.sparse`), the maximum number of features supported is currently $2^{31} - 1$.

The original formulation of the hashing trick by Weinberger et al. used two separate hash functions h and ξ to determine the column index and sign of a feature, respectively. The present implementation works under the assumption that the sign bit of MurmurHash3 is independent of its other bits.

Since a simple modulo is used to transform the hash function to a column index, it is advisable to use a power of two as the `n_features` parameter; otherwise the features will not be mapped evenly to the columns.

Text feature extraction

The Bag of Words representation

Text Analysis is a major application field for machine learning algorithms. However the raw data, a sequence of symbols cannot be fed directly to the algorithms themselves as most of them expect numerical feature vectors with a fixed size rather than the raw text documents with variable length.

In order to address this, scikit-learn provides utilities for the most common ways to extract numerical features from text content, namely:

- **tokenizing** strings and giving an integer id for each possible token, for instance by using white-spaces and punctuation as token separators.
- **counting** the occurrences of tokens in each document.
- **normalizing** and weighting with diminishing importance tokens that occur in the majority of samples / documents.

In this scheme, features and samples are defined as follows:

- each **individual token occurrence frequency** (normalized or not) is treated as a **feature**.
- the vector of all the token frequencies for a given **document** is considered a multivariate **sample**.

A corpus of documents can thus be represented by a matrix with one row per document and one column per token (e.g. word) occurring in the corpus.

We call **vectorization** the general process of turning a collection of text documents into numerical feature vectors. This specific strategy (tokenization, counting and normalization) is called the **Bag of Words** or "Bag of n-grams" representation. Documents are described by word occurrences while completely ignoring the relative position information of the words in the document.

Sparsity

As most documents will typically use a very small subset of the words used in the corpus, the resulting matrix will have many feature values that are zeros (typically more than 99% of them).

For instance a collection of 10,000 short text documents (such as emails) will use a vocabulary with a size in the order of 100,000 unique words in total while each document will use 100 to 1000 unique words individually.

In order to be able to store such a matrix in memory but also to speed up algebraic operations matrix / vector, implementations will typically use a sparse representation such as the implementations available in the `scipy.sparse` package.

Common Vectorizer usage

`CountVectorizer` implements both tokenization and occurrence counting in a single class:

```
>>> from sklearn.feature_extraction.text import CountVectorizer
```

This model has many parameters, however the default values are quite reasonable (please see the *reference documentation* for the details):

```
>>> vectorizer = CountVectorizer()
>>> vectorizer
CountVectorizer()
```

Let's use it to tokenize and count the word occurrences of a minimalistic corpus of text documents:

```
>>> corpus = [
...     'This is the first document.',
...     'This is the second second document.',
...     'And the third one.',
...     'Is this the first document?',
... ]
>>> X = vectorizer.fit_transform(corpus)
>>> X
<4x9 sparse matrix of type '<... 'numpy.int64'>'
    with 19 stored elements in Compressed Sparse ... format>
```

The default configuration tokenizes the string by extracting words of at least 2 letters. The specific function that does this step can be requested explicitly:

```
>>> analyze = vectorizer.build_analyzer()
>>> analyze("This is a text document to analyze.") == (
...     ['this', 'is', 'text', 'document', 'to', 'analyze'])
True
```

Each term found by the analyzer during the fit is assigned a unique integer index corresponding to a column in the resulting matrix. This interpretation of the columns can be retrieved as follows:

```
>>> vectorizer.get_feature_names() == (
...     ['and', 'document', 'first', 'is', 'one',
...      'second', 'the', 'third', 'this'])
True

>>> X.toarray()
array([[0, 1, 1, 1, 0, 0, 1, 0, 1],
       [0, 1, 0, 1, 0, 2, 1, 0, 1],
       [1, 0, 0, 0, 1, 0, 1, 1, 0],
       [0, 1, 1, 1, 0, 0, 1, 0, 1]]...)
```

The converse mapping from feature name to column index is stored in the `vocabulary_` attribute of the vectorizer:

```
>>> vectorizer.vocabulary_.get('document')
1
```

Hence words that were not seen in the training corpus will be completely ignored in future calls to the transform method:

```
>>> vectorizer.transform(['Something completely new.']).toarray()
array([[0, 0, 0, 0, 0, 0, 0, 0]]...)
```

Note that in the previous corpus, the first and the last documents have exactly the same words hence are encoded in equal vectors. In particular we lose the information that the last document is an interrogative form. To preserve some of the local ordering information we can extract 2-grams of words in addition to the 1-grams (individual words):

```
>>> bigram_vectorizer = CountVectorizer(ngram_range=(1, 2),
...                                     token_pattern=r'\b\w+\b', min_df=1)
>>> analyze = bigram_vectorizer.build_analyzer()
>>> analyze('Bi-grams are cool!') == (
...     ['bi', 'grams', 'are', 'cool', 'bi grams', 'grams are', 'are cool'])
True
```

The vocabulary extracted by this vectorizer is hence much bigger and can now resolve ambiguities encoded in local positioning patterns:

```
>>> X_2 = bigram_vectorizer.fit_transform(corpus).toarray()
>>> X_2
array([[0, 0, 1, 1, 1, 1, 1, 0, 0, 0, 0, 0, 1, 1, 0, 0, 0, 0, 1, 1, 0],
       [0, 0, 1, 0, 0, 1, 1, 0, 0, 2, 1, 1, 1, 0, 1, 0, 0, 0, 1, 1, 0],
       [1, 1, 0, 0, 0, 0, 0, 0, 1, 0, 0, 0, 1, 0, 0, 1, 1, 1, 0, 0, 0],
       [0, 0, 1, 1, 1, 1, 0, 1, 0, 0, 0, 0, 1, 1, 0, 0, 0, 0, 1, 0, 1]]...)
```

In particular the interrogative form “Is this” is only present in the last document:

```
>>> feature_index = bigram_vectorizer.vocabulary_.get('is this')
>>> X_2[:, feature_index]
array([0, 0, 0, 1]...)
```

Using stop words

Stop words are words like “and”, “the”, “him”, which are presumed to be uninformative in representing the content of a text, and which may be removed to avoid them being construed as signal for prediction. Sometimes, however, similar words are useful for prediction, such as in classifying writing style or personality.

There are several known issues in our provided 'english' stop word list. It does not aim to be a general, 'one-size-fits-all' solution as some tasks may require a more custom solution. See [NQY18] for more details.

Please take care in choosing a stop word list. Popular stop word lists may include words that are highly informative to some tasks, such as *computer*.

You should also make sure that the stop word list has had the same preprocessing and tokenization applied as the one used in the vectorizer. The word *we've* is split into *we* and *ve* by CountVectorizer's default tokenizer, so if *we've* is in `stop_words`, but *ve* is not, *ve* will be retained from *we've* in transformed text. Our vectorizers will try to identify and warn about some kinds of inconsistencies.

Tf–idf term weighting

In a large text corpus, some words will be very present (e.g. "the", "a", "is" in English) hence carrying very little meaningful information about the actual contents of the document. If we were to feed the direct count data directly to a classifier those very frequent terms would shadow the frequencies of rarer yet more interesting terms.

In order to re-weight the count features into floating point values suitable for usage by a classifier it is very common to use the tf–idf transform.

Tf means **term-frequency** while tf–idf means term-frequency times **inverse document-frequency**: tf-idf(t,d) $=$ tf(t,d) $\times$ idf(t).

Using the `TfidfTransformer`'s default settings, `TfidfTransformer(norm='l2', use_idf=True, smooth_idf=True, sublinear_tf=False)` the term frequency, the number of times a term occurs in a given document, is multiplied with idf component, which is computed as

$\text{idf}(t) = \log \frac{1+n}{1+\text{df}(t)} + 1,$

where n is the total number of documents in the document set, and $\text{df}(t)$ is the number of documents in the document set that contain term t. The resulting tf-idf vectors are then normalized by the Euclidean norm:

$v_{norm} = \frac{v}{||v||_2} = \frac{v}{\sqrt{{v_1}^2 + {v_2}^2 + \cdots + {v_n}^2}}.$

This was originally a term weighting scheme developed for information retrieval (as a ranking function for search engines results) that has also found good use in document classification and clustering.

The following sections contain further explanations and examples that illustrate how the tf-idfs are computed exactly and how the tf-idfs computed in scikit-learn's *TfidfTransformer* and *TfidfVectorizer* differ slightly from the standard textbook notation that defines the idf as

$\text{idf}(t) = \log \frac{n}{1+\text{df}(t)}.$

In the *TfidfTransformer* and *TfidfVectorizer* with `smooth_idf=False`, the "1" count is added to the idf instead of the idf's denominator:

$\text{idf}(t) = \log \frac{n}{\text{df}(t)} + 1$

This normalization is implemented by the *TfidfTransformer* class:

```
>>> from sklearn.feature_extraction.text import TfidfTransformer
>>> transformer = TfidfTransformer(smooth_idf=False)
>>> transformer
TfidfTransformer(smooth_idf=False)
```

Again please see the *reference documentation* for the details on all the parameters.

Let's take an example with the following counts. The first term is present 100% of the time hence not very interesting. The two other features only in less than 50% of the time hence probably more representative of the content of the documents:

```
>>> counts = [[3, 0, 1],
...           [2, 0, 0],
...           [3, 0, 0],
...           [4, 0, 0],
...           [3, 2, 0],
...           [3, 0, 2]]
...
>>> tfidf = transformer.fit_transform(counts)
>>> tfidf
<6x3 sparse matrix of type '<... 'numpy.float64'>'
    with 9 stored elements in Compressed Sparse ... format>

>>> tfidf.toarray()
array([[0.81940995, 0.        , 0.57320793],
       [1.        , 0.        , 0.        ],
       [1.        , 0.        , 0.        ],
       [1.        , 0.        , 0.        ],
       [0.47330339, 0.88089948, 0.        ],
       [0.58149261, 0.        , 0.81355169]])
```

Each row is normalized to have unit Euclidean norm:

$v_{norm} = \frac{v}{||v||_2} = \frac{v}{\sqrt{v_1{}^2 + v_2{}^2 + \cdots + v_n{}^2}}$

For example, we can compute the tf-idf of the first term in the first document in the `counts` array as follows:

$n = 6$

$\text{df}(t)_{\text{term1}} = 6$

$\text{idf}(t)_{\text{term1}} = \log \frac{n}{\text{df}(t)} + 1 = \log(1) + 1 = 1$

$\text{tf-idf}_{\text{term1}} = \text{tf} \times \text{idf} = 3 \times 1 = 3$

Now, if we repeat this computation for the remaining 2 terms in the document, we get

$\text{tf-idf}_{\text{term2}} = 0 \times (\log(6/1) + 1) = 0$

$\text{tf-idf}_{\text{term3}} = 1 \times (\log(6/2) + 1) \approx 2.0986$

and the vector of raw tf-idfs:

$\text{tf-idf}_{\text{raw}} = [3, 0, 2.0986]$.

Then, applying the Euclidean (L2) norm, we obtain the following tf-idfs for document 1:

$\frac{[3, 0, 2.0986]}{\sqrt{\left(3^2 + 0^2 + 2.0986^2\right)}} = [0.819, 0, 0.573]$.

Furthermore, the default parameter `smooth_idf=True` adds "1" to the numerator and denominator as if an extra document was seen containing every term in the collection exactly once, which prevents zero divisions:

$\text{idf}(t) = \log \frac{1+n}{1+\text{df}(t)} + 1$

Using this modification, the tf-idf of the third term in document 1 changes to 1.8473:

$\text{tf-idf}_{\text{term3}} = 1 \times \log(7/3) + 1 \approx 1.8473$

And the L2-normalized tf-idf changes to

$\frac{[3,0,1.8473]}{\sqrt{\left(3^2+0^2+1.8473^2\right)}} = [0.8515, 0, 0.5243]$:

```
>>> transformer = TfidfTransformer()
>>> transformer.fit_transform(counts).toarray()
array([[0.85151335, 0.        , 0.52433293],
       [1.        , 0.        , 0.        ],
       [1.        , 0.        , 0.        ],
       [1.        , 0.        , 0.        ],
       [0.55422893, 0.83236428, 0.        ],
       [0.63035731, 0.        , 0.77630514]])
```

The weights of each feature computed by the `fit` method call are stored in a model attribute:

```
>>> transformer.idf_
array([1. ..., 2.25..., 1.84...])
```

As tf–idf is very often used for text features, there is also another class called *`TfidfVectorizer`* that combines all the options of *`CountVectorizer`* and *`TfidfTransformer`* in a single model:

```
>>> from sklearn.feature_extraction.text import TfidfVectorizer
>>> vectorizer = TfidfVectorizer()
>>> vectorizer.fit_transform(corpus)
<4x9 sparse matrix of type '<... 'numpy.float64'>'
    with 19 stored elements in Compressed Sparse ... format>
```

While the tf–idf normalization is often very useful, there might be cases where the binary occurrence markers might offer better features. This can be achieved by using the `binary` parameter of *`CountVectorizer`*. In particular, some estimators such as *Bernoulli Naive Bayes* explicitly model discrete boolean random variables. Also, very short texts are likely to have noisy tf–idf values while the binary occurrence info is more stable.

As usual the best way to adjust the feature extraction parameters is to use a cross-validated grid search, for instance by pipelining the feature extractor with a classifier:

- *Sample pipeline for text feature extraction and evaluation*

Decoding text files

Text is made of characters, but files are made of bytes. These bytes represent characters according to some *encoding*. To work with text files in Python, their bytes must be *decoded* to a character set called Unicode. Common encodings are ASCII, Latin-1 (Western Europe), KOI8-R (Russian) and the universal encodings UTF-8 and UTF-16. Many others exist.

Note: An encoding can also be called a 'character set', but this term is less accurate: several encodings can exist for a single character set.

The text feature extractors in scikit-learn know how to decode text files, but only if you tell them what encoding the files are in. The *`CountVectorizer`* takes an `encoding` parameter for this purpose. For modern text files, the correct encoding is probably UTF-8, which is therefore the default (`encoding="utf-8"`).

If the text you are loading is not actually encoded with UTF-8, however, you will get a `UnicodeDecodeError`. The vectorizers can be told to be silent about decoding errors by setting the `decode_error` parameter to either `"ignore"` or `"replace"`. See the documentation for the Python function `bytes.decode` for more details (type `help(bytes.decode)` at the Python prompt).

If you are having trouble decoding text, here are some things to try:

- Find out what the actual encoding of the text is. The file might come with a header or README that tells you the encoding, or there might be some standard encoding you can assume based on where the text comes from.
- You may be able to find out what kind of encoding it is in general using the UNIX command `file`. The Python `chardet` module comes with a script called `chardetect.py` that will guess the specific encoding, though you cannot rely on its guess being correct.
- You could try UTF-8 and disregard the errors. You can decode byte strings with `bytes.decode(errors='replace')` to replace all decoding errors with a meaningless character, or set `decode_error='replace'` in the vectorizer. This may damage the usefulness of your features.
- Real text may come from a variety of sources that may have used different encodings, or even be sloppily decoded in a different encoding than the one it was encoded with. This is common in text retrieved from the Web. The Python package ftfy can automatically sort out some classes of decoding errors, so you could try decoding the unknown text as `latin-1` and then using `ftfy` to fix errors.
- If the text is in a mish-mash of encodings that is simply too hard to sort out (which is the case for the 20 Newsgroups dataset), you can fall back on a simple single-byte encoding such as `latin-1`. Some text may display incorrectly, but at least the same sequence of bytes will always represent the same feature.

For example, the following snippet uses `chardet` (not shipped with scikit-learn, must be installed separately) to figure out the encoding of three texts. It then vectorizes the texts and prints the learned vocabulary. The output is not shown here.

```
>>> import chardet    # doctest: +SKIP
>>> text1 = b"Sei mir gegr\xc3\xbc\xc3\x9ft mein Sauerkraut"
>>> text2 = b"holdselig sind deine Ger\xfcche"
>>> text3 = b"\xff\xfeA\x00u\x00f\x00 \x00F\x00l\x00\xfc\x00g\x00e\x00l\x00n\x00␣
↪\x00d\x00e\x00s\x00 \x00G\x00e\x00s\x00a\x00n\x00g\x00e\x00s\x00,\x00␣
↪\x00H\x00e\x00r\x00z\x00l\x00i\x00e\x00b\x00c\x00h\x00e\x00n\x00,\x00␣
↪\x00t\x00r\x00a\x00g\x00 \x00i\x00c\x00h\x00 \x00d\x00i\x00c\x00h\x00␣
↪\x00f\x00o\x00r\x00t\x00"
>>> decoded = [x.decode(chardet.detect(x)['encoding'])
...            for x in (text1, text2, text3)]        # doctest: +SKIP
>>> v = CountVectorizer().fit(decoded).vocabulary_    # doctest: +SKIP
>>> for term in v: print(v)                           # doctest: +SKIP
```

(Depending on the version of `chardet`, it might get the first one wrong.)

For an introduction to Unicode and character encodings in general, see Joel Spolsky's Absolute Minimum Every Software Developer Must Know About Unicode.

Applications and examples

The bag of words representation is quite simplistic but surprisingly useful in practice.

In particular in a **supervised setting** it can be successfully combined with fast and scalable linear models to train **document classifiers**, for instance:

- *Classification of text documents using sparse features*

In an **unsupervised setting** it can be used to group similar documents together by applying clustering algorithms such as *K-means*:

- *Clustering text documents using k-means*

Finally it is possible to discover the main topics of a corpus by relaxing the hard assignment constraint of clustering, for instance by using *Non-negative matrix factorization (NMF or NNMF)*:

- *Topic extraction with Non-negative Matrix Factorization and Latent Dirichlet Allocation*

Limitations of the Bag of Words representation

A collection of unigrams (what bag of words is) cannot capture phrases and multi-word expressions, effectively disregarding any word order dependence. Additionally, the bag of words model doesn't account for potential misspellings or word derivations.

N-grams to the rescue! Instead of building a simple collection of unigrams (n=1), one might prefer a collection of bigrams (n=2), where occurrences of pairs of consecutive words are counted.

One might alternatively consider a collection of character n-grams, a representation resilient against misspellings and derivations.

For example, let's say we're dealing with a corpus of two documents: `['words', 'wprds']`. The second document contains a misspelling of the word 'words'. A simple bag of words representation would consider these two as very distinct documents, differing in both of the two possible features. A character 2-gram representation, however, would find the documents matching in 4 out of 8 features, which may help the preferred classifier decide better:

```
>>> ngram_vectorizer = CountVectorizer(analyzer='char_wb', ngram_range=(2, 2))
>>> counts = ngram_vectorizer.fit_transform(['words', 'wprds'])
>>> ngram_vectorizer.get_feature_names() == (
...     [' w', 'ds', 'or', 'pr', 'rd', 's ', 'wo', 'wp'])
True
>>> counts.toarray().astype(int)
array([[1, 1, 1, 0, 1, 1, 1, 0],
       [1, 1, 0, 1, 1, 1, 0, 1]])
```

In the above example, `char_wb` analyzer is used, which creates n-grams only from characters inside word boundaries (padded with space on each side). The `char` analyzer, alternatively, creates n-grams that span across words:

```
>>> ngram_vectorizer = CountVectorizer(analyzer='char_wb', ngram_range=(5, 5))
>>> ngram_vectorizer.fit_transform(['jumpy fox'])
<1x4 sparse matrix of type '<... 'numpy.int64'>'
   with 4 stored elements in Compressed Sparse ... format>
>>> ngram_vectorizer.get_feature_names() == (
...     [' fox ', ' jump', 'jumpy', 'umpy '])
True

>>> ngram_vectorizer = CountVectorizer(analyzer='char', ngram_range=(5, 5))
>>> ngram_vectorizer.fit_transform(['jumpy fox'])
<1x5 sparse matrix of type '<... 'numpy.int64'>'
    with 5 stored elements in Compressed Sparse ... format>
>>> ngram_vectorizer.get_feature_names() == (
...     ['jumpy', 'mpy f', 'py fo', 'umpy ', 'y fox'])
True
```

The word boundaries-aware variant `char_wb` is especially interesting for languages that use white-spaces for word separation as it generates significantly less noisy features than the raw `char` variant in that case. For such languages it can increase both the predictive accuracy and convergence speed of classifiers trained using such features while retaining the robustness with regards to misspellings and word derivations.

While some local positioning information can be preserved by extracting n-grams instead of individual words, bag of words and bag of n-grams destroy most of the inner structure of the document and hence most of the meaning carried by that internal structure.

In order to address the wider task of Natural Language Understanding, the local structure of sentences and paragraphs should thus be taken into account. Many such models will thus be casted as "Structured output" problems which are currently outside of the scope of scikit-learn.

Vectorizing a large text corpus with the hashing trick

The above vectorization scheme is simple but the fact that it holds an **in- memory mapping from the string tokens to the integer feature indices** (the `vocabulary_` attribute) causes several **problems when dealing with large datasets**:

- the larger the corpus, the larger the vocabulary will grow and hence the memory use too,
- fitting requires the allocation of intermediate data structures of size proportional to that of the original dataset.
- building the word-mapping requires a full pass over the dataset hence it is not possible to fit text classifiers in a strictly online manner.
- pickling and un-pickling vectorizers with a large `vocabulary_` can be very slow (typically much slower than pickling / un-pickling flat data structures such as a NumPy array of the same size),
- it is not easily possible to split the vectorization work into concurrent sub tasks as the `vocabulary_` attribute would have to be a shared state with a fine grained synchronization barrier: the mapping from token string to feature index is dependent on ordering of the first occurrence of each token hence would have to be shared, potentially harming the concurrent workers' performance to the point of making them slower than the sequential variant.

It is possible to overcome those limitations by combining the "hashing trick" (*Feature hashing*) implemented by the *`sklearn.feature_extraction.FeatureHasher`* class and the text preprocessing and tokenization features of the *`CountVectorizer`*.

This combination is implementing in *`HashingVectorizer`*, a transformer class that is mostly API compatible with *`CountVectorizer`*. *`HashingVectorizer`* is stateless, meaning that you don't have to call `fit` on it:

```
>>> from sklearn.feature_extraction.text import HashingVectorizer
>>> hv = HashingVectorizer(n_features=10)
>>> hv.transform(corpus)
<4x10 sparse matrix of type '<... 'numpy.float64'>'
    with 16 stored elements in Compressed Sparse ... format>
```

You can see that 16 non-zero feature tokens were extracted in the vector output: this is less than the 19 non-zeros extracted previously by the *`CountVectorizer`* on the same toy corpus. The discrepancy comes from hash function collisions because of the low value of the `n_features` parameter.

In a real world setting, the `n_features` parameter can be left to its default value of `2 ** 20` (roughly one million possible features). If memory or downstream models size is an issue selecting a lower value such as `2 ** 18` might help without introducing too many additional collisions on typical text classification tasks.

Note that the dimensionality does not affect the CPU training time of algorithms which operate on CSR matrices (`LinearSVC(dual=True)`, `Perceptron`, `SGDClassifier`, `PassiveAggressive`) but it does for algorithms that work with CSC matrices (`LinearSVC(dual=False)`, `Lasso()`, etc).

Let's try again with the default setting:

```
>>> hv = HashingVectorizer()
>>> hv.transform(corpus)
<4x1048576 sparse matrix of type '<... 'numpy.float64'>'
    with 19 stored elements in Compressed Sparse ... format>
```

We no longer get the collisions, but this comes at the expense of a much larger dimensionality of the output space. Of course, other terms than the 19 used here might still collide with each other.

The *`HashingVectorizer`* also comes with the following limitations:

- it is not possible to invert the model (no `inverse_transform` method), nor to access the original string representation of the features, because of the one-way nature of the hash function that performs the mapping.

- it does not provide IDF weighting as that would introduce statefulness in the model. A *TfidfTransformer* can be appended to it in a pipeline if required.

Performing out-of-core scaling with HashingVectorizer

An interesting development of using a *HashingVectorizer* is the ability to perform out-of-core scaling. This means that we can learn from data that does not fit into the computer's main memory.

A strategy to implement out-of-core scaling is to stream data to the estimator in mini-batches. Each mini-batch is vectorized using *HashingVectorizer* so as to guarantee that the input space of the estimator has always the same dimensionality. The amount of memory used at any time is thus bounded by the size of a mini-batch. Although there is no limit to the amount of data that can be ingested using such an approach, from a practical point of view the learning time is often limited by the CPU time one wants to spend on the task.

For a full-fledged example of out-of-core scaling in a text classification task see *Out-of-core classification of text documents*.

Customizing the vectorizer classes

It is possible to customize the behavior by passing a callable to the vectorizer constructor:

```
>>> def my_tokenizer(s):
...     return s.split()
...
>>> vectorizer = CountVectorizer(tokenizer=my_tokenizer)
>>> vectorizer.build_analyzer()(u"Some... punctuation!") == (
...     ['some...', 'punctuation!'])
True
```

In particular we name:

- `preprocessor`: a callable that takes an entire document as input (as a single string), and returns a possibly transformed version of the document, still as an entire string. This can be used to remove HTML tags, lowercase the entire document, etc.
- `tokenizer`: a callable that takes the output from the preprocessor and splits it into tokens, then returns a list of these.
- `analyzer`: a callable that replaces the preprocessor and tokenizer. The default analyzers all call the preprocessor and tokenizer, but custom analyzers will skip this. N-gram extraction and stop word filtering take place at the analyzer level, so a custom analyzer may have to reproduce these steps.

(Lucene users might recognize these names, but be aware that scikit-learn concepts may not map one-to-one onto Lucene concepts.)

To make the preprocessor, tokenizer and analyzers aware of the model parameters it is possible to derive from the class and override the `build_preprocessor`, `build_tokenizer` and `build_analyzer` factory methods instead of passing custom functions.

Some tips and tricks:

- If documents are pre-tokenized by an external package, then store them in files (or strings) with the tokens separated by whitespace and pass `analyzer=str.split`
- Fancy token-level analysis such as stemming, lemmatizing, compound splitting, filtering based on part-of-speech, etc. are not included in the scikit-learn codebase, but can be added by customizing either the tokenizer or the analyzer. Here's a `CountVectorizer` with a tokenizer and lemmatizer using NLTK:

```
>>> from nltk import word_tokenize
>>> from nltk.stem import WordNetLemmatizer
>>> class LemmaTokenizer:
...     def __init__(self):
...         self.wnl = WordNetLemmatizer()
...     def __call__(self, doc):
...         return [self.wnl.lemmatize(t) for t in word_tokenize(doc)]
...
>>> vect = CountVectorizer(tokenizer=LemmaTokenizer())
```

(Note that this will not filter out punctuation.)

The following example will, for instance, transform some British spelling to American spelling:

```
>>> import re
>>> def to_british(tokens):
...     for t in tokens:
...         t = re.sub(r"(...)our$", r"\1or", t)
...         t = re.sub(r"([bt])re$", r"\1er", t)
...         t = re.sub(r"([iy])s(e$|ing|ation)", r"\1z\2", t)
...         t = re.sub(r"ogue$", "og", t)
...         yield t
...
>>> class CustomVectorizer(CountVectorizer):
...     def build_tokenizer(self):
...         tokenize = super().build_tokenizer()
...         return lambda doc: list(to_british(tokenize(doc)))
...
>>> print(CustomVectorizer().build_analyzer()(u"color colour"))
[...'color', ...'color']
```

for other styles of preprocessing; examples include stemming, lemmatization, or normalizing numerical tokens, with the latter illustrated in:

- *Biclustering documents with the Spectral Co-clustering algorithm*

Customizing the vectorizer can also be useful when handling Asian languages that do not use an explicit word separator such as whitespace.

Image feature extraction

Patch extraction

The *extract_patches_2d* function extracts patches from an image stored as a two-dimensional array, or three-dimensional with color information along the third axis. For rebuilding an image from all its patches, use *reconstruct_from_patches_2d*. For example let use generate a 4x4 pixel picture with 3 color channels (e.g. in RGB format):

```
>>> import numpy as np
>>> from sklearn.feature_extraction import image

>>> one_image = np.arange(4 * 4 * 3).reshape((4, 4, 3))
>>> one_image[:, :, 0]  # R channel of a fake RGB picture
array([[ 0,  3,  6,  9],
       [12, 15, 18, 21],
       [24, 27, 30, 33],
```

(continues on next page)

(continued from previous page)

```
       [36, 39, 42, 45]])

>>> patches = image.extract_patches_2d(one_image, (2, 2), max_patches=2,
...     random_state=0)
>>> patches.shape
(2, 2, 2, 3)
>>> patches[:, :, :, 0]
array([[[ 0,  3],
        [12, 15]],

       [[15, 18],
        [27, 30]]])
>>> patches = image.extract_patches_2d(one_image, (2, 2))
>>> patches.shape
(9, 2, 2, 3)
>>> patches[4, :, :, 0]
array([[15, 18],
       [27, 30]])
```

Let us now try to reconstruct the original image from the patches by averaging on overlapping areas:

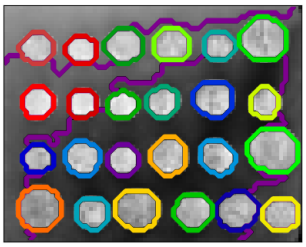
```
>>> reconstructed = image.reconstruct_from_patches_2d(patches, (4, 4, 3))
>>> np.testing.assert_array_equal(one_image, reconstructed)
```

The *PatchExtractor* class works in the same way as *extract_patches_2d*, only it supports multiple images as input. It is implemented as an estimator, so it can be used in pipelines. See:

```
>>> five_images = np.arange(5 * 4 * 4 * 3).reshape(5, 4, 4, 3)
>>> patches = image.PatchExtractor((2, 2)).transform(five_images)
>>> patches.shape
(45, 2, 2, 3)
```

Connectivity graph of an image

Several estimators in the scikit-learn can use connectivity information between features or samples. For instance Ward clustering (*Hierarchical clustering*) can cluster together only neighboring pixels of an image, thus forming contiguous patches:



For this purpose, the estimators use a 'connectivity' matrix, giving which samples are connected.

The function *img_to_graph* returns such a matrix from a 2D or 3D image. Similarly, *grid_to_graph* build a connectivity matrix for images given the shape of these image.

These matrices can be used to impose connectivity in estimators that use connectivity information, such as Ward clustering (*Hierarchical clustering*), but also to build precomputed kernels, or similarity matrices.

Note: Examples

- *A demo of structured Ward hierarchical clustering on an image of coins*
- *Spectral clustering for image segmentation*
- *Feature agglomeration vs. univariate selection*

4.6.3 Preprocessing data

The `sklearn.preprocessing` package provides several common utility functions and transformer classes to change raw feature vectors into a representation that is more suitable for the downstream estimators.

In general, learning algorithms benefit from standardization of the data set. If some outliers are present in the set, robust scalers or transformers are more appropriate. The behaviors of the different scalers, transformers, and normalizers on a dataset containing marginal outliers is highlighted in *Compare the effect of different scalers on data with outliers*.

Standardization, or mean removal and variance scaling

Standardization of datasets is a **common requirement for many machine learning estimators** implemented in scikit-learn; they might behave badly if the individual features do not more or less look like standard normally distributed data: Gaussian with **zero mean and unit variance**.

In practice we often ignore the shape of the distribution and just transform the data to center it by removing the mean value of each feature, then scale it by dividing non-constant features by their standard deviation.

For instance, many elements used in the objective function of a learning algorithm (such as the RBF kernel of Support Vector Machines or the l1 and l2 regularizers of linear models) assume that all features are centered around zero and have variance in the same order. If a feature has a variance that is orders of magnitude larger than others, it might dominate the objective function and make the estimator unable to learn from other features correctly as expected.

The function *scale* provides a quick and easy way to perform this operation on a single array-like dataset:

```
>>> from sklearn import preprocessing
>>> import numpy as np
>>> X_train = np.array([[ 1., -1.,  2.],
...                     [ 2.,  0.,  0.],
...                     [ 0.,  1., -1.]])
>>> X_scaled = preprocessing.scale(X_train)

>>> X_scaled
array([[ 0.  ..., -1.22...,  1.33...],
       [ 1.22...,  0.  ..., -0.26...],
       [-1.22...,  1.22..., -1.06...]])
```

Scaled data has zero mean and unit variance:

```
>>> X_scaled.mean(axis=0)
array([0., 0., 0.])

>>> X_scaled.std(axis=0)
array([1., 1., 1.])
```

The `preprocessing` module further provides a utility class *StandardScaler* that implements the `Transformer` API to compute the mean and standard deviation on a training set so as to be able to later reapply the same transformation on the testing set. This class is hence suitable for use in the early steps of a *sklearn.pipeline.Pipeline*:

```
>>> scaler = preprocessing.StandardScaler().fit(X_train)
>>> scaler
StandardScaler()

>>> scaler.mean_
array([1. ..., 0. ..., 0.33...])

>>> scaler.scale_
array([0.81..., 0.81..., 1.24...])

>>> scaler.transform(X_train)
array([[ 0.  ..., -1.22...,  1.33...],
       [ 1.22...,  0.  ..., -0.26...],
       [-1.22...,  1.22..., -1.06...]])
```

The scaler instance can then be used on new data to transform it the same way it did on the training set:

```
>>> X_test = [[-1., 1., 0.]]
>>> scaler.transform(X_test)
array([[-2.44...,  1.22..., -0.26...]])
```

It is possible to disable either centering or scaling by either passing `with_mean=False` or `with_std=False` to the constructor of *StandardScaler*.

Scaling features to a range

An alternative standardization is scaling features to lie between a given minimum and maximum value, often between zero and one, or so that the maximum absolute value of each feature is scaled to unit size. This can be achieved using *MinMaxScaler* or *MaxAbsScaler*, respectively.

The motivation to use this scaling include robustness to very small standard deviations of features and preserving zero entries in sparse data.

Here is an example to scale a toy data matrix to the `[0, 1]` range:

```
>>> X_train = np.array([[ 1., -1.,  2.],
...                     [ 2.,  0.,  0.],
...                     [ 0.,  1., -1.]])
...
>>> min_max_scaler = preprocessing.MinMaxScaler()
>>> X_train_minmax = min_max_scaler.fit_transform(X_train)
>>> X_train_minmax
array([[0.5       , 0.        , 1.        ],
       [1.        , 0.5       , 0.33333333],
       [0.        , 1.        , 0.        ]])
```

The same instance of the transformer can then be applied to some new test data unseen during the fit call: the same scaling and shifting operations will be applied to be consistent with the transformation performed on the train data:

```
>>> X_test = np.array([[-3., -1.,  4.]])
>>> X_test_minmax = min_max_scaler.transform(X_test)
```

(continues on next page)

(continued from previous page)

```
>>> X_test_minmax
array([[-1.5       ,  0.        ,  1.66666667]])
```

It is possible to introspect the scaler attributes to find about the exact nature of the transformation learned on the training data:

```
>>> min_max_scaler.scale_
array([0.5       , 0.5       , 0.33...])

>>> min_max_scaler.min_
array([0.        , 0.5       , 0.33...])
```

If *MinMaxScaler* is given an explicit `feature_range=(min, max)` the full formula is:

```
X_std = (X - X.min(axis=0)) / (X.max(axis=0) - X.min(axis=0))

X_scaled = X_std * (max - min) + min
```

MaxAbsScaler works in a very similar fashion, but scales in a way that the training data lies within the range `[-1, 1]` by dividing through the largest maximum value in each feature. It is meant for data that is already centered at zero or sparse data.

Here is how to use the toy data from the previous example with this scaler:

```
>>> X_train = np.array([[ 1., -1.,  2.],
...                     [ 2.,  0.,  0.],
...                     [ 0.,  1., -1.]])
...
>>> max_abs_scaler = preprocessing.MaxAbsScaler()
>>> X_train_maxabs = max_abs_scaler.fit_transform(X_train)
>>> X_train_maxabs
array([[ 0.5, -1. ,  1. ],
       [ 1. ,  0. ,  0. ],
       [ 0. ,  1. , -0.5]])
>>> X_test = np.array([[ -3., -1.,  4.]])
>>> X_test_maxabs = max_abs_scaler.transform(X_test)
>>> X_test_maxabs
array([[-1.5, -1. ,  2. ]])
>>> max_abs_scaler.scale_
array([2.,  1.,  2.])
```

As with *scale*, the module further provides convenience functions *minmax_scale* and *maxabs_scale* if you don't want to create an object.

Scaling sparse data

Centering sparse data would destroy the sparseness structure in the data, and thus rarely is a sensible thing to do. However, it can make sense to scale sparse inputs, especially if features are on different scales.

MaxAbsScaler and *maxabs_scale* were specifically designed for scaling sparse data, and are the recommended way to go about this. However, *scale* and *StandardScaler* can accept `scipy.sparse` matrices as input, as long as `with_mean=False` is explicitly passed to the constructor. Otherwise a `ValueError` will be raised as silently centering would break the sparsity and would often crash the execution by allocating excessive amounts of memory unintentionally. *RobustScaler* cannot be fitted to sparse inputs, but you can use the `transform` method on sparse inputs.

Note that the scalers accept both Compressed Sparse Rows and Compressed Sparse Columns format (see `scipy.sparse.csr_matrix` and `scipy.sparse.csc_matrix`). Any other sparse input will be **converted to the Compressed Sparse Rows representation**. To avoid unnecessary memory copies, it is recommended to choose the CSR or CSC representation upstream.

Finally, if the centered data is expected to be small enough, explicitly converting the input to an array using the `toarray` method of sparse matrices is another option.

Scaling data with outliers

If your data contains many outliers, scaling using the mean and variance of the data is likely to not work very well. In these cases, you can use *`robust_scale`* and *`RobustScaler`* as drop-in replacements instead. They use more robust estimates for the center and range of your data.

References:

Further discussion on the importance of centering and scaling data is available on this FAQ: Should I normalize/standardize/rescale the data?

Scaling vs Whitening

It is sometimes not enough to center and scale the features independently, since a downstream model can further make some assumption on the linear independence of the features.

To address this issue you can use *`sklearn.decomposition.PCA`* with `whiten=True` to further remove the linear correlation across features.

Scaling a 1D array

All above functions (i.e. *`scale`*, *`minmax_scale`*, *`maxabs_scale`*, and *`robust_scale`*) accept 1D array which can be useful in some specific case.

Centering kernel matrices

If you have a kernel matrix of a kernel K that computes a dot product in a feature space defined by function ϕ, a *`KernelCenterer`* can transform the kernel matrix so that it contains inner products in the feature space defined by ϕ followed by removal of the mean in that space.

Non-linear transformation

Two types of transformations are available: quantile transforms and power transforms. Both quantile and power transforms are based on monotonic transformations of the features and thus preserve the rank of the values along each feature.

Quantile transforms put all features into the same desired distribution based on the formula $G^{-1}(F(X))$ where F is the cumulative distribution function of the feature and G^{-1} the quantile function of the desired output distribution G. This formula is using the two following facts: (i) if X is a random variable with a continuous cumulative distribution function F then $F(X)$ is uniformly distributed on $[0, 1]$; (ii) if U is a random variable with uniform distribution on $[0, 1]$ then $G^{-1}(U)$ has distribution G. By performing a rank transformation, a quantile transform smooths out unusual

distributions and is less influenced by outliers than scaling methods. It does, however, distort correlations and distances within and across features.

Power transforms are a family of parametric transformations that aim to map data from any distribution to as close to a Gaussian distribution.

Mapping to a Uniform distribution

QuantileTransformer and *quantile_transform* provide a non-parametric transformation to map the data to a uniform distribution with values between 0 and 1:

```
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split
>>> X, y = load_iris(return_X_y=True)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
>>> quantile_transformer = preprocessing.QuantileTransformer(random_state=0)
>>> X_train_trans = quantile_transformer.fit_transform(X_train)
>>> X_test_trans = quantile_transformer.transform(X_test)
>>> np.percentile(X_train[:, 0], [0, 25, 50, 75, 100])
array([ 4.3,  5.1,  5.8,  6.5,  7.9])
```

This feature corresponds to the sepal length in cm. Once the quantile transformation applied, those landmarks approach closely the percentiles previously defined:

```
>>> np.percentile(X_train_trans[:, 0], [0, 25, 50, 75, 100])
...
array([ 0.00... ,  0.24...,  0.49...,  0.73...,  0.99... ])
```

This can be confirmed on a independent testing set with similar remarks:

```
>>> np.percentile(X_test[:, 0], [0, 25, 50, 75, 100])
...
array([ 4.4  ,  5.125,  5.75 ,  6.175,  7.3  ])
>>> np.percentile(X_test_trans[:, 0], [0, 25, 50, 75, 100])
...
array([ 0.01...,  0.25...,  0.46...,  0.60... ,  0.94...])
```

Mapping to a Gaussian distribution

In many modeling scenarios, normality of the features in a dataset is desirable. Power transforms are a family of parametric, monotonic transformations that aim to map data from any distribution to as close to a Gaussian distribution as possible in order to stabilize variance and minimize skewness.

PowerTransformer currently provides two such power transformations, the Yeo-Johnson transform and the Box-Cox transform.

The Yeo-Johnson transform is given by:

$$x_i^{(\lambda)} = \begin{cases} [(x_i + 1)^\lambda - 1]/\lambda & \text{if } \lambda \neq 0, x_i \geq 0, \\ \ln(x_i + 1) & \text{if } \lambda = 0, x_i \geq 0 \\ -[(-x_i + 1)^{2-\lambda} - 1]/(2 - \lambda) & \text{if } \lambda \neq 2, x_i < 0, \\ -\ln(-x_i + 1) & \text{if } \lambda = 2, x_i < 0 \end{cases}$$

while the Box-Cox transform is given by:

$$x_i^{(\lambda)} = \begin{cases} \dfrac{x_i^\lambda - 1}{\lambda} & \text{if } \lambda \neq 0, \\ \ln(x_i) & \text{if } \lambda = 0, \end{cases}$$

Box-Cox can only be applied to strictly positive data. In both methods, the transformation is parameterized by λ, which is determined through maximum likelihood estimation. Here is an example of using Box-Cox to map samples drawn from a lognormal distribution to a normal distribution:

```
>>> pt = preprocessing.PowerTransformer(method='box-cox', standardize=False)
>>> X_lognormal = np.random.RandomState(616).lognormal(size=(3, 3))
>>> X_lognormal
array([[1.28..., 1.18..., 0.84...],
       [0.94..., 1.60..., 0.38...],
       [1.35..., 0.21..., 1.09...]])
>>> pt.fit_transform(X_lognormal)
array([[ 0.49...,  0.17..., -0.15...],
       [-0.05...,  0.58..., -0.57...],
       [ 0.69..., -0.84...,  0.10...]])
```

While the above example sets the `standardize` option to `False`, *`PowerTransformer`* will apply zero-mean, unit-variance normalization to the transformed output by default.

Below are examples of Box-Cox and Yeo-Johnson applied to various probability distributions. Note that when applied to certain distributions, the power transforms achieve very Gaussian-like results, but with others, they are ineffective. This highlights the importance of visualizing the data before and after transformation.

It is also possible to map data to a normal distribution using *`QuantileTransformer`* by setting `output_distribution='normal'`. Using the earlier example with the iris dataset:

```
>>> quantile_transformer = preprocessing.QuantileTransformer(
...     output_distribution='normal', random_state=0)
>>> X_trans = quantile_transformer.fit_transform(X)
>>> quantile_transformer.quantiles_
array([[4.3, 2. , 1. , 0.1],
       [4.4, 2.2, 1.1, 0.1],
       [4.4, 2.2, 1.2, 0.1],
       ...,
       [7.7, 4.1, 6.7, 2.5],
       [7.7, 4.2, 6.7, 2.5],
       [7.9, 4.4, 6.9, 2.5]])
```

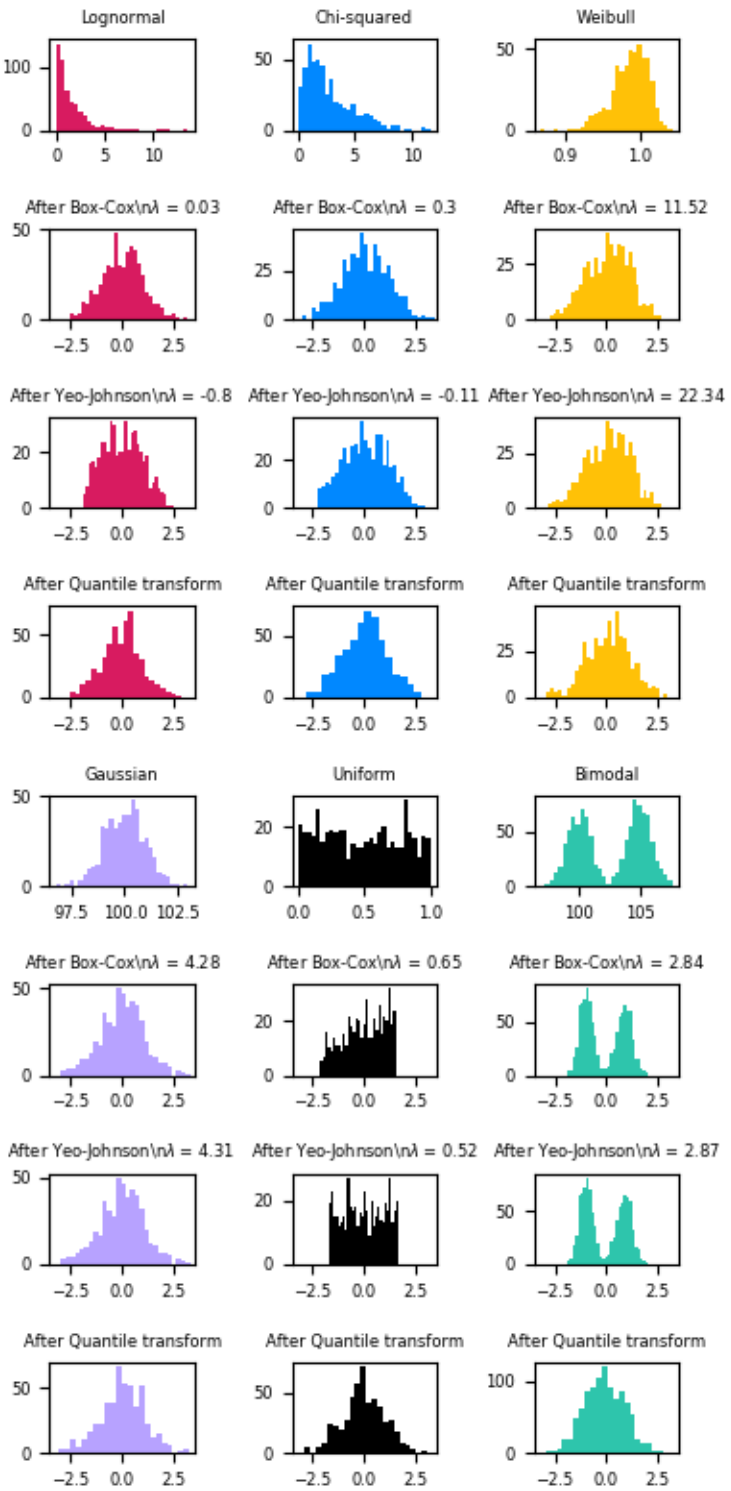
Thus the median of the input becomes the mean of the output, centered at 0. The normal output is clipped so that the input's minimum and maximum — corresponding to the 1e-7 and 1 - 1e-7 quantiles respectively — do not become infinite under the transformation.

Normalization

Normalization is the process of **scaling individual samples to have unit norm**. This process can be useful if you plan to use a quadratic form such as the dot-product or any other kernel to quantify the similarity of any pair of samples.

This assumption is the base of the Vector Space Model often used in text classification and clustering contexts.

The function *`normalize`* provides a quick and easy way to perform this operation on a single array-like dataset, either using the `l1` or `l2` norms:



Lognormal
Chi-squared
Weibull
After Box-Cox\nλ = 0.03
After Box-Cox\nλ = 0.3
After Box-Cox\nλ = 11.52
After Yeo-Johnson\nλ = -0.8
After Yeo-Johnson\nλ = -0.11
After Yeo-Johnson\nλ = 22.34
After Quantile transform
After Quantile transform
After Quantile transform
Gaussian
Uniform
Bimodal
After Box-Cox\nλ = 4.28
After Box-Cox\nλ = 0.65
After Box-Cox\nλ = 2.84
After Yeo-Johnson\nλ = 4.31
After Yeo-Johnson\nλ = 0.52
After Yeo-Johnson\nλ = 2.87
After Quantile transform
After Quantile transform
After Quantile transform

```
>>> X = [[ 1., -1.,  2.],
...      [ 2.,  0.,  0.],
...      [ 0.,  1., -1.]]
>>> X_normalized = preprocessing.normalize(X, norm='l2')

>>> X_normalized
array([[ 0.40..., -0.40...,  0.81...],
       [ 1.  ...,  0.  ...,  0.  ...],
       [ 0.  ...,  0.70..., -0.70...]])
```

The `preprocessing` module further provides a utility class *`Normalizer`* that implements the same operation using the `Transformer` API (even though the `fit` method is useless in this case: the class is stateless as this operation treats samples independently).

This class is hence suitable for use in the early steps of a *`sklearn.pipeline.Pipeline`*:

```
>>> normalizer = preprocessing.Normalizer().fit(X)  # fit does nothing
>>> normalizer
Normalizer()
```

The normalizer instance can then be used on sample vectors as any transformer:

```
>>> normalizer.transform(X)
array([[ 0.40..., -0.40...,  0.81...],
       [ 1.  ...,  0.  ...,  0.  ...],
       [ 0.  ...,  0.70..., -0.70...]])

>>> normalizer.transform([[-1.,  1., 0.]])
array([[-0.70...,  0.70...,  0.  ...]])
```

Note: L2 normalization is also known as spatial sign preprocessing.

Sparse input

`normalize` and *`Normalizer`* accept **both dense array-like and sparse matrices from scipy.sparse as input**.

For sparse input the data is **converted to the Compressed Sparse Rows representation** (see `scipy.sparse.csr_matrix`) before being fed to efficient Cython routines. To avoid unnecessary memory copies, it is recommended to choose the CSR representation upstream.

Encoding categorical features

Often features are not given as continuous values but categorical. For example a person could have features `["male", "female"]`, `["from Europe", "from US", "from Asia"]`, `["uses Firefox", "uses Chrome", "uses Safari", "uses Internet Explorer"]`. Such features can be efficiently coded as integers, for instance `["male", "from US", "uses Internet Explorer"]` could be expressed as `[0, 1, 3]` while `["female", "from Asia", "uses Chrome"]` would be `[1, 2, 1]`.

To convert categorical features to such integer codes, we can use the *`OrdinalEncoder`*. This estimator transforms each categorical feature to one new feature of integers (0 to n_categories - 1):

```
>>> enc = preprocessing.OrdinalEncoder()
>>> X = [['male', 'from US', 'uses Safari'], ['female', 'from Europe', 'uses Firefox
↪']]
```

(continues on next page)

(continued from previous page)

```
>>> enc.fit(X)
OrdinalEncoder()
>>> enc.transform([['female', 'from US', 'uses Safari']])
array([[0., 1., 1.]])
```

Such integer representation can, however, not be used directly with all scikit-learn estimators, as these expect continuous input, and would interpret the categories as being ordered, which is often not desired (i.e. the set of browsers was ordered arbitrarily).

Another possibility to convert categorical features to features that can be used with scikit-learn estimators is to use a one-of-K, also known as one-hot or dummy encoding. This type of encoding can be obtained with the *OneHotEncoder*, which transforms each categorical feature with `n_categories` possible values into `n_categories` binary features, with one of them 1, and all others 0.

Continuing the example above:

```
>>> enc = preprocessing.OneHotEncoder()
>>> X = [['male', 'from US', 'uses Safari'], ['female', 'from Europe', 'uses Firefox
↪']]
>>> enc.fit(X)
OneHotEncoder()
>>> enc.transform([['female', 'from US', 'uses Safari'],
...                ['male', 'from Europe', 'uses Safari']]).toarray()
array([[1., 0., 0., 1., 0., 1.],
       [0., 1., 1., 0., 0., 1.]])
```

By default, the values each feature can take is inferred automatically from the dataset and can be found in the `categories_` attribute:

```
>>> enc.categories_
[array(['female', 'male'], dtype=object), array(['from Europe', 'from US'],␣
↪dtype=object), array(['uses Firefox', 'uses Safari'], dtype=object)]
```

It is possible to specify this explicitly using the parameter `categories`. There are two genders, four possible continents and four web browsers in our dataset:

```
>>> genders = ['female', 'male']
>>> locations = ['from Africa', 'from Asia', 'from Europe', 'from US']
>>> browsers = ['uses Chrome', 'uses Firefox', 'uses IE', 'uses Safari']
>>> enc = preprocessing.OneHotEncoder(categories=[genders, locations, browsers])
>>> # Note that for there are missing categorical values for the 2nd and 3rd
>>> # feature
>>> X = [['male', 'from US', 'uses Safari'], ['female', 'from Europe', 'uses Firefox
↪']]
>>> enc.fit(X)
OneHotEncoder(categories=[['female', 'male'],
                          ['from Africa', 'from Asia', 'from Europe',
                           'from US'],
                          ['uses Chrome', 'uses Firefox', 'uses IE',
                           'uses Safari']])
>>> enc.transform([['female', 'from Asia', 'uses Chrome']]).toarray()
array([[1., 0., 0., 1., 0., 0., 1., 0., 0., 0.]])
```

If there is a possibility that the training data might have missing categorical features, it can often be better to specify `handle_unknown='ignore'` instead of setting the `categories` manually as above. When `handle_unknown='ignore'` is specified and unknown categories are encountered during transform, no error will be raised but the resulting one-hot encoded columns for this feature will be all zeros

(handle_unknown='ignore' is only supported for one-hot encoding):

```
>>> enc = preprocessing.OneHotEncoder(handle_unknown='ignore')
>>> X = [['male', 'from US', 'uses Safari'], ['female', 'from Europe', 'uses Firefox
↪']]
>>> enc.fit(X)
OneHotEncoder(handle_unknown='ignore')
>>> enc.transform([['female', 'from Asia', 'uses Chrome']]).toarray()
array([[1., 0., 0., 0., 0., 0.]])
```

It is also possible to encode each column into n_categories - 1 columns instead of n_categories columns by using the drop parameter. This parameter allows the user to specify a category for each feature to be dropped. This is useful to avoid co-linearity in the input matrix in some classifiers. Such functionality is useful, for example, when using non-regularized regression (*LinearRegression*), since co-linearity would cause the covariance matrix to be non-invertible. When this paramenter is not None, handle_unknown must be set to error:

```
>>> X = [['male', 'from US', 'uses Safari'], ['female', 'from Europe', 'uses Firefox
↪']]
>>> drop_enc = preprocessing.OneHotEncoder(drop='first').fit(X)
>>> drop_enc.categories_
[array(['female', 'male'], dtype=object), array(['from Europe', 'from US'],␣
↪dtype=object), array(['uses Firefox', 'uses Safari'], dtype=object)]
>>> drop_enc.transform(X).toarray()
array([[1., 1., 1.],
       [0., 0., 0.]])
```

See *Loading features from dicts* for categorical features that are represented as a dict, not as scalars.

Discretization

Discretization (otherwise known as quantization or binning) provides a way to partition continuous features into discrete values. Certain datasets with continuous features may benefit from discretization, because discretization can transform the dataset of continuous attributes to one with only nominal attributes.

One-hot encoded discretized features can make a model more expressive, while maintaining interpretability. For instance, pre-processing with a discretizer can introduce nonlinearity to linear models.

K-bins discretization

KBinsDiscretizer discretizes features into k bins:

```
>>> X = np.array([[ -3., 5., 15 ],
...               [  0., 6., 14 ],
...               [  6., 3., 11 ]])
>>> est = preprocessing.KBinsDiscretizer(n_bins=[3, 2, 2], encode='ordinal').fit(X)
```

By default the output is one-hot encoded into a sparse matrix (See *Encoding categorical features*) and this can be configured with the encode parameter. For each feature, the bin edges are computed during fit and together with the number of bins, they will define the intervals. Therefore, for the current example, these intervals are defined as:

- feature 1: $[-\infty, -1), [-1, 2), [2, \infty)$
- feature 2: $[-\infty, 5), [5, \infty)$
- feature 3: $[-\infty, 14), [14, \infty)$

Based on these bin intervals, X is transformed as follows:

```
>>> est.transform(X)
array([[ 0., 1., 1.],
       [ 1., 1., 1.],
       [ 2., 0., 0.]])
```

The resulting dataset contains ordinal attributes which can be further used in a *sklearn.pipeline.Pipeline*.

Discretization is similar to constructing histograms for continuous data. However, histograms focus on counting features which fall into particular bins, whereas discretization focuses on assigning feature values to these bins.

KBinsDiscretizer implements different binning strategies, which can be selected with the `strategy` parameter. The 'uniform' strategy uses constant-width bins. The 'quantile' strategy uses the quantiles values to have equally populated bins in each feature. The 'kmeans' strategy defines bins based on a k-means clustering procedure performed on each feature independently.

Examples:

- *Using KBinsDiscretizer to discretize continuous features*
- *Feature discretization*
- *Demonstrating the different strategies of KBinsDiscretizer*

Feature binarization

Feature binarization is the process of **thresholding numerical features to get boolean values**. This can be useful for downstream probabilistic estimators that make assumption that the input data is distributed according to a multi-variate Bernoulli distribution. For instance, this is the case for the *sklearn.neural_network.BernoulliRBM*.

It is also common among the text processing community to use binary feature values (probably to simplify the probabilistic reasoning) even if normalized counts (a.k.a. term frequencies) or TF-IDF valued features often perform slightly better in practice.

As for the *Normalizer*, the utility class *Binarizer* is meant to be used in the early stages of *sklearn.pipeline.Pipeline*. The `fit` method does nothing as each sample is treated independently of others:

```
>>> X = [[ 1., -1.,  2.],
...      [ 2.,  0.,  0.],
...      [ 0.,  1., -1.]]

>>> binarizer = preprocessing.Binarizer().fit(X)  # fit does nothing
>>> binarizer
Binarizer()

>>> binarizer.transform(X)
array([[1., 0., 1.],
       [1., 0., 0.],
       [0., 1., 0.]])
```

It is possible to adjust the threshold of the binarizer:

```
>>> binarizer = preprocessing.Binarizer(threshold=1.1)
>>> binarizer.transform(X)
array([[0., 0., 1.],
       [1., 0., 0.],
       [0., 0., 0.]])
```

As for the *StandardScaler* and *Normalizer* classes, the preprocessing module provides a companion function *binarize* to be used when the transformer API is not necessary.

Note that the *Binarizer* is similar to the *KBinsDiscretizer* when `k = 2`, and when the bin edge is at the value `threshold`.

Sparse input

binarize and *Binarizer* accept **both dense array-like and sparse matrices from scipy.sparse as input**.

For sparse input the data is **converted to the Compressed Sparse Rows representation** (see `scipy.sparse.csr_matrix`). To avoid unnecessary memory copies, it is recommended to choose the CSR representation upstream.

Imputation of missing values

Tools for imputing missing values are discussed at *Imputation of missing values*.

Generating polynomial features

Often it's useful to add complexity to the model by considering nonlinear features of the input data. A simple and common method to use is polynomial features, which can get features' high-order and interaction terms. It is implemented in *PolynomialFeatures*:

```
>>> import numpy as np
>>> from sklearn.preprocessing import PolynomialFeatures
>>> X = np.arange(6).reshape(3, 2)
>>> X
array([[0, 1],
       [2, 3],
       [4, 5]])
>>> poly = PolynomialFeatures(2)
>>> poly.fit_transform(X)
array([[ 1.,  0.,  1.,  0.,  0.,  1.],
       [ 1.,  2.,  3.,  4.,  6.,  9.],
       [ 1.,  4.,  5., 16., 20., 25.]])
```

The features of X have been transformed from (X_1, X_2) to $(1, X_1, X_2, X_1^2, X_1X_2, X_2^2)$.

In some cases, only interaction terms among features are required, and it can be gotten with the setting `interaction_only=True`:

```
>>> X = np.arange(9).reshape(3, 3)
>>> X
array([[0, 1, 2],
       [3, 4, 5],
       [6, 7, 8]])
>>> poly = PolynomialFeatures(degree=3, interaction_only=True)
>>> poly.fit_transform(X)
array([[  1.,   0.,   1.,   2.,   0.,   0.,   2.,   0.],
       [  1.,   3.,   4.,   5.,  12.,  15.,  20.,  60.],
       [  1.,   6.,   7.,   8.,  42.,  48.,  56., 336.]])
```

The features of X have been transformed from (X_1, X_2, X_3) to $(1, X_1, X_2, X_3, X_1X_2, X_1X_3, X_2X_3, X_1X_2X_3)$.

Note that polynomial features are used implicitly in kernel methods (e.g., *sklearn.svm.SVC*, *sklearn.decomposition.KernelPCA*) when using polynomial *Kernel functions*.

See *Polynomial interpolation* for Ridge regression using created polynomial features.

Custom transformers

Often, you will want to convert an existing Python function into a transformer to assist in data cleaning or processing. You can implement a transformer from an arbitrary function with *FunctionTransformer*. For example, to build a transformer that applies a log transformation in a pipeline, do:

```
>>> import numpy as np
>>> from sklearn.preprocessing import FunctionTransformer
>>> transformer = FunctionTransformer(np.log1p, validate=True)
>>> X = np.array([[0, 1], [2, 3]])
>>> transformer.transform(X)
array([[0.        , 0.69314718],
       [1.09861229, 1.38629436]])
```

You can ensure that `func` and `inverse_func` are the inverse of each other by setting `check_inverse=True` and calling `fit` before `transform`. Please note that a warning is raised and can be turned into an error with a `filterwarnings`:

```
>>> import warnings
>>> warnings.filterwarnings("error", message=".*check_inverse*.",
...                         category=UserWarning, append=False)
```

For a full code example that demonstrates using a *FunctionTransformer* to do custom feature selection, see *Using FunctionTransformer to select columns*

4.6.4 Imputation of missing values

For various reasons, many real world datasets contain missing values, often encoded as blanks, NaNs or other placeholders. Such datasets however are incompatible with scikit-learn estimators which assume that all values in an array are numerical, and that all have and hold meaning. A basic strategy to use incomplete datasets is to discard entire rows and/or columns containing missing values. However, this comes at the price of losing data which may be valuable (even though incomplete). A better strategy is to impute the missing values, i.e., to infer them from the known part of the data. See the *Glossary of Common Terms and API Elements* entry on imputation.

Univariate vs. Multivariate Imputation

One type of imputation algorithm is univariate, which imputes values in the i-th feature dimension using only non-missing values in that feature dimension (e.g. `impute.SimpleImputer`). By contrast, multivariate imputation algorithms use the entire set of available feature dimensions to estimate the missing values (e.g. `impute.IterativeImputer`).

Univariate feature imputation

The *SimpleImputer* class provides basic strategies for imputing missing values. Missing values can be imputed with a provided constant value, or using the statistics (mean, median or most frequent) of each column in which the missing values are located. This class also allows for different missing values encodings.

The following snippet demonstrates how to replace missing values, encoded as `np.nan`, using the mean value of the columns (axis 0) that contain the missing values:

```
>>> import numpy as np
>>> from sklearn.impute import SimpleImputer
>>> imp = SimpleImputer(missing_values=np.nan, strategy='mean')
>>> imp.fit([[1, 2], [np.nan, 3], [7, 6]])
SimpleImputer()
>>> X = [[np.nan, 2], [6, np.nan], [7, 6]]
>>> print(imp.transform(X))
[[4.          2.        ]
 [6.          3.666...]
 [7.          6.        ]]
```

The *SimpleImputer* class also supports sparse matrices:

```
>>> import scipy.sparse as sp
>>> X = sp.csc_matrix([[1, 2], [0, -1], [8, 4]])
>>> imp = SimpleImputer(missing_values=-1, strategy='mean')
>>> imp.fit(X)
SimpleImputer(missing_values=-1)
>>> X_test = sp.csc_matrix([[-1, 2], [6, -1], [7, 6]])
>>> print(imp.transform(X_test).toarray())
[[3. 2.]
 [6. 3.]
 [7. 6.]]
```

Note that this format is not meant to be used to implicitly store missing values in the matrix because it would densify it at transform time. Missing values encoded by 0 must be used with dense input.

The *SimpleImputer* class also supports categorical data represented as string values or pandas categoricals when using the `'most_frequent'` or `'constant'` strategy:

```
>>> import pandas as pd
>>> df = pd.DataFrame([["a", "x"],
...                    [np.nan, "y"],
...                    ["a", np.nan],
...                    ["b", "y"]], dtype="category")
...
>>> imp = SimpleImputer(strategy="most_frequent")
>>> print(imp.fit_transform(df))
[['a' 'x']
 ['a' 'y']
 ['a' 'y']
 ['b' 'y']]
```

Multivariate feature imputation

A more sophisticated approach is to use the *IterativeImputer* class, which models each feature with missing values as a function of other features, and uses that estimate for imputation. It does so in an iterated round-robin fashion: at each step, a feature column is designated as output `y` and the other feature columns are treated as inputs `X`. A regressor is fit on `(X, y)` for known `y`. Then, the regressor is used to predict the missing values of `y`. This is done for each feature in an iterative fashion, and then is repeated for `max_iter` imputation rounds. The results of the final imputation round are returned.

Note: This estimator is still **experimental** for now: the predictions and the API might change without any deprecation

cycle. To use it, you need to explicitly import `enable_iterative_imputer`.

```
>>> import numpy as np
>>> from sklearn.experimental import enable_iterative_imputer
>>> from sklearn.impute import IterativeImputer
>>> imp = IterativeImputer(max_iter=10, random_state=0)
>>> imp.fit([[1, 2], [3, 6], [4, 8], [np.nan, 3], [7, np.nan]])
IterativeImputer(random_state=0)
>>> X_test = [[np.nan, 2], [6, np.nan], [np.nan, 6]]
>>> # the model learns that the second feature is double the first
>>> print(np.round(imp.transform(X_test)))
[[ 1.  2.]
 [ 6. 12.]
 [ 3.  6.]]
```

Both *SimpleImputer* and *IterativeImputer* can be used in a Pipeline as a way to build a composite estimator that supports imputation. See *Imputing missing values before building an estimator*.

Flexibility of IterativeImputer

There are many well-established imputation packages in the R data science ecosystem: Amelia, mi, mice, missForest, etc. missForest is popular, and turns out to be a particular instance of different sequential imputation algorithms that can all be implemented with *IterativeImputer* by passing in different regressors to be used for predicting missing feature values. In the case of missForest, this regressor is a Random Forest. See *Imputing missing values with variants of IterativeImputer*.

Multiple vs. Single Imputation

In the statistics community, it is common practice to perform multiple imputations, generating, for example, `m` separate imputations for a single feature matrix. Each of these `m` imputations is then put through the subsequent analysis pipeline (e.g. feature engineering, clustering, regression, classification). The `m` final analysis results (e.g. held-out validation errors) allow the data scientist to obtain understanding of how analytic results may differ as a consequence of the inherent uncertainty caused by the missing values. The above practice is called multiple imputation.

Our implementation of *IterativeImputer* was inspired by the R MICE package (Multivariate Imputation by Chained Equations)[1], but differs from it by returning a single imputation instead of multiple imputations. However, *IterativeImputer* can also be used for multiple imputations by applying it repeatedly to the same dataset with different random seeds when `sample_posterior=True`. See[2], chapter 4 for more discussion on multiple vs. single imputations.

It is still an open problem as to how useful single vs. multiple imputation is in the context of prediction and classification when the user is not interested in measuring uncertainty due to missing values.

Note that a call to the `transform` method of *IterativeImputer* is not allowed to change the number of samples. Therefore multiple imputations cannot be achieved by a single call to `transform`.

Nearest neighbors imputation

The *KNNImputer* class provides imputation for filling in missing values using the k-Nearest Neighbors approach. By default, a euclidean distance metric that supports missing values, `nan_euclidean_distances`, is used to find the nearest neighbors. Each missing feature is imputed using values from `n_neighbors` nearest neighbors that have a value for the feature. The feature of the neighbors are averaged uniformly or weighted by distance to each neighbor. If a sample has more than one feature missing, then the neighbors for that sample can be different depending on the particular feature being imputed. When the number of available neighbors is less than `n_neighbors` and there are no defined distances to the training set, the training set average for that feature is used during imputation. If there is at least one neighbor with a defined distance, the weighted or unweighted average of the remaining neighbors will be used during imputation. If a feature is always missing in training, it is removed during `transform`. For more information on the methodology, see ref. [OL2001].

The following snippet demonstrates how to replace missing values, encoded as `np.nan`, using the mean feature value of the two nearest neighbors of samples with missing values:

```
>>> import numpy as np
>>> from sklearn.impute import KNNImputer
>>> nan = np.nan
>>> X = [[1, 2, nan], [3, 4, 3], [nan, 6, 5], [8, 8, 7]]
>>> imputer = KNNImputer(n_neighbors=2, weights="uniform")
>>> imputer.fit_transform(X)
array([[1. , 2. , 4. ],
       [3. , 4. , 3. ],
       [5.5, 6. , 5. ],
       [8. , 8. , 7. ]])
```

Marking imputed values

The *MissingIndicator* transformer is useful to transform a dataset into corresponding binary matrix indicating the presence of missing values in the dataset. This transformation is useful in conjunction with imputation. When using imputation, preserving the information about which values had been missing can be informative. Note that both the *SimpleImputer* and *IterativeImputer* have the boolean parameter `add_indicator` (`False` by default) which when set to `True` provides a convenient way of stacking the output of the *MissingIndicator* transformer with the output of the imputer.

`NaN` is usually used as the placeholder for missing values. However, it enforces the data type to be float. The parameter `missing_values` allows to specify other placeholder such as integer. In the following example, we will use `-1` as missing values:

```
>>> from sklearn.impute import MissingIndicator
>>> X = np.array([[-1, -1, 1, 3],
...               [4, -1, 0, -1],
...               [8, -1, 1, 0]])
>>> indicator = MissingIndicator(missing_values=-1)
>>> mask_missing_values_only = indicator.fit_transform(X)
>>> mask_missing_values_only
array([[ True,  True, False],
       [False,  True,  True],
       [False,  True, False]])
```

The `features` parameter is used to choose the features for which the mask is constructed. By default, it is `'missing-only'` which returns the imputer mask of the features containing missing values at `fit` time:

```
>>> indicator.features_
array([0, 1, 3])
```

The `features` parameter can be set to `'all'` to return all features whether or not they contain missing values:

```
>>> indicator = MissingIndicator(missing_values=-1, features="all")
>>> mask_all = indicator.fit_transform(X)
>>> mask_all
array([[ True,  True, False, False],
       [False,  True, False,  True],
       [False,  True, False, False]])
>>> indicator.features_
array([0, 1, 2, 3])
```

When using the *MissingIndicator* in a `Pipeline`, be sure to use the `FeatureUnion` or `ColumnTransformer` to add the indicator features to the regular features. First we obtain the `iris` dataset, and add some missing values to it.

```
>>> from sklearn.datasets import load_iris
>>> from sklearn.impute import SimpleImputer, MissingIndicator
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.pipeline import FeatureUnion, make_pipeline
>>> from sklearn.tree import DecisionTreeClassifier
>>> X, y = load_iris(return_X_y=True)
>>> mask = np.random.randint(0, 2, size=X.shape).astype(np.bool)
>>> X[mask] = np.nan
>>> X_train, X_test, y_train, _ = train_test_split(X, y, test_size=100,
...                                                random_state=0)
```

Now we create a `FeatureUnion`. All features will be imputed using *SimpleImputer*, in order to enable classifiers to work with this data. Additionally, it adds the the indicator variables from *MissingIndicator*.

```
>>> transformer = FeatureUnion(
...     transformer_list=[
...         ('features', SimpleImputer(strategy='mean')),
...         ('indicators', MissingIndicator())])
>>> transformer = transformer.fit(X_train, y_train)
>>> results = transformer.transform(X_test)
>>> results.shape
(100, 8)
```

Of course, we cannot use the transformer to make any predictions. We should wrap this in a `Pipeline` with a classifier (e.g., a `DecisionTreeClassifier`) to be able to make predictions.

```
>>> clf = make_pipeline(transformer, DecisionTreeClassifier())
>>> clf = clf.fit(X_train, y_train)
>>> results = clf.predict(X_test)
>>> results.shape
(100,)
```

4.6.5 Unsupervised dimensionality reduction

If your number of features is high, it may be useful to reduce it with an unsupervised step prior to supervised steps. Many of the *Unsupervised learning* methods implement a `transform` method that can be used to reduce the dimensionality. Below we discuss two specific example of this pattern that are heavily used.

Pipelining

The unsupervised data reduction and the supervised estimator can be chained in one step. See *Pipeline: chaining estimators*.

PCA: principal component analysis

`decomposition.PCA` looks for a combination of features that capture well the variance of the original features. See *Decomposing signals in components (matrix factorization problems)*.

Examples

- *Faces recognition example using eigenfaces and SVMs*

Random projections

The module: `random_projection` provides several tools for data reduction by random projections. See the relevant section of the documentation: *Random Projection*.

Examples

- *The Johnson-Lindenstrauss bound for embedding with random projections*

Feature agglomeration

`cluster.FeatureAgglomeration` applies *Hierarchical clustering* to group together features that behave similarly.

Examples

- *Feature agglomeration vs. univariate selection*
- *Feature agglomeration*

Feature scaling

Note that if features have very different scaling or statistical properties, `cluster.FeatureAgglomeration` may not be able to capture the links between related features. Using a `preprocessing.StandardScaler` can be useful in these settings.

4.6.6 Random Projection

The `sklearn.random_projection` module implements a simple and computationally efficient way to reduce the dimensionality of the data by trading a controlled amount of accuracy (as additional variance) for faster processing

times and smaller model sizes. This module implements two types of unstructured random matrix: *Gaussian random matrix* and *sparse random matrix*.

The dimensions and distribution of random projections matrices are controlled so as to preserve the pairwise distances between any two samples of the dataset. Thus random projection is a suitable approximation technique for distance based method.

The Johnson-Lindenstrauss lemma

The main theoretical result behind the efficiency of random projection is the Johnson-Lindenstrauss lemma (quoting Wikipedia):

> In mathematics, the Johnson-Lindenstrauss lemma is a result concerning low-distortion embeddings of points from high-dimensional into low-dimensional Euclidean space. The lemma states that a small set of points in a high-dimensional space can be embedded into a space of much lower dimension in such a way that distances between the points are nearly preserved. The map used for the embedding is at least Lipschitz, and can even be taken to be an orthogonal projection.

Knowing only the number of samples, the *sklearn.random_projection.johnson_lindenstrauss_min_dim* estimates conservatively the minimal size of the random subspace to guarantee a bounded distortion introduced by the random projection:

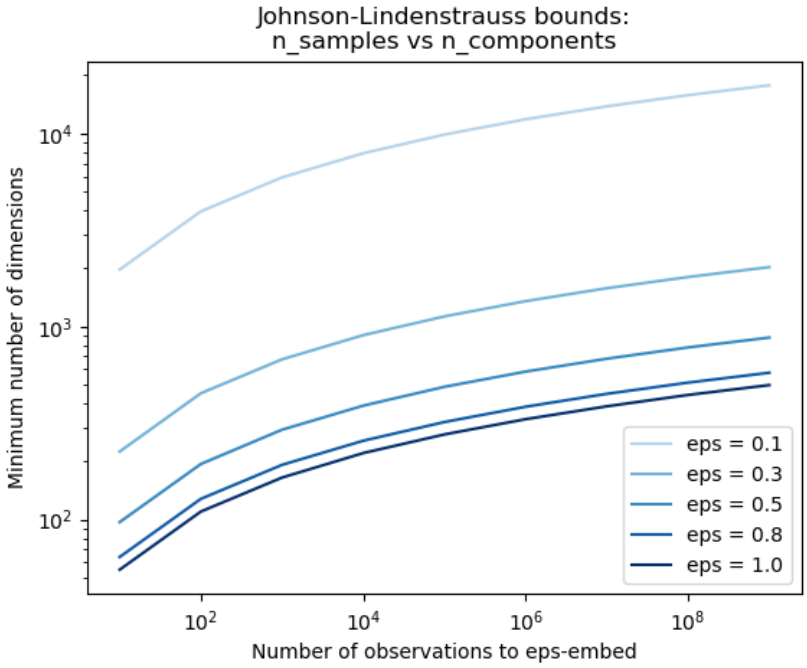
```
>>> from sklearn.random_projection import johnson_lindenstrauss_min_dim
>>> johnson_lindenstrauss_min_dim(n_samples=1e6, eps=0.5)
663
>>> johnson_lindenstrauss_min_dim(n_samples=1e6, eps=[0.5, 0.1, 0.01])
array([    663,   11841, 1112658])
>>> johnson_lindenstrauss_min_dim(n_samples=[1e4, 1e5, 1e6], eps=0.1)
array([ 7894,  9868, 11841])
```

Example:

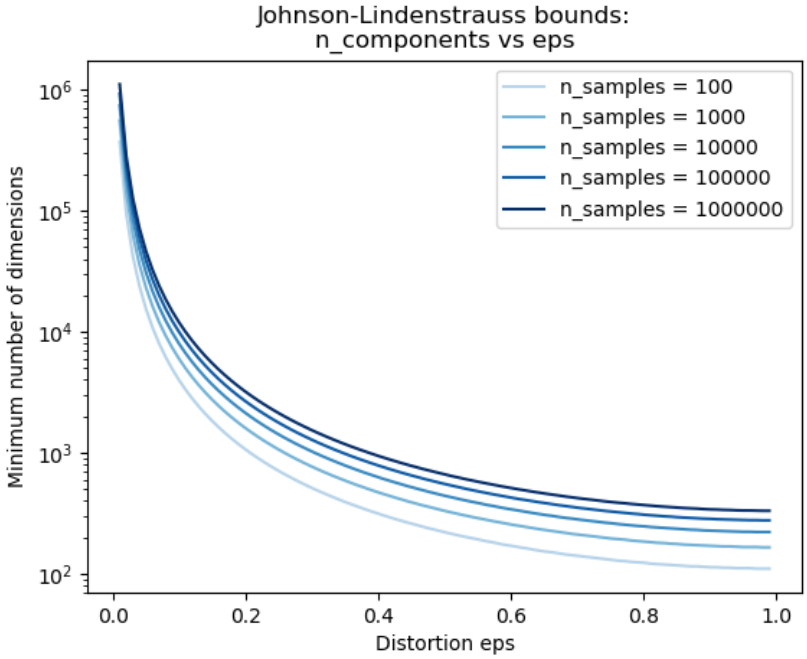
- See *The Johnson-Lindenstrauss bound for embedding with random projections* for a theoretical explication on the Johnson-Lindenstrauss lemma and an empirical validation using sparse random matrices.

References:

- Sanjoy Dasgupta and Anupam Gupta, 1999. An elementary proof of the Johnson-Lindenstrauss Lemma.



Johnson-Lindenstrauss bounds:
n_samples vs n_components
Minimum number of dimensions
Number of observations to eps-embed
eps = 0.1
eps = 0.3
eps = 0.5
eps = 0.8
eps = 1.0



Johnson-Lindenstrauss bounds:
n_components vs eps
Minimum number of dimensions
Distortion eps
n_samples = 100
n_samples = 1000
n_samples = 10000
n_samples = 100000
n_samples = 1000000

Gaussian random projection

The *sklearn.random_projection.GaussianRandomProjection* reduces the dimensionality by projecting the original input space on a randomly generated matrix where components are drawn from the following distribution $N(0, \frac{1}{n_{components}})$.

Here a small excerpt which illustrates how to use the Gaussian random projection transformer:

```
>>> import numpy as np
>>> from sklearn import random_projection
>>> X = np.random.rand(100, 10000)
>>> transformer = random_projection.GaussianRandomProjection()
>>> X_new = transformer.fit_transform(X)
>>> X_new.shape
(100, 3947)
```

Sparse random projection

The *sklearn.random_projection.SparseRandomProjection* reduces the dimensionality by projecting the original input space using a sparse random matrix.

Sparse random matrices are an alternative to dense Gaussian random projection matrix that guarantees similar embedding quality while being much more memory efficient and allowing faster computation of the projected data.

If we define `s = 1 / density`, the elements of the random matrix are drawn from

$$\begin{cases} -\sqrt{\frac{s}{n_{\text{components}}}} & \\ 0 & \text{with probability} \\ +\sqrt{\frac{s}{n_{\text{components}}}} & \end{cases} \begin{matrix} \\ 1/2s \\ 1 - 1/s \\ 1/2s \end{matrix}$$

where $n_{\text{components}}$ is the size of the projected subspace. By default the density of non zero elements is set to the minimum density as recommended by Ping Li et al.: $1/\sqrt{n_{\text{features}}}$.

Here a small excerpt which illustrates how to use the sparse random projection transformer:

```
>>> import numpy as np
>>> from sklearn import random_projection
>>> X = np.random.rand(100, 10000)
>>> transformer = random_projection.SparseRandomProjection()
>>> X_new = transformer.fit_transform(X)
>>> X_new.shape
(100, 3947)
```

4.6.7 Kernel Approximation

This submodule contains functions that approximate the feature mappings that correspond to certain kernels, as they are used for example in support vector machines (see *Support Vector Machines*). The following feature functions perform non-linear transformations of the input, which can serve as a basis for linear classification or other algorithms.

The advantage of using approximate explicit feature maps compared to the kernel trick, which makes use of feature maps implicitly, is that explicit mappings can be better suited for online learning and can significantly reduce the cost of learning with very large datasets. Standard kernelized SVMs do not scale well to large datasets, but using an approximate kernel map it is possible to use much more efficient linear SVMs. In particular, the combination of kernel map approximations with `SGDClassifier` can make non-linear learning on large datasets possible.

Since there has not been much empirical work using approximate embeddings, it is advisable to compare results against exact kernel methods when possible.

See also:

Polynomial regression: extending linear models with basis functions for an exact polynomial transformation.

Nystroem Method for Kernel Approximation

The Nystroem method, as implemented in `Nystroem` is a general method for low-rank approximations of kernels. It achieves this by essentially subsampling the data on which the kernel is evaluated. By default `Nystroem` uses the `rbf` kernel, but it can use any kernel function or a precomputed kernel matrix. The number of samples used - which is also the dimensionality of the features computed - is given by the parameter `n_components`.

Radial Basis Function Kernel

The `RBFSampler` constructs an approximate mapping for the radial basis function kernel, also known as *Random Kitchen Sinks* [RR2007]. This transformation can be used to explicitly model a kernel map, prior to applying a linear algorithm, for example a linear SVM:

```
>>> from sklearn.kernel_approximation import RBFSampler
>>> from sklearn.linear_model import SGDClassifier
>>> X = [[0, 0], [1, 1], [1, 0], [0, 1]]
>>> y = [0, 0, 1, 1]
>>> rbf_feature = RBFSampler(gamma=1, random_state=1)
>>> X_features = rbf_feature.fit_transform(X)
>>> clf = SGDClassifier(max_iter=5)
>>> clf.fit(X_features, y)
SGDClassifier(max_iter=5)
>>> clf.score(X_features, y)
1.0
```

The mapping relies on a Monte Carlo approximation to the kernel values. The `fit` function performs the Monte Carlo sampling, whereas the `transform` method performs the mapping of the data. Because of the inherent randomness of the process, results may vary between different calls to the `fit` function.

The `fit` function takes two arguments: `n_components`, which is the target dimensionality of the feature transform, and `gamma`, the parameter of the RBF-kernel. A higher `n_components` will result in a better approximation of the kernel and will yield results more similar to those produced by a kernel SVM. Note that "fitting" the feature function does not actually depend on the data given to the `fit` function. Only the dimensionality of the data is used. Details on the method can be found in [RR2007].

For a given value of `n_components` `RBFSampler` is often less accurate as `Nystroem`. `RBFSampler` is cheaper to compute, though, making use of larger feature spaces more efficient.

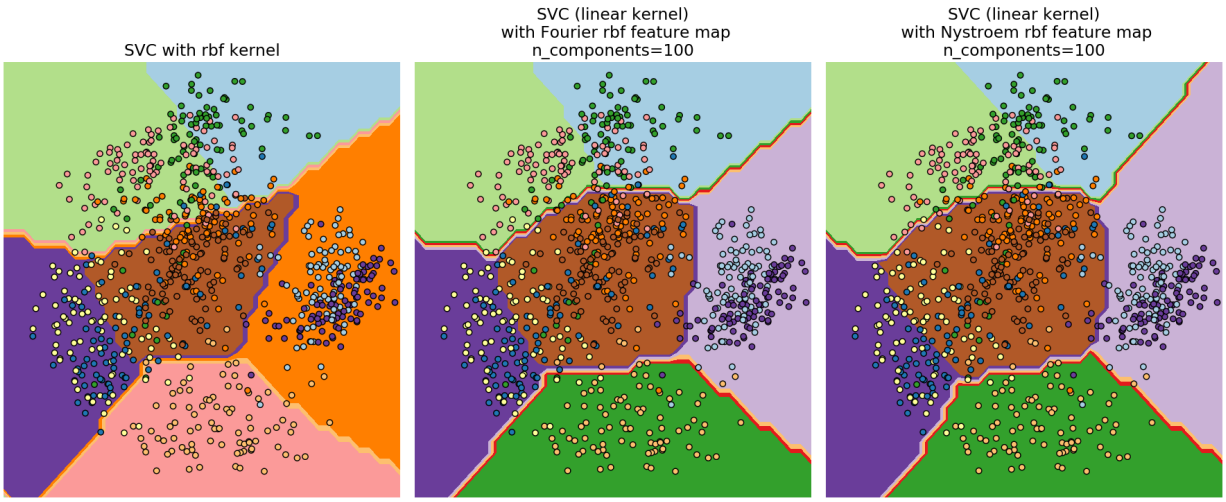

Fig. 9: Comparing an exact RBF kernel (left) with the approximation (right)

Examples:

- *Explicit feature map approximation for RBF kernels*

Additive Chi Squared Kernel

The additive chi squared kernel is a kernel on histograms, often used in computer vision.

The additive chi squared kernel as used here is given by

$$k(x, y) = \sum_i \frac{2x_i y_i}{x_i + y_i}$$

This is not exactly the same as `sklearn.metrics.additive_chi2_kernel`. The authors of [VZ2010] prefer the version above as it is always positive definite. Since the kernel is additive, it is possible to treat all components x_i separately for embedding. This makes it possible to sample the Fourier transform in regular intervals, instead of approximating using Monte Carlo sampling.

The class *`AdditiveChi2Sampler`* implements this component wise deterministic sampling. Each component is sampled n times, yielding $2n + 1$ dimensions per input dimension (the multiple of two stems from the real and complex part of the Fourier transform). In the literature, n is usually chosen to be 1 or 2, transforming the dataset to size `n_samples * 5 * n_features` (in the case of $n = 2$).

The approximate feature map provided by *`AdditiveChi2Sampler`* can be combined with the approximate feature map provided by *`RBFSampler`* to yield an approximate feature map for the exponentiated chi squared kernel. See the [VZ2010] for details and [VVZ2010] for combination with the *`RBFSampler`*.

Skewed Chi Squared Kernel

The skewed chi squared kernel is given by:

$$k(x, y) = \prod_i \frac{2\sqrt{x_i + c}\sqrt{y_i + c}}{x_i + y_i + 2c}$$

It has properties that are similar to the exponentiated chi squared kernel often used in computer vision, but allows for a simple Monte Carlo approximation of the feature map.

The usage of the *SkewedChi2Sampler* is the same as the usage described above for the *RBFSampler*. The only difference is in the free parameter, that is called c. For a motivation for this mapping and the mathematical details see [LS2010].

Mathematical Details

Kernel methods like support vector machines or kernelized PCA rely on a property of reproducing kernel Hilbert spaces. For any positive definite kernel function k (a so called Mercer kernel), it is guaranteed that there exists a mapping ϕ into a Hilbert space $\mathcal{H}$, such that

$$k(x, y) = \langle \phi(x), \phi(y) \rangle$$

Where $\langle \cdot, \cdot \rangle$ denotes the inner product in the Hilbert space.

If an algorithm, such as a linear support vector machine or PCA, relies only on the scalar product of data points x_i, one may use the value of $k(x_i, x_j)$, which corresponds to applying the algorithm to the mapped data points $\phi(x_i)$. The advantage of using k is that the mapping ϕ never has to be calculated explicitly, allowing for arbitrary large features (even infinite).

One drawback of kernel methods is, that it might be necessary to store many kernel values $k(x_i, x_j)$ during optimization. If a kernelized classifier is applied to new data y_j, $k(x_i, y_j)$ needs to be computed to make predictions, possibly for many different x_i in the training set.

The classes in this submodule allow to approximate the embedding ϕ, thereby working explicitly with the representations $\phi(x_i)$, which obviates the need to apply the kernel or store training examples.

References:

4.6.8 Pairwise metrics, Affinities and Kernels

The *sklearn.metrics.pairwise* submodule implements utilities to evaluate pairwise distances or affinity of sets of samples.

This module contains both distance metrics and kernels. A brief summary is given on the two here.

Distance metrics are functions `d(a, b)` such that `d(a, b) < d(a, c)` if objects `a` and `b` are considered "more similar" than objects `a` and `c`. Two objects exactly alike would have a distance of zero. One of the most popular examples is Euclidean distance. To be a 'true' metric, it must obey the following four conditions:

```
1. d(a, b) >= 0, for all a and b
2. d(a, b) == 0, if and only if a = b, positive definiteness
3. d(a, b) == d(b, a), symmetry
4. d(a, c) <= d(a, b) + d(b, c), the triangle inequality
```

Kernels are measures of similarity, i.e. `s(a, b) > s(a, c)` if objects `a` and `b` are considered "more similar" than objects `a` and `c`. A kernel must also be positive semi-definite.

There are a number of ways to convert between a distance metric and a similarity measure, such as a kernel. Let `D` be the distance, and `S` be the kernel:

1. `S = np.exp(-D * gamma)`, where one heuristic for choosing `gamma` is `1 / num_features`
2. `S = 1. / (D / np.max(D))`

The distances between the row vectors of X and the row vectors of Y can be evaluated using *pairwise_distances*. If Y is omitted the pairwise distances of the row vectors of X are calculated. Similarly, *pairwise.pairwise_kernels* can be used to calculate the kernel between X and Y using different kernel functions. See the API reference for more details.

```
>>> import numpy as np
>>> from sklearn.metrics import pairwise_distances
>>> from sklearn.metrics.pairwise import pairwise_kernels
>>> X = np.array([[2, 3], [3, 5], [5, 8]])
>>> Y = np.array([[1, 0], [2, 1]])
>>> pairwise_distances(X, Y, metric='manhattan')
array([[ 4.,  2.],
       [ 7.,  5.],
       [12., 10.]])
>>> pairwise_distances(X, metric='manhattan')
array([[0., 3., 8.],
       [3., 0., 5.],
       [8., 5., 0.]])
>>> pairwise_kernels(X, Y, metric='linear')
array([[ 2.,  7.],
       [ 3., 11.],
       [ 5., 18.]])
```

Cosine similarity

cosine_similarity computes the L2-normalized dot product of vectors. That is, if x and y are row vectors, their cosine similarity k is defined as:

$$k(x, y) = \frac{xy^\top}{\|x\|\|y\|}$$

This is called cosine similarity, because Euclidean (L2) normalization projects the vectors onto the unit sphere, and their dot product is then the cosine of the angle between the points denoted by the vectors.

This kernel is a popular choice for computing the similarity of documents represented as tf-idf vectors. *cosine_similarity* accepts scipy.sparse matrices. (Note that the tf-idf functionality in sklearn.feature_extraction.text can produce normalized vectors, in which case *cosine_similarity* is equivalent to *linear_kernel*, only slower.)

References:

- C.D. Manning, P. Raghavan and H. Schütze (2008). Introduction to Information Retrieval. Cambridge University Press. https://nlp.stanford.edu/IR-book/html/htmledition/the-vector-space-model-for-scoring-1.html

Linear kernel

The function *linear_kernel* computes the linear kernel, that is, a special case of *polynomial_kernel* with degree=1 and coef0=0 (homogeneous). If x and y are column vectors, their linear kernel is:

$$k(x, y) = x^\top y$$

Polynomial kernel

The function *polynomial_kernel* computes the degree-d polynomial kernel between two vectors. The polynomial kernel represents the similarity between two vectors. Conceptually, the polynomial kernels considers not only the similarity between vectors under the same dimension, but also across dimensions. When used in machine learning algorithms, this allows to account for feature interaction.

The polynomial kernel is defined as:

$$k(x, y) = (\gamma x^\top y + c_0)^d$$

where:

- x, y are the input vectors
- d is the kernel degree

If $c_0 = 0$ the kernel is said to be homogeneous.

Sigmoid kernel

The function *sigmoid_kernel* computes the sigmoid kernel between two vectors. The sigmoid kernel is also known as hyperbolic tangent, or Multilayer Perceptron (because, in the neural network field, it is often used as neuron activation function). It is defined as:

$$k(x, y) = \tanh(\gamma x^\top y + c_0)$$

where:

- x, y are the input vectors
- γ is known as slope
- c_0 is known as intercept

RBF kernel

The function *rbf_kernel* computes the radial basis function (RBF) kernel between two vectors. This kernel is defined as:

$$k(x, y) = \exp(-\gamma \|x - y\|^2)$$

where x and y are the input vectors. If $\gamma = \sigma^{-2}$ the kernel is known as the Gaussian kernel of variance σ^2.

Laplacian kernel

The function *laplacian_kernel* is a variant on the radial basis function kernel defined as:

$$k(x, y) = \exp(-\gamma \|x - y\|_1)$$

where x and y are the input vectors and $\|x - y\|_1$ is the Manhattan distance between the input vectors.

It has proven useful in ML applied to noiseless data. See e.g. Machine learning for quantum mechanics in a nutshell.

Chi-squared kernel

The chi-squared kernel is a very popular choice for training non-linear SVMs in computer vision applications. It can be computed using *chi2_kernel* and then passed to an *sklearn.svm.SVC* with `kernel="precomputed"`:

```
>>> from sklearn.svm import SVC
>>> from sklearn.metrics.pairwise import chi2_kernel
>>> X = [[0, 1], [1, 0], [.2, .8], [.7, .3]]
>>> y = [0, 1, 0, 1]
>>> K = chi2_kernel(X, gamma=.5)
>>> K
array([[1.        , 0.36787944, 0.89483932, 0.58364548],
       [0.36787944, 1.        , 0.51341712, 0.83822343],
       [0.89483932, 0.51341712, 1.        , 0.7768366 ],
       [0.58364548, 0.83822343, 0.7768366 , 1.        ]])

>>> svm = SVC(kernel='precomputed').fit(K, y)
>>> svm.predict(K)
array([0, 1, 0, 1])
```

It can also be directly used as the `kernel` argument:

```
>>> svm = SVC(kernel=chi2_kernel).fit(X, y)
>>> svm.predict(X)
array([0, 1, 0, 1])
```

The chi squared kernel is given by

$$k(x, y) = \exp\left(-\gamma \sum_i \frac{(x[i] - y[i])^2}{x[i] + y[i]}\right)$$

The data is assumed to be non-negative, and is often normalized to have an L1-norm of one. The normalization is rationalized with the connection to the chi squared distance, which is a distance between discrete probability distributions.

The chi squared kernel is most commonly used on histograms (bags) of visual words.

- Zhang, J. and Marszalek, M. and Lazebnik, S. and Schmid, C. Local features and kernels for classification of texture and object categories: A comprehensive study International Journal of Computer Vision 2007 https://research.microsoft.com/en-us/um/people/manik/projects/trade-off/papers/ZhangIJCV06.pdf

4.6.9 Transforming the prediction target (`y`)

These are transformers that are not intended to be used on features, only on supervised learning targets. See also *Transforming target in regression* if you want to transform the prediction target for learning, but evaluate the model in the original (untransformed) space.

Label binarization

LabelBinarizer is a utility class to help create a label indicator matrix from a list of multi-class labels:

```
>>> from sklearn import preprocessing
>>> lb = preprocessing.LabelBinarizer()
>>> lb.fit([1, 2, 6, 4, 2])
LabelBinarizer()
>>> lb.classes_
array([1, 2, 4, 6])
>>> lb.transform([1, 6])
array([[1, 0, 0, 0],
       [0, 0, 0, 1]])
```

For multiple labels per instance, use *MultiLabelBinarizer*:

```
>>> lb = preprocessing.MultiLabelBinarizer()
>>> lb.fit_transform([(1, 2), (3,)])
array([[1, 1, 0],
       [0, 0, 1]])
>>> lb.classes_
array([1, 2, 3])
```

Label encoding

LabelEncoder is a utility class to help normalize labels such that they contain only values between 0 and n_classes-1. This is sometimes useful for writing efficient Cython routines. *LabelEncoder* can be used as follows:

```
>>> from sklearn import preprocessing
>>> le = preprocessing.LabelEncoder()
>>> le.fit([1, 2, 2, 6])
LabelEncoder()
>>> le.classes_
array([1, 2, 6])
>>> le.transform([1, 1, 2, 6])
array([0, 0, 1, 2])
>>> le.inverse_transform([0, 0, 1, 2])
array([1, 1, 2, 6])
```

It can also be used to transform non-numerical labels (as long as they are hashable and comparable) to numerical labels:

```
>>> le = preprocessing.LabelEncoder()
>>> le.fit(["paris", "paris", "tokyo", "amsterdam"])
LabelEncoder()
>>> list(le.classes_)
['amsterdam', 'paris', 'tokyo']
>>> le.transform(["tokyo", "tokyo", "paris"])
array([2, 2, 1])
>>> list(le.inverse_transform([2, 2, 1]))
['tokyo', 'tokyo', 'paris']
```

4.7 Dataset loading utilities

The `sklearn.datasets` package embeds some small toy datasets as introduced in the *Getting Started* section.

This package also features helpers to fetch larger datasets commonly used by the machine learning community to benchmark algorithms on data that comes from the 'real world'.

To evaluate the impact of the scale of the dataset (`n_samples` and `n_features`) while controlling the statistical properties of the data (typically the correlation and informativeness of the features), it is also possible to generate synthetic data.

4.7.1 General dataset API

There are three main kinds of dataset interfaces that can be used to get datasets depending on the desired type of dataset.

The dataset loaders. They can be used to load small standard datasets, described in the *Toy datasets* section.

The dataset fetchers. They can be used to download and load larger datasets, described in the *Real world datasets* section.

Both loaders and fetchers functions return a dictionary-like object holding at least two items: an array of shape `n_samples` * `n_features` with key `data` (except for 20newsgroups) and a numpy array of length `n_samples`, containing the target values, with key `target`.

It's also possible for almost all of these function to constrain the output to be a tuple containing only the data and the target, by setting the `return_X_y` parameter to `True`.

The datasets also contain a full description in their `DESCR` attribute and some contain `feature_names` and `target_names`. See the dataset descriptions below for details.

The dataset generation functions. They can be used to generate controlled synthetic datasets, described in the *Generated datasets* section.

These functions return a tuple `(X, y)` consisting of a `n_samples` * `n_features` numpy array `X` and an array of length `n_samples` containing the targets `y`.

In addition, there are also miscellaneous tools to load datasets of other formats or from other locations, described in the *Loading other datasets* section.

4.7.2 Toy datasets

scikit-learn comes with a few small standard datasets that do not require to download any file from some external website.

They can be loaded using the following functions:

load_boston([return_X_y])	Load and return the boston house-prices dataset (regression).
load_iris([return_X_y])	Load and return the iris dataset (classification).
load_diabetes([return_X_y])	Load and return the diabetes dataset (regression).
load_digits([n_class, return_X_y])	Load and return the digits dataset (classification).
load_linnerud([return_X_y])	Load and return the linnerud dataset (multivariate regression).
load_wine([return_X_y])	Load and return the wine dataset (classification).
load_breast_cancer([return_X_y])	Load and return the breast cancer wisconsin dataset (classification).

These datasets are useful to quickly illustrate the behavior of the various algorithms implemented in scikit-learn. They are however often too small to be representative of real world machine learning tasks.

Boston house prices dataset

Data Set Characteristics:

Number of Instances 506

Number of Attributes 13 numeric/categorical predictive. Median Value (attribute 14) is usually the target.

Attribute Information (in order)

- CRIM per capita crime rate by town
- ZN proportion of residential land zoned for lots over 25,000 sq.ft.
- INDUS proportion of non-retail business acres per town
- CHAS Charles River dummy variable (= 1 if tract bounds river; 0 otherwise)
- NOX nitric oxides concentration (parts per 10 million)
- RM average number of rooms per dwelling
- AGE proportion of owner-occupied units built prior to 1940
- DIS weighted distances to five Boston employment centres
- RAD index of accessibility to radial highways
- TAX full-value property-tax rate per $10,000
- PTRATIO pupil-teacher ratio by town
- B 1000(Bk - 0.63)^2 where Bk is the proportion of blacks by town
- LSTAT % lower status of the population
- MEDV Median value of owner-occupied homes in $1000's

Missing Attribute Values None

Creator Harrison, D. and Rubinfeld, D.L.

This is a copy of UCI ML housing dataset. https://archive.ics.uci.edu/ml/machine-learning-databases/housing/

This dataset was taken from the StatLib library which is maintained at Carnegie Mellon University.

The Boston house-price data of Harrison, D. and Rubinfeld, D.L. 'Hedonic prices and the demand for clean air', J. Environ. Economics & Management, vol.5, 81-102, 1978. Used in Belsley, Kuh & Welsch, 'Regression diagnostics ...', Wiley, 1980. N.B. Various transformations are used in the table on pages 244-261 of the latter.

The Boston house-price data has been used in many machine learning papers that address regression problems.

Iris plants dataset

Data Set Characteristics:

Number of Instances 150 (50 in each of three classes)

Number of Attributes 4 numeric, predictive attributes and the class

Attribute Information

- sepal length in cm
- sepal width in cm
- petal length in cm
- petal width in cm
- **class:**
  - Iris-Setosa
  - Iris-Versicolour
  - Iris-Virginica

Summary Statistics

sepal length:	4.3	7.9	5.84	0.83	0.7826
sepal width:	2.0	4.4	3.05	0.43	-0.4194
petal length:	1.0	6.9	3.76	1.76	0.9490 (high!)
petal width:	0.1	2.5	1.20	0.76	0.9565 (high!)

Missing Attribute Values None

Class Distribution 33.3% for each of 3 classes.

Creator R.A. Fisher

Donor Michael Marshall (MARSHALL%PLU@io.arc.nasa.gov)

Date July, 1988

The famous Iris database, first used by Sir R.A. Fisher. The dataset is taken from Fisher's paper. Note that it's the same as in R, but not as in the UCI Machine Learning Repository, which has two wrong data points.

This is perhaps the best known database to be found in the pattern recognition literature. Fisher's paper is a classic in the field and is referenced frequently to this day. (See Duda & Hart, for example.) The data set contains 3 classes of 50 instances each, where each class refers to a type of iris plant. One class is linearly separable from the other 2; the latter are NOT linearly separable from each other.

Diabetes dataset

Ten baseline variables, age, sex, body mass index, average blood pressure, and six blood serum measurements were obtained for each of n = 442 diabetes patients, as well as the response of interest, a quantitative measure of disease progression one year after baseline.

Data Set Characteristics:

Number of Instances 442

Number of Attributes First 10 columns are numeric predictive values

Target Column 11 is a quantitative measure of disease progression one year after baseline

Attribute Information

- Age
- Sex
- Body mass index
- Average blood pressure
- S1
- S2
- S3
- S4
- S5
- S6

Note: Each of these 10 feature variables have been mean centered and scaled by the standard deviation times `n_samples` (i.e. the sum of squares of each column totals 1).

Creator

E. Alpaydin (alpaydin '@' boun.edu.tr)

Date July; 1998

This is a copy of the test set of the UCI ML hand-written digits datasets https://archive.ics.uci.edu/ml/datasets/Optical+Recognition+of+Handwritten+Digits

The data set contains images of hand-written digits: 10 classes where each class refers to a digit.

Preprocessing programs made available by NIST were used to extract normalized bitmaps of handwritten digits from a preprinted form. From a total of 43 people, 30 contributed to the training set and different 13 to the test set. 32x32 bitmaps are divided into nonoverlapping blocks of 4x4 and the number of on pixels are counted in each block. This generates an input matrix of 8x8 where each element is an integer in the range 0..16. This reduces dimensionality and gives invariance to small distortions.

For info on NIST preprocessing routines, see M. D. Garris, J. L. Blue, G. T. Candela, D. L. Dimmick, J. Geist, P. J. Grother, S. A. Janet, and C. L. Wilson, NIST Form-Based Handprint Recognition System, NISTIR 5469, 1994.

Breast cancer wisconsin (diagnostic) dataset

Data Set Characteristics:

Number of Instances 569

Number of Attributes 30 numeric, predictive attributes and the class

Attribute Information

- radius (mean of distances from center to points on the perimeter)
- texture (standard deviation of gray-scale values)
- perimeter
- area
- smoothness (local variation in radius lengths)
- compactness (perimeter^2 / area - 1.0)
- concavity (severity of concave portions of the contour)
- concave points (number of concave portions of the contour)
- symmetry
- fractal dimension ("coastline approximation" - 1)

The mean, standard error, and "worst" or largest (mean of the three largest values) of these features were computed for each image, resulting in 30 features. For instance, field 3 is Mean Radius, field 13 is Radius SE, field 23 is Worst Radius.

- **class:**
  - WDBC-Malignant
  - WDBC-Benign

Summary Statistics

radius (mean):	6.981	28.11

Creator Dr. William H. Wolberg, W. Nick Street, Olvi L. Mangasarian

Donor Nick Street

Date November, 1995

This is a copy of UCI ML Breast Cancer Wisconsin (Diagnostic) datasets. https://goo.gl/U2Uwz2

Features are computed from a digitized image of a fine needle aspirate (FNA) of a breast mass. They describe characteristics of the cell nuclei present in the image.

Separating plane described above was obtained using Multisurface Method-Tree (MSM-T) [K. P. Bennett, "Decision Tree Construction Via Linear Programming." Proceedings of the 4th Midwest Artificial Intelligence and Cognitive Science Society, pp. 97-101, 1992], a classification method which uses linear programming to construct a decision tree. Relevant features were selected using an exhaustive search in the space of 1-4 features and 1-3 separating planes.

The actual linear program used to obtain the separating plane in the 3-dimensional space is that described in: [K. P. Bennett and O. L. Mangasarian: "Robust Linear Programming Discrimination of Two Linearly Inseparable Sets", Optimization Methods and Software 1, 1992, 23-34].

This database is also available through the UW CS ftp server:

ftp ftp.cs.wisc.edu cd math-prog/cpo-dataset/machine-learn/WDBC/

4.7.3 Real world datasets

scikit-learn provides tools to load larger datasets, downloading them if necessary.

They can be loaded using the following functions:

fetch_olivetti_faces([data_home, shuffle, ...])	Load the Olivetti faces data-set from AT&T (classification).
fetch_20newsgroups([data_home, subset, ...])	Load the filenames and data from the 20 newsgroups dataset (classification).
fetch_20newsgroups_vectorized([subset, ...])	Load the 20 newsgroups dataset and vectorize it into token counts (classification).
fetch_lfw_people([data_home, funneled, ...])	Load the Labeled Faces in the Wild (LFW) people dataset (classification).
fetch_lfw_pairs([subset, data_home, ...])	Load the Labeled Faces in the Wild (LFW) pairs dataset (classification).
fetch_covtype([data_home, ...])	Load the covertype dataset (classification).
fetch_rcv1([data_home, subset, ...])	Load the RCV1 multilabel dataset (classification).
fetch_kddcup99([subset, data_home, shuffle, ...])	Load the kddcup99 dataset (classification).
fetch_california_housing([data_home, ...])	Load the California housing dataset (regression).

The Olivetti faces dataset

This dataset contains a set of face images taken between April 1992 and April 1994 at AT&T Laboratories Cambridge. The *sklearn.datasets.fetch_olivetti_faces* function is the data fetching / caching function that downloads the data archive from AT&T.

As described on the original website:

There are ten different images of each of 40 distinct subjects. For some subjects, the images were taken at different times, varying the lighting, facial expressions (open / closed eyes, smiling / not smiling) and facial details (glasses / no glasses). All the images were taken against a dark homogeneous background with the subjects in an upright, frontal position (with tolerance for some side movement).

Data Set Characteristics:

Classes	40
Samples total	400
Dimensionality	4096
Features	real, between 0 and 1

The image is quantized to 256 grey levels and stored as unsigned 8-bit integers; the loader will convert these to floating point values on the interval [0, 1], which are easier to work with for many algorithms.

The "target" for this database is an integer from 0 to 39 indicating the identity of the person pictured; however, with only 10 examples per class, this relatively small dataset is more interesting from an unsupervised or semi-supervised perspective.

The original dataset consisted of 92 x 112, while the version available here consists of 64x64 images.

When using these images, please give credit to AT&T Laboratories Cambridge.

The 20 newsgroups text dataset

The 20 newsgroups dataset comprises around 18000 newsgroups posts on 20 topics split in two subsets: one for training (or development) and the other one for testing (or for performance evaluation). The split between the train and test set is based upon a messages posted before and after a specific date.

This module contains two loaders. The first one, *sklearn.datasets.fetch_20newsgroups*, returns a list of the raw texts that can be fed to text feature extractors such as *sklearn.feature_extraction.text.CountVectorizer* with custom parameters so as to extract feature vectors. The second one, *sklearn.datasets.fetch_20newsgroups_vectorized*, returns ready-to-use features, i.e., it is not necessary to use a feature extractor.

Data Set Characteristics:

Classes	20
Samples total	18846
Dimensionality	1
Features	text

Usage

The *sklearn.datasets.fetch_20newsgroups* function is a data fetching / caching functions that downloads the data archive from the original 20 newsgroups website, extracts the archive contents in the `~/scikit_learn_data/20news_home` folder and calls the *sklearn.datasets.load_files* on either the training or testing set folder, or both of them:

```
>>> from sklearn.datasets import fetch_20newsgroups
>>> newsgroups_train = fetch_20newsgroups(subset='train')

>>> from pprint import pprint
>>> pprint(list(newsgroups_train.target_names))
```

(continues on next page)

(continued from previous page)

```
['alt.atheism',
 'comp.graphics',
 'comp.os.ms-windows.misc',
 'comp.sys.ibm.pc.hardware',
 'comp.sys.mac.hardware',
 'comp.windows.x',
 'misc.forsale',
 'rec.autos',
 'rec.motorcycles',
 'rec.sport.baseball',
 'rec.sport.hockey',
 'sci.crypt',
 'sci.electronics',
 'sci.med',
 'sci.space',
 'soc.religion.christian',
 'talk.politics.guns',
 'talk.politics.mideast',
 'talk.politics.misc',
 'talk.religion.misc']
```

The real data lies in the `filenames` and `target` attributes. The target attribute is the integer index of the category:

```
>>> newsgroups_train.filenames.shape
(11314,)
>>> newsgroups_train.target.shape
(11314,)
>>> newsgroups_train.target[:10]
array([ 7,  4,  4,  1, 14, 16, 13,  3,  2,  4])
```

It is possible to load only a sub-selection of the categories by passing the list of the categories to load to the *sklearn.datasets.fetch_20newsgroups* function:

```
>>> cats = ['alt.atheism', 'sci.space']
>>> newsgroups_train = fetch_20newsgroups(subset='train', categories=cats)

>>> list(newsgroups_train.target_names)
['alt.atheism', 'sci.space']
>>> newsgroups_train.filenames.shape
(1073,)
>>> newsgroups_train.target.shape
(1073,)
>>> newsgroups_train.target[:10]
array([0, 1, 1, 1, 0, 1, 1, 0, 0, 0])
```

Converting text to vectors

In order to feed predictive or clustering models with the text data, one first need to turn the text into vectors of numerical values suitable for statistical analysis. This can be achieved with the utilities of the `sklearn.feature_extraction.text` as demonstrated in the following example that extract TF-IDF vectors of unigram tokens from a subset of 20news:

```
>>> from sklearn.feature_extraction.text import TfidfVectorizer
>>> categories = ['alt.atheism', 'talk.religion.misc',
```

(continues on next page)

(continued from previous page)

```
...                'comp.graphics', 'sci.space']
>>> newsgroups_train = fetch_20newsgroups(subset='train',
...                                       categories=categories)
>>> vectorizer = TfidfVectorizer()
>>> vectors = vectorizer.fit_transform(newsgroups_train.data)
>>> vectors.shape
(2034, 34118)
```

The extracted TF-IDF vectors are very sparse, with an average of 159 non-zero components by sample in a more than 30000-dimensional space (less than .5% non-zero features):

```
>>> vectors.nnz / float(vectors.shape[0])
159.01327...
```

sklearn.datasets.fetch_20newsgroups_vectorized is a function which returns ready-to-use token counts features instead of file names.

Filtering text for more realistic training

It is easy for a classifier to overfit on particular things that appear in the 20 Newsgroups data, such as newsgroup headers. Many classifiers achieve very high F-scores, but their results would not generalize to other documents that aren't from this window of time.

For example, let's look at the results of a multinomial Naive Bayes classifier, which is fast to train and achieves a decent F-score:

```
>>> from sklearn.naive_bayes import MultinomialNB
>>> from sklearn import metrics
>>> newsgroups_test = fetch_20newsgroups(subset='test',
...                                      categories=categories)
>>> vectors_test = vectorizer.transform(newsgroups_test.data)
>>> clf = MultinomialNB(alpha=.01)
>>> clf.fit(vectors, newsgroups_train.target)
MultinomialNB(alpha=0.01, class_prior=None, fit_prior=True)

>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(newsgroups_test.target, pred, average='macro')
0.88213...
```

(The example *Classification of text documents using sparse features* shuffles the training and test data, instead of segmenting by time, and in that case multinomial Naive Bayes gets a much higher F-score of 0.88. Are you suspicious yet of what's going on inside this classifier?)

Let's take a look at what the most informative features are:

```
>>> import numpy as np
>>> def show_top10(classifier, vectorizer, categories):
...     feature_names = np.asarray(vectorizer.get_feature_names())
...     for i, category in enumerate(categories):
...         top10 = np.argsort(classifier.coef_[i])[-10:]
...         print("%s: %s" % (category, " ".join(feature_names[top10])))
...
>>> show_top10(clf, vectorizer, newsgroups_train.target_names)
alt.atheism: edu it and in you that is of to the
comp.graphics: edu in graphics it is for and of to the
```

(continues on next page)

(continued from previous page)

```
sci.space: edu it that is in and space to of the
talk.religion.misc: not it you in is that and to of the
```

You can now see many things that these features have overfit to:

- Almost every group is distinguished by whether headers such as `NNTP-Posting-Host:` and `Distribution:` appear more or less often.
- Another significant feature involves whether the sender is affiliated with a university, as indicated either by their headers or their signature.
- The word "article" is a significant feature, based on how often people quote previous posts like this: "In article [article ID], [name] <[e-mail address]> wrote:"
- Other features match the names and e-mail addresses of particular people who were posting at the time.

With such an abundance of clues that distinguish newsgroups, the classifiers barely have to identify topics from text at all, and they all perform at the same high level.

For this reason, the functions that load 20 Newsgroups data provide a parameter called **remove**, telling it what kinds of information to strip out of each file. **remove** should be a tuple containing any subset of `('headers', 'footers', 'quotes')`, telling it to remove headers, signature blocks, and quotation blocks respectively.

```
>>> newsgroups_test = fetch_20newsgroups(subset='test',
...                                      remove=('headers', 'footers', 'quotes'),
...                                      categories=categories)
>>> vectors_test = vectorizer.transform(newsgroups_test.data)
>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(pred, newsgroups_test.target, average='macro')
0.77310...
```

This classifier lost over a lot of its F-score, just because we removed metadata that has little to do with topic classification. It loses even more if we also strip this metadata from the training data:

```
>>> newsgroups_train = fetch_20newsgroups(subset='train',
...                                       remove=('headers', 'footers', 'quotes'),
...                                       categories=categories)
>>> vectors = vectorizer.fit_transform(newsgroups_train.data)
>>> clf = MultinomialNB(alpha=.01)
>>> clf.fit(vectors, newsgroups_train.target)
MultinomialNB(alpha=0.01, class_prior=None, fit_prior=True)
```

```
>>> vectors_test = vectorizer.transform(newsgroups_test.data)
>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(newsgroups_test.target, pred, average='macro')
0.76995...
```

Some other classifiers cope better with this harder version of the task. Try running *Sample pipeline for text feature extraction and evaluation* with and without the `--filter` option to compare the results.

Recommendation

When evaluating text classifiers on the 20 Newsgroups data, you should strip newsgroup-related metadata. In scikit-learn, you can do this by setting `remove=('headers', 'footers', 'quotes')`. The F-score will be lower because it is more realistic.

Examples

- *Sample pipeline for text feature extraction and evaluation*
- *Classification of text documents using sparse features*

The Labeled Faces in the Wild face recognition dataset

This dataset is a collection of JPEG pictures of famous people collected over the internet, all details are available on the official website:

http://vis-www.cs.umass.edu/lfw/

Each picture is centered on a single face. The typical task is called Face Verification: given a pair of two pictures, a binary classifier must predict whether the two images are from the same person.

An alternative task, Face Recognition or Face Identification is: given the picture of the face of an unknown person, identify the name of the person by referring to a gallery of previously seen pictures of identified persons.

Both Face Verification and Face Recognition are tasks that are typically performed on the output of a model trained to perform Face Detection. The most popular model for Face Detection is called Viola-Jones and is implemented in the OpenCV library. The LFW faces were extracted by this face detector from various online websites.

Data Set Characteristics:

Classes	5749
Samples total	13233
Dimensionality	5828
Features	real, between 0 and 255

Usage

`scikit-learn` provides two loaders that will automatically download, cache, parse the metadata files, decode the jpeg and convert the interesting slices into memmapped numpy arrays. This dataset size is more than 200 MB. The first load typically takes more than a couple of minutes to fully decode the relevant part of the JPEG files into numpy arrays. If the dataset has been loaded once, the following times the loading times less than 200ms by using a memmapped version memoized on the disk in the `~/scikit_learn_data/lfw_home/` folder using `joblib`.

The first loader is used for the Face Identification task: a multi-class classification task (hence supervised learning):

```
>>> from sklearn.datasets import fetch_lfw_people
>>> lfw_people = fetch_lfw_people(min_faces_per_person=70, resize=0.4)

>>> for name in lfw_people.target_names:
...     print(name)
...
Ariel Sharon
Colin Powell
Donald Rumsfeld
George W Bush
Gerhard Schroeder
Hugo Chavez
Tony Blair
```

The default slice is a rectangular shape around the face, removing most of the background:

```
>>> lfw_people.data.dtype
dtype('float32')

>>> lfw_people.data.shape
(1288, 1850)

>>> lfw_people.images.shape
(1288, 50, 37)
```

Each of the `1140` faces is assigned to a single person id in the `target` array:

```
>>> lfw_people.target.shape
(1288,)

>>> list(lfw_people.target[:10])
[5, 6, 3, 1, 0, 1, 3, 4, 3, 0]
```

The second loader is typically used for the face verification task: each sample is a pair of two picture belonging or not to the same person:

```
>>> from sklearn.datasets import fetch_lfw_pairs
>>> lfw_pairs_train = fetch_lfw_pairs(subset='train')

>>> list(lfw_pairs_train.target_names)
['Different persons', 'Same person']

>>> lfw_pairs_train.pairs.shape
(2200, 2, 62, 47)

>>> lfw_pairs_train.data.shape
(2200, 5828)

>>> lfw_pairs_train.target.shape
(2200,)
```

Both for the *`sklearn.datasets.fetch_lfw_people`* and *`sklearn.datasets.fetch_lfw_pairs`* function it is possible to get an additional dimension with the RGB color channels by passing `color=True`, in that case the shape will be `(2200, 2, 62, 47, 3)`.

The *`sklearn.datasets.fetch_lfw_pairs`* datasets is subdivided into 3 subsets: the development `train` set, the development `test` set and an evaluation `10_folds` set meant to compute performance metrics using a 10-folds cross validation scheme.

Examples

Faces recognition example using eigenfaces and SVMs

Forest covertypes

The samples in this dataset correspond to 30×30m patches of forest in the US, collected for the task of predicting each patch's cover type, i.e. the dominant species of tree. There are seven covertypes, making this a multiclass classification problem. Each sample has 54 features, described on the dataset's homepage. Some of the features are boolean indicators, while others are discrete or continuous measurements.

Data Set Characteristics:

Classes	7
Samples total	581012
Dimensionality	54
Features	int

sklearn.datasets.fetch_covtype will load the covertype dataset; it returns a dictionary-like object with the feature matrix in the `data` member and the target values in `target`. The dataset will be downloaded from the web if necessary.

RCV1 dataset

Reuters Corpus Volume I (RCV1) is an archive of over 800,000 manually categorized newswire stories made available by Reuters, Ltd. for research purposes. The dataset is extensively described in[1].

Data Set Characteristics:

Classes	103
Samples total	804414
Dimensionality	47236
Features	real, between 0 and 1

sklearn.datasets.fetch_rcv1 will load the following version: RCV1-v2, vectors, full sets, topics multilabels:

```
>>> from sklearn.datasets import fetch_rcv1
>>> rcv1 = fetch_rcv1()
```

It returns a dictionary-like object, with the following attributes:

`data`: The feature matrix is a scipy CSR sparse matrix, with 804414 samples and 47236 features. Non-zero values contains cosine-normalized, log TF-IDF vectors. A nearly chronological split is proposed in[1]: The first 23149 samples are the training set. The last 781265 samples are the testing set. This follows the official LYRL2004 chronological split. The array has 0.16% of non zero values:

```
>>> rcv1.data.shape
(804414, 47236)
```

`target`: The target values are stored in a scipy CSR sparse matrix, with 804414 samples and 103 categories. Each sample has a value of 1 in its categories, and 0 in others. The array has 3.15% of non zero values:

```
>>> rcv1.target.shape
(804414, 103)
```

[1] Lewis, D. D., Yang, Y., Rose, T. G., & Li, F. (2004). RCV1: A new benchmark collection for text categorization research. The Journal of Machine Learning Research, 5, 361-397.

`sample_id`: Each sample can be identified by its ID, ranging (with gaps) from 2286 to 810596:

```
>>> rcv1.sample_id[:3]
array([2286, 2287, 2288], dtype=uint32)
```

`target_names`: The target values are the topics of each sample. Each sample belongs to at least one topic, and to up to 17 topics. There are 103 topics, each represented by a string. Their corpus frequencies span five orders of magnitude, from 5 occurrences for 'GMIL', to 381327 for 'CCAT':

```
>>> rcv1.target_names[:3].tolist()
['E11', 'ECAT', 'M11']
```

The dataset will be downloaded from the rcv1 homepage if necessary. The compressed size is about 656 MB.

References

Kddcup 99 dataset

The KDD Cup '99 dataset was created by processing the tcpdump portions of the 1998 DARPA Intrusion Detection System (IDS) Evaluation dataset, created by MIT Lincoln Lab [1]. The artificial data (described on the dataset's homepage) was generated using a closed network and hand-injected attacks to produce a large number of different types of attack with normal activity in the background. As the initial goal was to produce a large training set for supervised learning algorithms, there is a large proportion (80.1%) of abnormal data which is unrealistic in real world, and inappropriate for unsupervised anomaly detection which aims at detecting 'abnormal' data, ie

1) qualitatively different from normal data

2) in large minority among the observations.

We thus transform the KDD Data set into two different data sets: SA and SF.

-SA is obtained by simply selecting all the normal data, and a small proportion of abnormal data to gives an anomaly proportion of 1%.

-SF is obtained as in [2] by simply picking up the data whose attribute logged_in is positive, thus focusing on the intrusion attack, which gives a proportion of 0.3% of attack.

-http and smtp are two subsets of SF corresponding with third feature equal to 'http' (resp. to 'smtp')

General KDD structure :

Samples total	4898431
Dimensionality	41
Features	discrete (int) or continuous (float)
Targets	str, 'normal.' or name of the anomaly type

SA structure :

Samples total	976158
Dimensionality	41
Features	discrete (int) or continuous (float)
Targets	str, 'normal.' or name of the anomaly type

SF structure :

Samples total	699691
Dimensionality	4
Features	discrete (int) or continuous (float)
Targets	str, 'normal.' or name of the anomaly type

http structure :

Samples total	619052
Dimensionality	3
Features	discrete (int) or continuous (float)
Targets	str, 'normal.' or name of the anomaly type

smtp structure :

Samples total	95373
Dimensionality	3
Features	discrete (int) or continuous (float)
Targets	str, 'normal.' or name of the anomaly type

sklearn.datasets.fetch_kddcup99 will load the kddcup99 dataset; it returns a dictionary-like object with the feature matrix in the `data` member and the target values in `target`. The dataset will be downloaded from the web if necessary.

California Housing dataset

Data Set Characteristics:

Number of Instances 20640

Number of Attributes 8 numeric, predictive attributes and the target

Attribute Information

- MedInc median income in block
- HouseAge median house age in block
- AveRooms average number of rooms
- AveBedrms average number of bedrooms
- Population block population
- AveOccup average house occupancy
- Latitude house block latitude
- Longitude house block longitude

Missing Attribute Values None

This dataset was obtained from the StatLib repository. http://lib.stat.cmu.edu/datasets/

The target variable is the median house value for California districts.

This dataset was derived from the 1990 U.S. census, using one row per census block group. A block group is the smallest geographical unit for which the U.S. Census Bureau publishes sample data (a block group typically has a population of 600 to 3,000 people).

It can be downloaded/loaded using the `sklearn.datasets.fetch_california_housing` function.

4.7.4 Generated datasets

In addition, scikit-learn includes various random sample generators that can be used to build artificial datasets of controlled size and complexity.

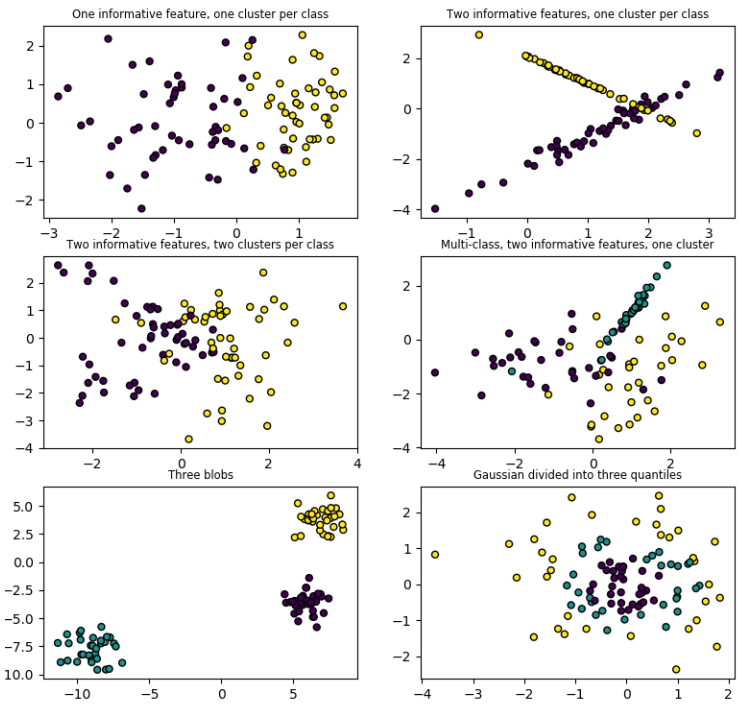
Generators for classification and clustering

These generators produce a matrix of features and corresponding discrete targets.

Single label

Both `make_blobs` and `make_classification` create multiclass datasets by allocating each class one or more normally-distributed clusters of points. `make_blobs` provides greater control regarding the centers and standard deviations of each cluster, and is used to demonstrate clustering. `make_classification` specialises in introducing noise by way of: correlated, redundant and uninformative features; multiple Gaussian clusters per class; and linear transformations of the feature space.

`make_gaussian_quantiles` divides a single Gaussian cluster into near-equal-size classes separated by concentric hyperspheres. `make_hastie_10_2` generates a similar binary, 10-dimensional problem.

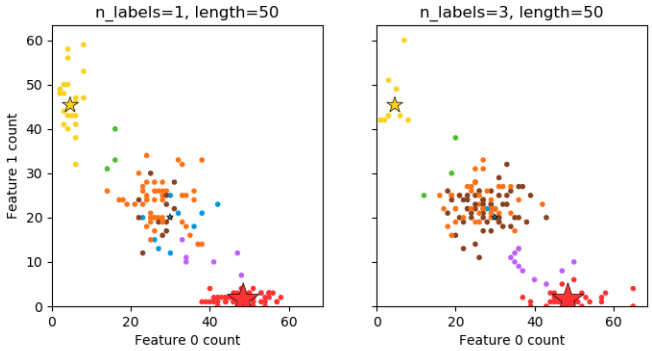


make_circles and *make_moons* generate 2d binary classification datasets that are challenging to certain algorithms (e.g. centroid-based clustering or linear classification), including optional Gaussian noise. They are useful for visualisation. *make_circles* produces Gaussian data with a spherical decision boundary for binary classification, while *make_moons* produces two interleaving half circles.

Multilabel

make_multilabel_classification generates random samples with multiple labels, reflecting a bag of words drawn from a mixture of topics. The number of topics for each document is drawn from a Poisson distribution, and the topics themselves are drawn from a fixed random distribution. Similarly, the number of words is drawn from Poisson, with words drawn from a multinomial, where each topic defines a probability distribution over words. Simplifications with respect to true bag-of-words mixtures include:

- Per-topic word distributions are independently drawn, where in reality all would be affected by a sparse base distribution, and would be correlated.
- For a document generated from multiple topics, all topics are weighted equally in generating its bag of words.
- Documents without labels words at random, rather than from a base distribution.



Biclustering

make_biclusters(shape, n_clusters[, noise, ...])	Generate an array with constant block diagonal structure for biclustering.
make_checkerboard(shape, n_clusters[, ...])	Generate an array with block checkerboard structure for biclustering.

Generators for regression

make_regression produces regression targets as an optionally-sparse random linear combination of random features, with noise. Its informative features may be uncorrelated, or low rank (few features account for most of the variance).

Other regression generators generate functions deterministically from randomized features. *make_sparse_uncorrelated* produces a target as a linear combination of four features with fixed coefficients. Others encode explicitly non-linear relations: *make_friedman1* is related by polynomial and sine transforms; *make_friedman2* includes feature multiplication and reciprocation; and *make_friedman3* is similar with an arctan transformation on the target.

Generators for manifold learning

make_s_curve([n_samples, noise, random_state])	Generate an S curve dataset.
make_swiss_roll([n_samples, noise, random_state])	Generate a swiss roll dataset.

Generators for decomposition

make_low_rank_matrix([n_samples, ...])	Generate a mostly low rank matrix with bell-shaped singular values
make_sparse_coded_signal(n_samples, ...[, ...])	Generate a signal as a sparse combination of dictionary elements.
make_spd_matrix(n_dim[, random_state])	Generate a random symmetric, positive-definite matrix.
make_sparse_spd_matrix([dim, alpha, ...])	Generate a sparse symmetric definite positive matrix.

4.7.5 Loading other datasets

Sample images

Scikit-learn also embed a couple of sample JPEG images published under Creative Commons license by their authors. Those images can be useful to test algorithms and pipeline on 2D data.

load_sample_images()	Load sample images for image manipulation.
load_sample_image(image_name)	Load the numpy array of a single sample image

Warning: The default coding of images is based on the `uint8` dtype to spare memory. Often machine learning algorithms work best if the input is converted to a floating point representation first. Also, if you plan to use `matplotlib.pyplpt.imshow` don't forget to scale to the range 0 - 1 as done in the following example.

Examples:

- *Color Quantization using K-Means*

Datasets in svmlight / libsvm format

scikit-learn includes utility functions for loading datasets in the svmlight / libsvm format. In this format, each line takes the form `<label> <feature-id>:<feature-value> <feature-id>:<feature-value> ..`

.. This format is especially suitable for sparse datasets. In this module, scipy sparse CSR matrices are used for `X` and numpy arrays are used for `y`.

You may load a dataset like as follows:

```
>>> from sklearn.datasets import load_svmlight_file
>>> X_train, y_train = load_svmlight_file("/path/to/train_dataset.txt")
...
```

You may also load two (or more) datasets at once:

```
>>> X_train, y_train, X_test, y_test = load_svmlight_files(
...     ("/path/to/train_dataset.txt", "/path/to/test_dataset.txt"))
...
```

In this case, `X_train` and `X_test` are guaranteed to have the same number of features. Another way to achieve the same result is to fix the number of features:

```
>>> X_test, y_test = load_svmlight_file(
...     "/path/to/test_dataset.txt", n_features=X_train.shape[1])
...
```

Downloading datasets from the openml.org repository

openml.org is a public repository for machine learning data and experiments, that allows everybody to upload open datasets.

The `sklearn.datasets` package is able to download datasets from the repository using the function *`sklearn.datasets.fetch_openml`*.

For example, to download a dataset of gene expressions in mice brains:

```
>>> from sklearn.datasets import fetch_openml
>>> mice = fetch_openml(name='miceprotein', version=4)
```

To fully specify a dataset, you need to provide a name and a version, though the version is optional, see *Dataset Versions* below. The dataset contains a total of 1080 examples belonging to 8 different classes:

```
>>> mice.data.shape
(1080, 77)
>>> mice.target.shape
(1080,)
>>> np.unique(mice.target)
array(['c-CS-m', 'c-CS-s', 'c-SC-m', 'c-SC-s', 't-CS-m', 't-CS-s', 't-SC-m', 't-SC-s
↪'], dtype=object)
```

You can get more information on the dataset by looking at the `DESCR` and `details` attributes:

```
>>> print(mice.DESCR)
**Author**: Clara Higuera, Katheleen J. Gardiner, Krzysztof J. Cios
**Source**: [UCI](https://archive.ics.uci.edu/ml/datasets/Mice+Protein+Expression) -␣
↪2015
**Please cite**: Higuera C, Gardiner KJ, Cios KJ (2015) Self-Organizing
Feature Maps Identify Proteins Critical to Learning in a Mouse Model of Down
Syndrome. PLoS ONE 10(6): e0129126...

>>> mice.details
{'id': '40966', 'name': 'MiceProtein', 'version': '4', 'format': 'ARFF',
'upload_date': '2017-11-08T16:00:15', 'licence': 'Public',
'url': 'https://www.openml.org/data/v1/download/17928620/MiceProtein.arff',
'file_id': '17928620', 'default_target_attribute': 'class',
'row_id_attribute': 'MouseID',
'ignore_attribute': ['Genotype', 'Treatment', 'Behavior'],
'tag': ['OpenML-CC18', 'study_135', 'study_98', 'study_99'],
'visibility': 'public', 'status': 'active',
'md5_checksum': '3c479a6885bfa0438971388283a1ce32'}
```

The `DESCR` contains a free-text description of the data, while `details` contains a dictionary of meta-data stored by openml, like the dataset id. For more details, see the OpenML documentation The `data_id` of the mice protein dataset is 40966, and you can use this (or the name) to get more information on the dataset on the openml website:

```
>>> mice.url
'https://www.openml.org/d/40966'
```

The `data_id` also uniquely identifies a dataset from OpenML:

```
>>> mice = fetch_openml(data_id=40966)
>>> mice.details
{'id': '4550', 'name': 'MiceProtein', 'version': '1', 'format': 'ARFF',
'creator': ...,
'upload_date': '2016-02-17T14:32:49', 'licence': 'Public', 'url':
'https://www.openml.org/data/v1/download/1804243/MiceProtein.ARFF', 'file_id':
'1804243', 'default_target_attribute': 'class', 'citation': 'Higuera C,
Gardiner KJ, Cios KJ (2015) Self-Organizing Feature Maps Identify Proteins
Critical to Learning in a Mouse Model of Down Syndrome. PLoS ONE 10(6):
e0129126. [Web Link] journal.pone.0129126', 'tag': ['OpenML100', 'study_14',
'study_34'], 'visibility': 'public', 'status': 'active', 'md5_checksum':
'3c479a6885bfa0438971388283a1ce32'}
```

Dataset Versions

A dataset is uniquely specified by its `data_id`, but not necessarily by its name. Several different "versions" of a dataset with the same name can exist which can contain entirely different datasets. If a particular version of a dataset has been found to contain significant issues, it might be deactivated. Using a name to specify a dataset will yield the earliest version of a dataset that is still active. That means that `fetch_openml(name="miceprotein")` can yield different results at different times if earlier versions become inactive. You can see that the dataset with `data_id` 40966 that we fetched above is the version 1 of the "miceprotein" dataset:

```
>>> mice.details['version']
'1'
```

In fact, this dataset only has one version. The iris dataset on the other hand has multiple versions:

```
>>> iris = fetch_openml(name="iris")
>>> iris.details['version']
'1'
>>> iris.details['id']
'61'

>>> iris_61 = fetch_openml(data_id=61)
>>> iris_61.details['version']
'1'
>>> iris_61.details['id']
'61'

>>> iris_969 = fetch_openml(data_id=969)
>>> iris_969.details['version']
'3'
>>> iris_969.details['id']
'969'
```

Specifying the dataset by the name "iris" yields the lowest version, version 1, with the `data_id` 61. To make sure you always get this exact dataset, it is safest to specify it by the dataset `data_id`. The other dataset, with `data_id` 969, is version 3 (version 2 has become inactive), and contains a binarized version of the data:

```
>>> np.unique(iris_969.target)
array(['N', 'P'], dtype=object)
```

You can also specify both the name and the version, which also uniquely identifies the dataset:

```
>>> iris_version_3 = fetch_openml(name="iris", version=3)
>>> iris_version_3.details['version']
'3'
>>> iris_version_3.details['id']
'969'
```

Loading from external datasets

scikit-learn works on any numeric data stored as numpy arrays or scipy sparse matrices. Other types that are convertible to numeric arrays such as pandas DataFrame are also acceptable.

Here are some recommended ways to load standard columnar data into a format usable by scikit-learn:

- pandas.io provides tools to read data from common formats including CSV, Excel, JSON and SQL. DataFrames may also be constructed from lists of tuples or dicts. Pandas handles heterogeneous data smoothly and provides tools for manipulation and conversion into a numeric array suitable for scikit-learn.
- scipy.io specializes in binary formats often used in scientific computing context such as .mat and .arff
- numpy/routines.io for standard loading of columnar data into numpy arrays
- scikit-learn's `datasets.load_svmlight_file` for the svmlight or libSVM sparse format

- scikit-learn's `datasets.load_files` for directories of text files where the name of each directory is the name of each category and each file inside of each directory corresponds to one sample from that category

For some miscellaneous data such as images, videos, and audio, you may wish to refer to:

- skimage.io or Imageio for loading images and videos into numpy arrays
- scipy.io.wavfile.read for reading WAV files into a numpy array

Categorical (or nominal) features stored as strings (common in pandas DataFrames) will need converting to numerical features using *`sklearn.preprocessing.OneHotEncoder`* or *`sklearn.preprocessing.OrdinalEncoder`* or similar. See *Preprocessing data*.

Note: if you manage your own numerical data it is recommended to use an optimized file format such as HDF5 to reduce data load times. Various libraries such as H5Py, PyTables and pandas provides a Python interface for reading and writing data in that format.

4.8 Computing with scikit-learn

4.8.1 Strategies to scale computationally: bigger data

For some applications the amount of examples, features (or both) and/or the speed at which they need to be processed are challenging for traditional approaches. In these cases scikit-learn has a number of options you can consider to make your system scale.

Scaling with instances using out-of-core learning

Out-of-core (or "external memory") learning is a technique used to learn from data that cannot fit in a computer's main memory (RAM).

Here is a sketch of a system designed to achieve this goal:

1. a way to stream instances
2. a way to extract features from instances
3. an incremental algorithm

Streaming instances

Basically, 1. may be a reader that yields instances from files on a hard drive, a database, from a network stream etc. However, details on how to achieve this are beyond the scope of this documentation.

Extracting features

2. could be any relevant way to extract features among the different *feature extraction* methods supported by scikit-learn. However, when working with data that needs vectorization and where the set of features or values is not known in advance one should take explicit care. A good example is text classification where unknown terms are likely to be found during training. It is possible to use a stateful vectorizer if making multiple passes over the data is reasonable from an application point of view. Otherwise, one can turn up the difficulty by using a stateless feature extractor. Currently the preferred way to do this is to use the so-called *hashing trick* as implemented by *`sklearn.feature_extraction.FeatureHasher`* for datasets with categorical variables represented as list of Python dicts or *`sklearn.feature_extraction.text.HashingVectorizer`* for text documents.

Incremental learning

Finally, for 3. we have a number of options inside scikit-learn. Although not all algorithms can learn incrementally (i.e. without seeing all the instances at once), all estimators implementing the `partial_fit` API are candidates. Actually, the ability to learn incrementally from a mini-batch of instances (sometimes called "online learning") is key to out-of-core learning as it guarantees that at any given time there will be only a small amount of instances in the main memory. Choosing a good size for the mini-batch that balances relevancy and memory footprint could involve some tuning[1].

Here is a list of incremental estimators for different tasks:

- **Classification**
  - *sklearn.naive_bayes.MultinomialNB*
  - *sklearn.naive_bayes.BernoulliNB*
  - *sklearn.linear_model.Perceptron*
  - *sklearn.linear_model.SGDClassifier*
  - *sklearn.linear_model.PassiveAggressiveClassifier*
  - *sklearn.neural_network.MLPClassifier*
- **Regression**
  - *sklearn.linear_model.SGDRegressor*
  - *sklearn.linear_model.PassiveAggressiveRegressor*
  - *sklearn.neural_network.MLPRegressor*
- **Clustering**
  - *sklearn.cluster.MiniBatchKMeans*
  - *sklearn.cluster.Birch*
- **Decomposition / feature Extraction**
  - *sklearn.decomposition.MiniBatchDictionaryLearning*
  - *sklearn.decomposition.IncrementalPCA*
  - *sklearn.decomposition.LatentDirichletAllocation*
- **Preprocessing**
  - *sklearn.preprocessing.StandardScaler*
  - *sklearn.preprocessing.MinMaxScaler*
  - *sklearn.preprocessing.MaxAbsScaler*

For classification, a somewhat important thing to note is that although a stateless feature extraction routine may be able to cope with new/unseen attributes, the incremental learner itself may be unable to cope with new/unseen targets classes. In this case you have to pass all the possible classes to the first `partial_fit` call using the `classes=` parameter.

Another aspect to consider when choosing a proper algorithm is that not all of them put the same importance on each example over time. Namely, the `Perceptron` is still sensitive to badly labeled examples even after many examples whereas the `SGD*` and `PassiveAggressive*` families are more robust to this kind of artifacts. Conversely, the

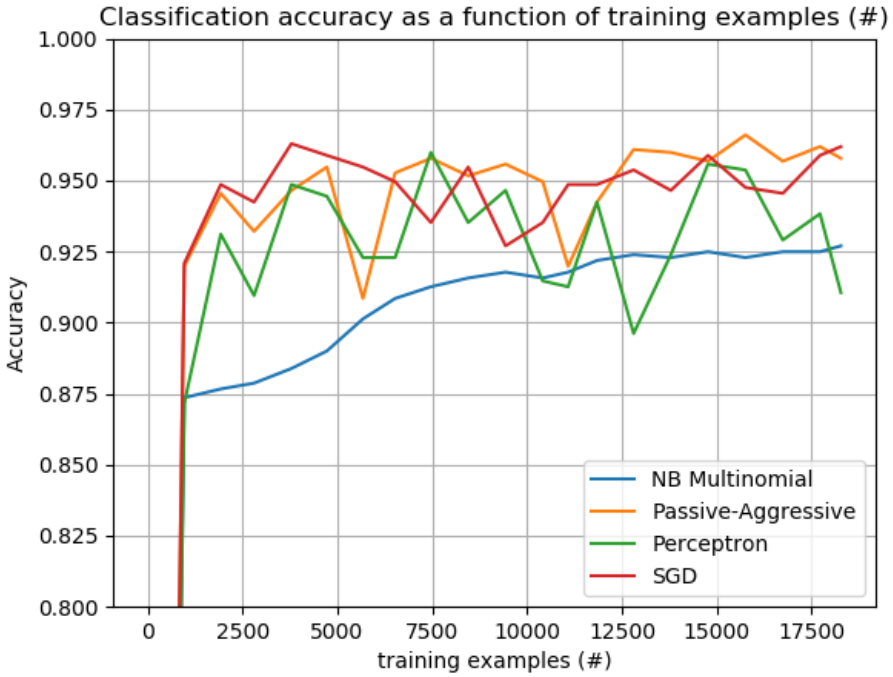
[1] Depending on the algorithm the mini-batch size can influence results or not. SGD*, PassiveAggressive*, and discrete NaiveBayes are truly online and are not affected by batch size. Conversely, MiniBatchKMeans convergence rate is affected by the batch size. Also, its memory footprint can vary dramatically with batch size.

latter also tend to give less importance to remarkably different, yet properly labeled examples when they come late in the stream as their learning rate decreases over time.

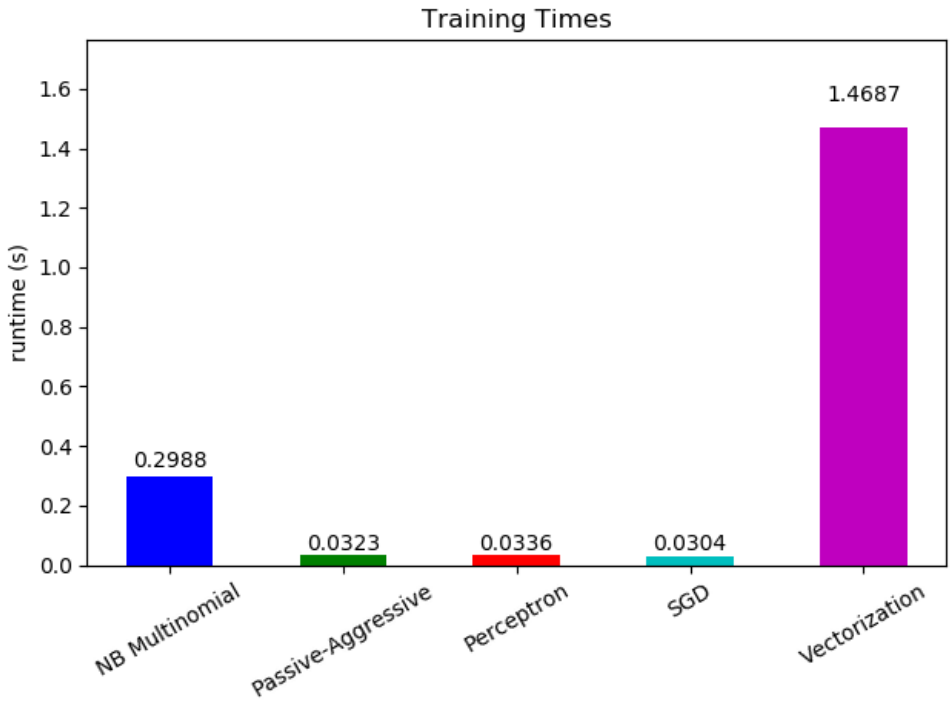
Examples

Finally, we have a full-fledged example of *Out-of-core classification of text documents*. It is aimed at providing a starting point for people wanting to build out-of-core learning systems and demonstrates most of the notions discussed above.

Furthermore, it also shows the evolution of the performance of different algorithms with the number of processed examples.



Now looking at the computation time of the different parts, we see that the vectorization is much more expensive than learning itself. From the different algorithms, `MultinomialNB` is the most expensive, but its overhead can be mitigated by increasing the size of the mini-batches (exercise: change `minibatch_size` to 100 and 10000 in the program and compare).



Notes

4.8.2 Computational Performance

For some applications the performance (mainly latency and throughput at prediction time) of estimators is crucial. It may also be of interest to consider the training throughput but this is often less important in a production setup (where it often takes place offline).

We will review here the orders of magnitude you can expect from a number of scikit-learn estimators in different contexts and provide some tips and tricks for overcoming performance bottlenecks.

Prediction latency is measured as the elapsed time necessary to make a prediction (e.g. in micro-seconds). Latency is often viewed as a distribution and operations engineers often focus on the latency at a given percentile of this distribution (e.g. the 90 percentile).

Prediction throughput is defined as the number of predictions the software can deliver in a given amount of time (e.g. in predictions per second).

An important aspect of performance optimization is also that it can hurt prediction accuracy. Indeed, simpler models (e.g. linear instead of non-linear, or with fewer parameters) often run faster but are not always able to take into account the same exact properties of the data as more complex ones.

Prediction Latency

One of the most straight-forward concerns one may have when using/choosing a machine learning toolkit is the latency at which predictions can be made in a production environment.

The main factors that influence the prediction latency are

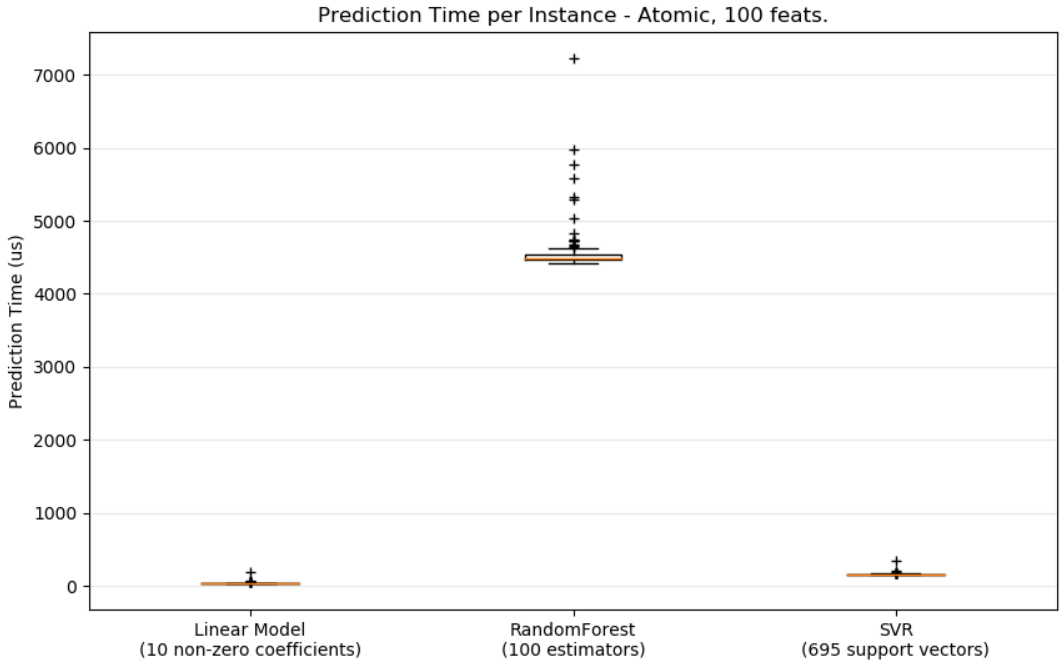
1. Number of features

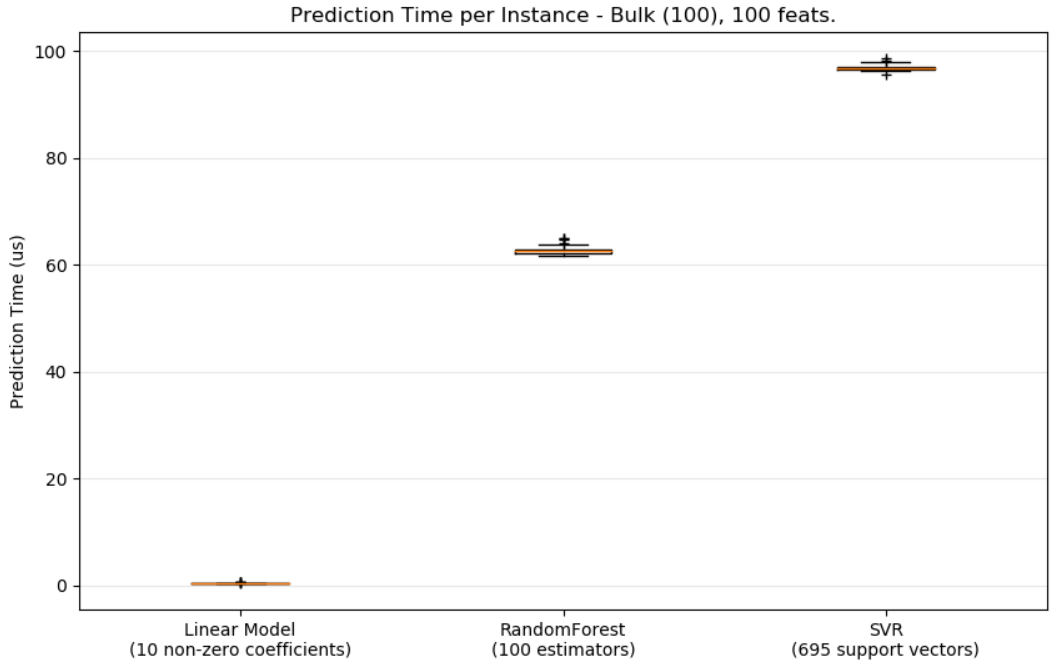
2. Input data representation and sparsity
3. Model complexity
4. Feature extraction

A last major parameter is also the possibility to do predictions in bulk or one-at-a-time mode.

Bulk versus Atomic mode

In general doing predictions in bulk (many instances at the same time) is more efficient for a number of reasons (branching predictability, CPU cache, linear algebra libraries optimizations etc.). Here we see on a setting with few features that independently of estimator choice the bulk mode is always faster, and for some of them by 1 to 2 orders of magnitude:





To benchmark different estimators for your case you can simply change the `n_features` parameter in this example: *Prediction Latency*. This should give you an estimate of the order of magnitude of the prediction latency.

Configuring Scikit-learn for reduced validation overhead

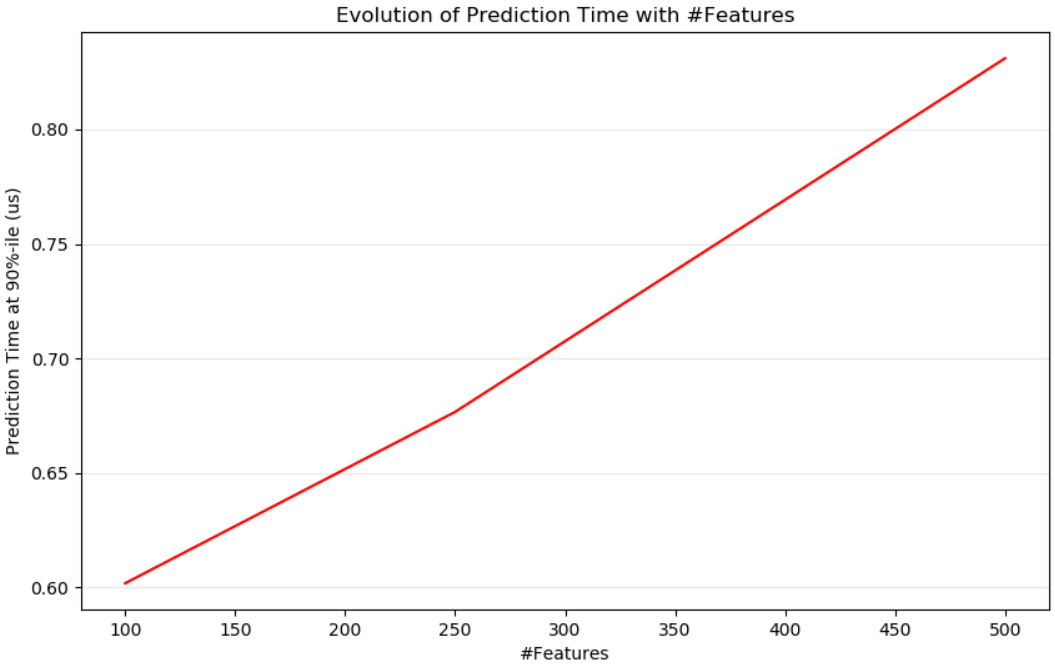
Scikit-learn does some validation on data that increases the overhead per call to `predict` and similar functions. In particular, checking that features are finite (not NaN or infinite) involves a full pass over the data. If you ensure that your data is acceptable, you may suppress checking for finiteness by setting the environment variable `SKLEARN_ASSUME_FINITE` to a non-empty string before importing scikit-learn, or configure it in Python with *`sklearn.set_config`*. For more control than these global settings, a `config_context` allows you to set this configuration within a specified context:

```
>>> import sklearn
>>> with sklearn.config_context(assume_finite=True):
...     pass  # do learning/prediction here with reduced validation
```

Note that this will affect all uses of *`sklearn.utils.assert_all_finite`* within the context.

Influence of the Number of Features

Obviously when the number of features increases so does the memory consumption of each example. Indeed, for a matrix of M instances with N features, the space complexity is in $O(NM)$. From a computing perspective it also means that the number of basic operations (e.g., multiplications for vector-matrix products in linear models) increases too. Here is a graph of the evolution of the prediction latency with the number of features:



Overall you can expect the prediction time to increase at least linearly with the number of features (non-linear cases can happen depending on the global memory footprint and estimator).

Influence of the Input Data Representation

Scipy provides sparse matrix data structures which are optimized for storing sparse data. The main feature of sparse formats is that you don't store zeros so if your data is sparse then you use much less memory. A non-zero value in a sparse (CSR or CSC) representation will only take on average one 32bit integer position + the 64 bit floating point value + an additional 32bit per row or column in the matrix. Using sparse input on a dense (or sparse) linear model can speedup prediction by quite a bit as only the non zero valued features impact the dot product and thus the model predictions. Hence if you have 100 non zeros in 1e6 dimensional space, you only need 100 multiply and add operation instead of 1e6.

Calculation over a dense representation, however, may leverage highly optimised vector operations and multithreading in BLAS, and tends to result in fewer CPU cache misses. So the sparsity should typically be quite high (10% non-zeros max, to be checked depending on the hardware) for the sparse input representation to be faster than the dense input representation on a machine with many CPUs and an optimized BLAS implementation.

Here is sample code to test the sparsity of your input:

```
def sparsity_ratio(X):
    return 1.0 - np.count_nonzero(X) / float(X.shape[0] * X.shape[1])
print("input sparsity ratio:", sparsity_ratio(X))
```

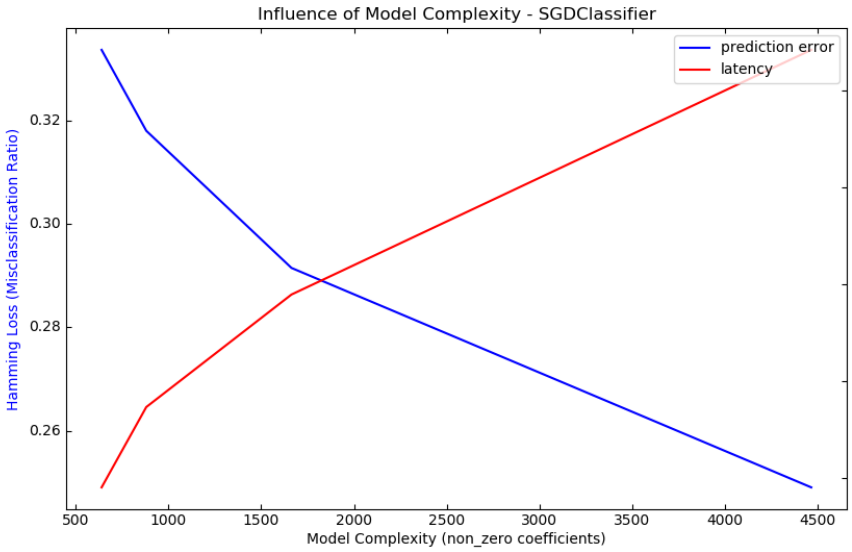
As a rule of thumb you can consider that if the sparsity ratio is greater than 90% you can probably benefit from sparse formats. Check Scipy's sparse matrix formats documentation for more information on how to build (or convert your data to) sparse matrix formats. Most of the time the `CSR` and `CSC` formats work best.

Influence of the Model Complexity

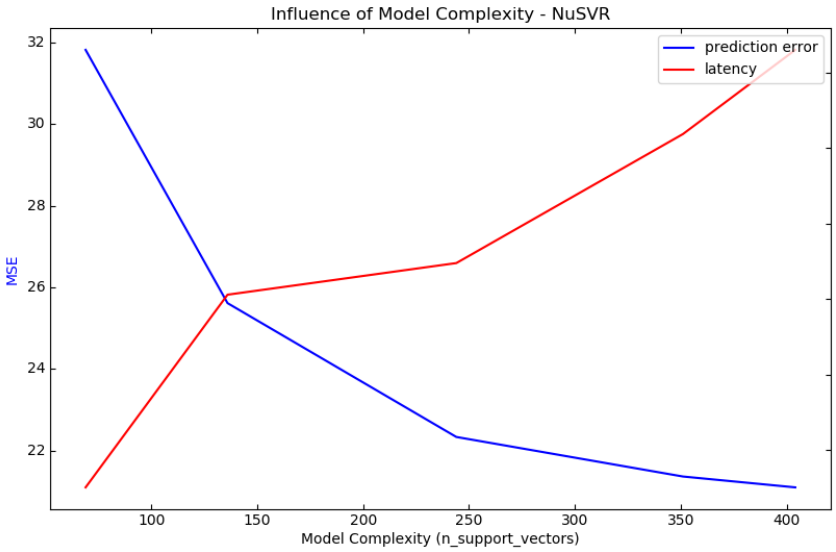
Generally speaking, when model complexity increases, predictive power and latency are supposed to increase. Increasing predictive power is usually interesting, but for many applications we would better not increase prediction latency too much. We will now review this idea for different families of supervised models.

For *sklearn.linear_model* (e.g. Lasso, ElasticNet, SGDClassifier/Regressor, Ridge & RidgeClassifier, PassiveAggressiveClassifier/Regressor, LinearSVC, LogisticRegression...) the decision function that is applied at prediction time is the same (a dot product) , so latency should be equivalent.

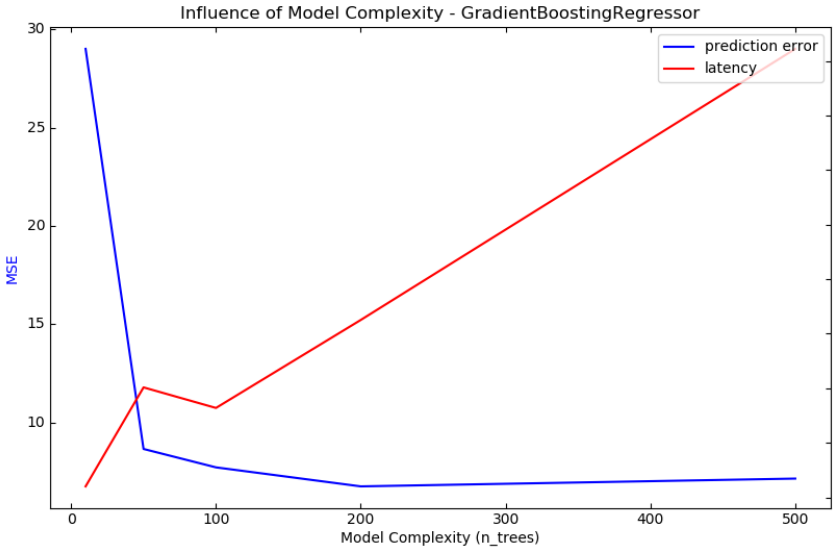
Here is an example using *sklearn.linear_model.SGDClassifier* with the `elasticnet` penalty. The regularization strength is globally controlled by the `alpha` parameter. With a sufficiently high `alpha`, one can then increase the `l1_ratio` parameter of `elasticnet` to enforce various levels of sparsity in the model coefficients. Higher sparsity here is interpreted as less model complexity as we need fewer coefficients to describe it fully. Of course sparsity influences in turn the prediction time as the sparse dot-product takes time roughly proportional to the number of non-zero coefficients.



For the *sklearn.svm* family of algorithms with a non-linear kernel, the latency is tied to the number of support vectors (the fewer the faster). Latency and throughput should (asymptotically) grow linearly with the number of support vectors in a SVC or SVR model. The kernel will also influence the latency as it is used to compute the projection of the input vector once per support vector. In the following graph the `nu` parameter of *sklearn.svm.NuSVR* was used to influence the number of support vectors.



For *sklearn.ensemble* of trees (e.g. RandomForest, GBT, ExtraTrees etc) the number of trees and their depth play the most important role. Latency and throughput should scale linearly with the number of trees. In this case we used directly the `n_estimators` parameter of `sklearn.ensemble.gradient_boosting.GradientBoostingRegressor`.

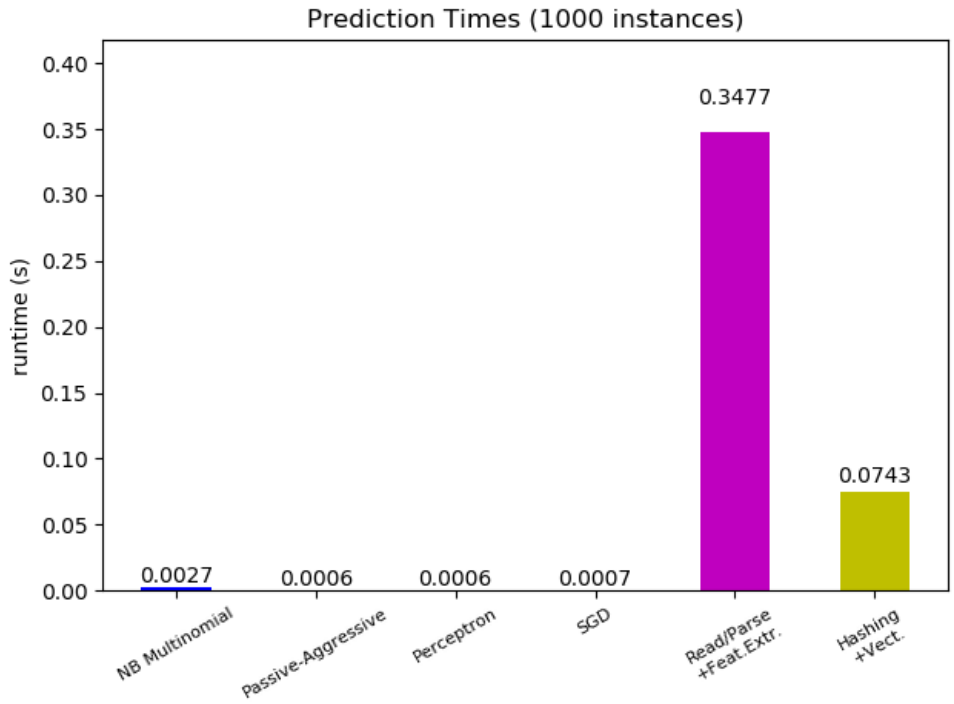


In any case be warned that decreasing model complexity can hurt accuracy as mentioned above. For instance a non-linearly separable problem can be handled with a speedy linear model but prediction power will very likely suffer in the process.

Feature Extraction Latency

Most scikit-learn models are usually pretty fast as they are implemented either with compiled Cython extensions or optimized computing libraries. On the other hand, in many real world applications the feature extraction process (i.e.

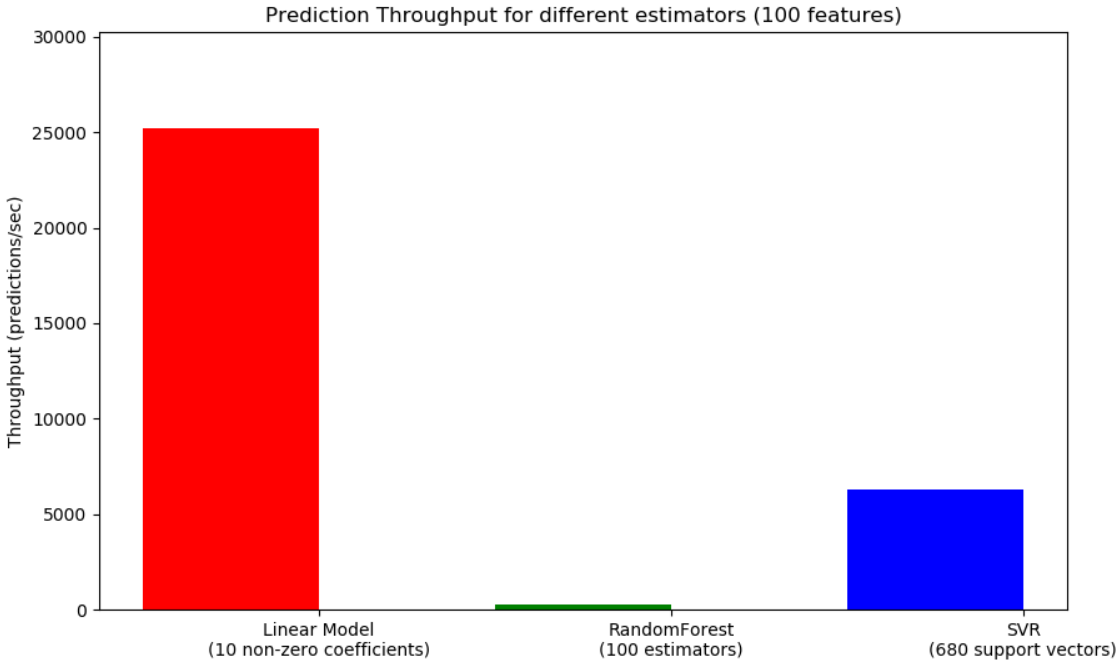
turning raw data like database rows or network packets into numpy arrays) governs the overall prediction time. For example on the Reuters text classification task the whole preparation (reading and parsing SGML files, tokenizing the text and hashing it into a common vector space) is taking 100 to 500 times more time than the actual prediction code, depending on the chosen model.



In many cases it is thus recommended to carefully time and profile your feature extraction code as it may be a good place to start optimizing when your overall latency is too slow for your application.

Prediction Throughput

Another important metric to care about when sizing production systems is the throughput i.e. the number of predictions you can make in a given amount of time. Here is a benchmark from the *Prediction Latency* example that measures this quantity for a number of estimators on synthetic data:



These throughputs are achieved on a single process. An obvious way to increase the throughput of your application is to spawn additional instances (usually processes in Python because of the GIL) that share the same model. One might also add machines to spread the load. A detailed explanation on how to achieve this is beyond the scope of this documentation though.

Tips and Tricks

Linear algebra libraries

As scikit-learn relies heavily on Numpy/Scipy and linear algebra in general it makes sense to take explicit care of the versions of these libraries. Basically, you ought to make sure that Numpy is built using an optimized BLAS / LAPACK library.

Not all models benefit from optimized BLAS and Lapack implementations. For instance models based on (randomized) decision trees typically do not rely on BLAS calls in their inner loops, nor do kernel SVMs (`SVC`, `SVR`, `NuSVC`, `NuSVR`). On the other hand a linear model implemented with a BLAS DGEMM call (via `numpy.dot`) will typically benefit hugely from a tuned BLAS implementation and lead to orders of magnitude speedup over a non-optimized BLAS.

You can display the BLAS / LAPACK implementation used by your NumPy / SciPy / scikit-learn install with the following commands:

```
from numpy.distutils.system_info import get_info
print(get_info('blas_opt'))
print(get_info('lapack_opt'))
```

Optimized BLAS / LAPACK implementations include:

- Atlas (need hardware specific tuning by rebuilding on the target machine)
- OpenBLAS

- MKL
- Apple Accelerate and vecLib frameworks (OSX only)

More information can be found on the Scipy install page and in this blog post from Daniel Nouri which has some nice step by step install instructions for Debian / Ubuntu.

Limiting Working Memory

Some calculations when implemented using standard numpy vectorized operations involve using a large amount of temporary memory. This may potentially exhaust system memory. Where computations can be performed in fixed-memory chunks, we attempt to do so, and allow the user to hint at the maximum size of this working memory (defaulting to 1GB) using *sklearn.set_config* or `config_context`. The following suggests to limit temporary working memory to 128 MiB:

```
>>> import sklearn
>>> with sklearn.config_context(working_memory=128):
...     pass  # do chunked work here
```

An example of a chunked operation adhering to this setting is `metric.pairwise_distances_chunked`, which facilitates computing row-wise reductions of a pairwise distance matrix.

Model Compression

Model compression in scikit-learn only concerns linear models for the moment. In this context it means that we want to control the model sparsity (i.e. the number of non-zero coordinates in the model vectors). It is generally a good idea to combine model sparsity with sparse input data representation.

Here is sample code that illustrates the use of the `sparsify()` method:

```
clf = SGDRegressor(penalty='elasticnet', l1_ratio=0.25)
clf.fit(X_train, y_train).sparsify()
clf.predict(X_test)
```

In this example we prefer the `elasticnet` penalty as it is often a good compromise between model compactness and prediction power. One can also further tune the `l1_ratio` parameter (in combination with the regularization strength `alpha`) to control this tradeoff.

A typical benchmark on synthetic data yields a >30% decrease in latency when both the model and input are sparse (with 0.000024 and 0.027400 non-zero coefficients ratio respectively). Your mileage may vary depending on the sparsity and size of your data and model. Furthermore, sparsifying can be very useful to reduce the memory usage of predictive models deployed on production servers.

Model Reshaping

Model reshaping consists in selecting only a portion of the available features to fit a model. In other words, if a model discards features during the learning phase we can then strip those from the input. This has several benefits. Firstly it reduces memory (and therefore time) overhead of the model itself. It also allows to discard explicit feature selection components in a pipeline once we know which features to keep from a previous run. Finally, it can help reduce processing time and I/O usage upstream in the data access and feature extraction layers by not collecting and building features that are discarded by the model. For instance if the raw data come from a database, it can make it possible to write simpler and faster queries or reduce I/O usage by making the queries return lighter records. At the moment, reshaping needs to be performed manually in scikit-learn. In the case of sparse input (particularly in `CSR` format), it is generally sufficient to not generate the relevant features, leaving their columns empty.

4.8.3 Parallelism, resource management, and configuration

Parallelism

Some scikit-learn estimators and utilities can parallelize costly operations using multiple CPU cores, thanks to the following components:

- via the joblib library. In this case the number of threads or processes can be controlled with the `n_jobs` parameter.
- via OpenMP, used in C or Cython code.

In addition, some of the numpy routines that are used internally by scikit-learn may also be parallelized if numpy is installed with specific numerical libraries such as MKL, OpenBLAS, or BLIS.

We describe these 3 scenarios in the following subsections.

Joblib-based parallelism

When the underlying implementation uses joblib, the number of workers (threads or processes) that are spawned in parallel can be controlled via the `n_jobs` parameter.

Note: Where (and how) parallelization happens in the estimators is currently poorly documented. Please help us by improving our docs and tackle issue 14228!

Joblib is able to support both multi-processing and multi-threading. Whether joblib chooses to spawn a thread or a process depends on the **backend** that it's using.

Scikit-learn generally relies on the `loky` backend, which is joblib's default backend. Loky is a multi-processing backend. When doing multi-processing, in order to avoid duplicating the memory in each process (which isn't reasonable with big datasets), joblib will create a memmap that all processes can share, when the data is bigger than 1MB.

In some specific cases (when the code that is run in parallel releases the GIL), scikit-learn will indicate to `joblib` that a multi-threading backend is preferable.

As a user, you may control the backend that joblib will use (regardless of what scikit-learn recommends) by using a context manager:

```
from joblib import parallel_backend

with parallel_backend('threading', n_jobs=2):
    # Your scikit-learn code here
```

Please refer to the joblib's docs for more details.

In practice, whether parallelism is helpful at improving runtime depends on many factors. It is usually a good idea to experiment rather than assuming that increasing the number of workers is always a good thing. In some cases it can be highly detrimental to performance to run multiple copies of some estimators or functions in parallel (see oversubscription below).

OpenMP-based parallelism

OpenMP is used to parallelize code written in Cython or C, relying on multi-threading exclusively. By default (and unless joblib is trying to avoid oversubscription), the implementation will use as many threads as possible.

You can control the exact number of threads that are used via the `OMP_NUM_THREADS` environment variable:

```
OMP_NUM_THREADS=4 python my_script.py
```

Parallel Numpy routines from numerical libraries

Scikit-learn relies heavily on NumPy and SciPy, which internally call multi-threaded linear algebra routines implemented in libraries such as MKL, OpenBLAS or BLIS.

The number of threads used by the OpenBLAS, MKL or BLIS libraries can be set via the `MKL_NUM_THREADS`, `OPENBLAS_NUM_THREADS`, and `BLIS_NUM_THREADS` environment variables.

Please note that scikit-learn has no direct control over these implementations. Scikit-learn solely relies on Numpy and Scipy.

Note: At the time of writing (2019), NumPy and SciPy packages distributed on pypi.org (used by `pip`) and on the conda-forge channel are linked with OpenBLAS, while conda packages shipped on the "defaults" channel from anaconda.org are linked by default with MKL.

Oversubscription: spawning too many threads

It is generally recommended to avoid using significantly more processes or threads than the number of CPUs on a machine. Over-subscription happens when a program is running too many threads at the same time.

Suppose you have a machine with 8 CPUs. Consider a case where you're running a `GridSearchCV` (parallelized with joblib) with `n_jobs=8` over a `HistGradientBoostingClassifier` (parallelized with OpenMP). Each instance of `HistGradientBoostingClassifier` will spawn 8 threads (since you have 8 CPUs). That's a total of `8 * 8 = 64` threads, which leads to oversubscription of physical CPU resources and to scheduling overhead.

Oversubscription can arise in the exact same fashion with parallelized routines from MKL, OpenBLAS or BLIS that are nested in joblib calls.

Starting from `joblib >= 0.14`, when the `loky` backend is used (which is the default), joblib will tell its child **processes** to limit the number of threads they can use, so as to avoid oversubscription. In practice the heuristic that joblib uses is to tell the processes to use `max_threads = n_cpus // n_jobs`, via their corresponding environment variable. Back to our example from above, since the joblib backend of `GridSearchCV` is `loky`, each process will only be able to use 1 thread instead of 8, thus mitigating the oversubscription issue.

Note that:

- Manually setting one of the environment variables (`OMP_NUM_THREADS`, `MKL_NUM_THREADS`, `OPENBLAS_NUM_THREADS`, or `BLIS_NUM_THREADS`) will take precedence over what joblib tries to do. The total number of threads will be `n_jobs * <LIB>_NUM_THREADS`. Note that setting this limit will also impact your computations in the main process, which will only use `<LIB>_NUM_THREADS`. Joblib exposes a context manager for finer control over the number of threads in its workers (see joblib docs linked below).
- Joblib is currently unable to avoid oversubscription in a multi-threading context. It can only do so with the `loky` backend (which spawns processes).

You will find additional details about joblib mitigation of oversubscription in joblib documentation.

Configuration switches

Python runtime

sklearn.set_config controls the following behaviors:

assume_finite used to skip validation, which enables faster computations but may lead to segmentation faults if the data contains NaNs.

working_memory the optimal size of temporary arrays used by some algorithms.

Environment variables

These environment variables should be set before importing scikit-learn.

SKLEARN_SITE_JOBLIB When this environment variable is set to a non zero value, scikit-learn uses the site joblib rather than its vendored version. Consequently, joblib must be installed for scikit-learn to run. Note that using the site joblib is at your own risks: the versions of scikit-learn and joblib need to be compatible. Currently, joblib 0.11+ is supported. In addition, dumps from joblib.Memory might be incompatible, and you might loose some caches and have to redownload some datasets.

Deprecated since version 0.21: As of version 0.21 this parameter has no effect, vendored joblib was removed and site joblib is always used.

SKLEARN_ASSUME_FINITE Sets the default value for the `assume_finite` argument of *sklearn.set_config*.

SKLEARN_WORKING_MEMORY Sets the default value for the `working_memory` argument of *sklearn.set_config*.

SKLEARN_SEED Sets the seed of the global random generator when running the tests, for reproducibility.

SKLEARN_SKIP_NETWORK_TESTS When this environment variable is set to a non zero value, the tests that need network access are skipped.

CHAPTER

FIVE

GLOSSARY OF COMMON TERMS AND API ELEMENTS

This glossary hopes to definitively represent the tacit and explicit conventions applied in Scikit-learn and its API, while providing a reference for users and contributors. It aims to describe the concepts and either detail their corresponding API or link to other relevant parts of the documentation which do so. By linking to glossary entries from the API Reference and User Guide, we may minimize redundancy and inconsistency.

We begin by listing general concepts (and any that didn't fit elsewhere), but more specific sets of related terms are listed below: *Class APIs and Estimator Types*, *Target Types*, *Methods*, *Parameters*, *Attributes*, *Data and sample properties*.

5.1 General Concepts

1d

1d array One-dimensional array. A NumPy array whose `.shape` has length 1. A vector.

2d

2d array Two-dimensional array. A NumPy array whose `.shape` has length 2. Often represents a matrix.

API Refers to both the *specific* interfaces for estimators implemented in Scikit-learn and the *generalized* conventions across types of estimators as described in this glossary and *overviewed in the contributor documentation*.

The specific interfaces that constitute Scikit-learn's public API are largely documented in *API Reference*. However we less formally consider anything as public API if none of the identifiers required to access it begins with _. We generally try to maintain *backwards compatibility* for all objects in the public API.

Private API, including functions, modules and methods beginning _ are not assured to be stable.

array-like The most common data format for *input* to Scikit-learn estimators and functions, array-like is any type object for which `numpy.asarray` will produce an array of appropriate shape (usually 1 or 2-dimensional) of appropriate dtype (usually numeric).

This includes:

- a numpy array
- a list of numbers
- a list of length-k lists of numbers for some fixed length k
- a `pandas.DataFrame` with all columns numeric
- a numeric `pandas.Series`

It excludes:

- a *sparse matrix*
- an iterator

- a generator

Note that *output* from scikit-learn estimators and functions (e.g. predictions) should generally be arrays or sparse matrices, or lists thereof (as in multi-output `tree.DecisionTreeClassifier`'s `predict_proba`). An estimator where `predict()` returns a list or a `pandas.Series` is not valid.

attribute

attributes We mostly use attribute to refer to how model information is stored on an estimator during fitting. Any public attribute stored on an estimator instance is required to begin with an alphabetic character and end in a single underscore if it is set in *fit* or *partial_fit*. These are what is documented under an estimator's *Attributes* documentation. The information stored in attributes is usually either: sufficient statistics used for prediction or transformation; *transductive* outputs such as *labels_* or *embedding_*; or diagnostic data, such as *feature_importances_*. Common attributes are listed *below*.

A public attribute may have the same name as a constructor *parameter*, with a _ appended. This is used to store a validated or estimated version of the user's input. For example, `decomposition.PCA` is constructed with an `n_components` parameter. From this, together with other parameters and the data, PCA estimates the attribute `n_components_`.

Further private attributes used in prediction/transformation/etc. may also be set when fitting. These begin with a single underscore and are not assured to be stable for public access.

A public attribute on an estimator instance that does not end in an underscore should be the stored, unmodified value of an `__init__` *parameter* of the same name. Because of this equivalence, these are documented under an estimator's *Parameters* documentation.

backwards compatibility We generally try to maintain backwards compatibility (i.e. interfaces and behaviors may be extended but not changed or removed) from release to release but this comes with some exceptions:

Public API only The behaviour of objects accessed through private identifiers (those beginning _) may be changed arbitrarily between versions.

As documented We will generally assume that the users have adhered to the documented parameter types and ranges. If the documentation asks for a list and the user gives a tuple, we do not assure consistent behavior from version to version.

Deprecation Behaviors may change following a *deprecation* period (usually two releases long). Warnings are issued using Python's `warnings` module.

Keyword arguments We may sometimes assume that all optional parameters (other than X and y to *fit* and similar methods) are passed as keyword arguments only and may be positionally reordered.

Bug fixes and enhancements Bug fixes and – less often – enhancements may change the behavior of estimators, including the predictions of an estimator trained on the same data and *random_state*. When this happens, we attempt to note it clearly in the changelog.

Serialization We make no assurances that pickling an estimator in one version will allow it to be unpickled to an equivalent model in the subsequent version. (For estimators in the sklearn package, we issue a warning when this unpickling is attempted, even if it may happen to work.) See *Security & maintainability limitations*.

`utils.estimator_checks.check_estimator` We provide limited backwards compatibility assurances for the estimator checks: we may add extra requirements on estimators tested with this function, usually when these were informally assumed but not formally tested.

Despite this informal contract with our users, the software is provided as is, as stated in the licence. When a release inadvertently introduces changes that are not backwards compatible, these are known as software regressions.

callable A function, class or an object which implements the `__call__` method; anything that returns True when the argument of callable().

categorical feature A categorical or nominal *feature* is one that has a finite set of discrete values across the population of data. These are commonly represented as columns of integers or strings. Strings will be rejected by most scikit-learn estimators, and integers will be treated as ordinal or count-valued. For the use with most estimators, categorical variables should be one-hot encoded. Notable exceptions include tree-based models such as random forests and gradient boosting models that often work better and faster with integer-coded categorical variables. `OrdinalEncoder` helps encoding string-valued categorical features as ordinal integers, and `OneHotEncoder` can be used to one-hot encode categorical features. See also *Encoding categorical features* and the categorical-encoding package for tools related to encoding categorical features.

clone

cloned To copy an *estimator instance* and create a new one with identical *parameters*, but without any fitted *attributes*, using `clone`.

When `fit` is called, a *meta-estimator* usually clones a wrapped estimator instance before fitting the cloned instance. (Exceptions, for legacy reasons, include `Pipeline` and `FeatureUnion`.)

common tests This refers to the tests run on almost every estimator class in Scikit-learn to check they comply with basic API conventions. They are available for external use through `utils.estimator_checks.check_estimator`, with most of the implementation in `sklearn/utils/estimator_checks.py`.

Note: Some exceptions to the common testing regime are currently hard-coded into the library, but we hope to replace this by marking exceptional behaviours on the estimator using semantic *estimator tags*.

deprecation We use deprecation to slowly violate our *backwards compatibility* assurances, usually to to:

- change the default value of a parameter; or
- remove a parameter, attribute, method, class, etc.

We will ordinarily issue a warning when a deprecated element is used, although there may be limitations to this. For instance, we will raise a warning when someone sets a parameter that has been deprecated, but may not when they access that parameter's attribute on the estimator instance.

See the *Contributors' Guide*.

dimensionality May be used to refer to the number of *features* (i.e. *n_features*), or columns in a 2d feature matrix. Dimensions are, however, also used to refer to the length of a NumPy array's shape, distinguishing a 1d array from a 2d matrix.

docstring The embedded documentation for a module, class, function, etc., usually in code as a string at the beginning of the object's definition, and accessible as the object's `__doc__` attribute.

We try to adhere to PEP257, and follow NumpyDoc conventions.

double underscore

double underscore notation When specifying parameter names for nested estimators, `__` may be used to separate between parent and child in some contexts. The most common use is when setting parameters through a meta-estimator with *set_params* and hence in specifying a search grid in *parameter search*. See *parameter*. It is also used in `pipeline.Pipeline.fit` for passing *sample properties* to the `fit` methods of estimators in the pipeline.

dtype

data type NumPy arrays assume a homogeneous data type throughout, available in the `.dtype` attribute of an array (or sparse matrix). We generally assume simple data types for scikit-learn data: float or integer. We may support object or string data types for arrays before encoding or vectorizing. Our estimators do not work with struct arrays, for instance.

TODO: Mention efficiency and precision issues; casting policy.

duck typing We try to apply duck typing to determine how to handle some input values (e.g. checking whether a given estimator is a classifier). That is, we avoid using `isinstance` where possible, and rely on the presence or absence of attributes to determine an object's behaviour. Some nuance is required when following this approach:

- For some estimators, an attribute may only be available once it is *fitted*. For instance, we cannot a priori determine if *predict_proba* is available in a grid search where the grid includes alternating between a probabilistic and a non-probabilistic predictor in the final step of the pipeline. In the following, we can only determine if `clf` is probabilistic after fitting it on some data:

```
>>> from sklearn.model_selection import GridSearchCV
>>> from sklearn.linear_model import SGDClassifier
>>> clf = GridSearchCV(SGDClassifier(),
...                    param_grid={'loss': ['log', 'hinge']})
```

  This means that we can only check for duck-typed attributes after fitting, and that we must be careful to make *meta-estimators* only present attributes according to the state of the underlying estimator after fitting.

- Checking if an attribute is present (using `hasattr`) is in general just as expensive as getting the attribute (`getattr` or dot notation). In some cases, getting the attribute may indeed be expensive (e.g. for some implementations of *feature_importances_*, which may suggest this is an API design flaw). So code which does `hasattr` followed by `getattr` should be avoided; `getattr` within a try-except block is preferred.

- For determining some aspects of an estimator's expectations or support for some feature, we use *estimator tags* instead of duck typing.

early stopping This consists in stopping an iterative optimization method before the convergence of the training loss, to avoid over-fitting. This is generally done by monitoring the generalization score on a validation set. When available, it is activated through the parameter `early_stopping` or by setting a positive *n_iter_no_change*.

estimator instance We sometimes use this terminology to distinguish an *estimator* class from a constructed instance. For example, in the following, `cls` is an estimator class, while `est1` and `est2` are instances:

```
cls = RandomForestClassifier
est1 = cls()
est2 = RandomForestClassifier()
```

examples We try to give examples of basic usage for most functions and classes in the API:

- as doctests in their docstrings (i.e. within the `sklearn/` library code itself).

- as examples in the *example gallery* rendered (using sphinx-gallery) from scripts in the `examples/` directory, exemplifying key features or parameters of the estimator/function. These should also be referenced from the User Guide.

- sometimes in the *User Guide* (built from `doc/`) alongside a technical description of the estimator.

evaluation metric

evaluation metrics Evaluation metrics give a measure of how well a model performs. We may use this term specifically to refer to the functions in `metrics` (disregarding `metrics.pairwise`), as distinct from the *score* method and the *scoring* API used in cross validation. See *Metrics and scoring: quantifying the quality of predictions*.

These functions usually accept a ground truth (or the raw data where the metric evaluates clustering without a ground truth) and a prediction, be it the output of *predict* (`y_pred`), of *predict_proba* (`y_proba`), or of an arbitrary score function including *decision_function* (`y_score`). Functions are usually named to end with `_score` if a greater score indicates a better model, and `_loss` if a lesser score indicates a better model. This diversity of interface motivates the scoring API.

Note that some estimators can calculate metrics that are not included in `metrics` and are estimator-specific, notably model likelihoods.

estimator tags A proposed feature (e.g. #8022) by which the capabilities of an estimator are described through a set of semantic tags. This would enable some runtime behaviors based on estimator inspection, but it also allows each estimator to be tested for appropriate invariances while being excepted from other *common tests*.

Some aspects of estimator tags are currently determined through the *duck typing* of methods like `predict_proba` and through some special attributes on estimator objects:

`_estimator_type` This string-valued attribute identifies an estimator as being a classifier, regressor, etc. It is set by mixins such as *`base.ClassifierMixin`*, but needs to be more explicitly adopted on a *meta-estimator*. Its value should usually be checked by way of a helper such as *`base.is_classifier`*.

`_pairwise` This boolean attribute indicates whether the data (`X`) passed to `fit` and similar methods consists of pairwise measures over samples rather than a feature representation for each sample. It is usually `True` where an estimator has a `metric` or `affinity` or `kernel` parameter with value 'precomputed'. Its primary purpose is that when a *meta-estimator* extracts a sub-sample of data intended for a pairwise estimator, the data needs to be indexed on both axes, while other data is indexed only on the first axis.

feature

features

feature vector In the abstract, a feature is a function (in its mathematical sense) mapping a sampled object to a numeric or categorical quantity. "Feature" is also commonly used to refer to these quantities, being the individual elements of a vector representing a sample. In a data matrix, features are represented as columns: each column contains the result of applying a feature function to a set of samples.

Elsewhere features are known as attributes, predictors, regressors, or independent variables.

Nearly all estimators in scikit-learn assume that features are numeric, finite and not missing, even when they have semantically distinct domains and distributions (categorical, ordinal, count-valued, real-valued, interval). See also *categorical feature* and *missing values*.

`n_features` indicates the number of features in a dataset.

fitting Calling *fit* (or *fit_transform*, *fit_predict*, etc.) on an estimator.

fitted The state of an estimator after *fitting*.

There is no conventional procedure for checking if an estimator is fitted. However, an estimator that is not fitted:

- should raise *`exceptions.NotFittedError`* when a prediction method (*predict*, *transform*, etc.) is called. (*`utils.validation.check_is_fitted`* is used internally for this purpose.)
- should not have any *attributes* beginning with an alphabetic character and ending with an underscore. (Note that a descriptor for the attribute may still be present on the class, but hasattr should return False)

function We provide ad hoc function interfaces for many algorithms, while *estimator* classes provide a more consistent interface.

In particular, Scikit-learn may provide a function interface that fits a model to some data and returns the learnt model parameters, as in *`linear_model.enet_path`*. For transductive models, this also returns the embedding or cluster labels, as in *`manifold.spectral_embedding`* or *`cluster.dbscan`*. Many preprocessing transformers also provide a function interface, akin to calling *fit_transform*, as in *`preprocessing.maxabs_scale`*. Users should be careful to avoid *data leakage* when making use of these `fit_transform`-equivalent functions.

We do not have a strict policy about when to or when not to provide function forms of estimators, but maintainers should consider consistency with existing interfaces, and whether providing a function would lead users astray from best practices (as regards data leakage, etc.)

gallery See *examples*.

hyperparameter

hyper-parameter See *parameter*.

impute

imputation Most machine learning algorithms require that their inputs have no *missing values*, and will not work if this requirement is violated. Algorithms that attempt to fill in (or impute) missing values are referred to as imputation algorithms.

indexable An *array-like*, *sparse matrix*, pandas DataFrame or sequence (usually a list).

induction

inductive Inductive (contrasted with *transductive*) machine learning builds a model of some data that can then be applied to new instances. Most estimators in Scikit-learn are inductive, having *predict* and/or *transform* methods.

joblib A Python library (https://joblib.readthedocs.io) used in Scikit-learn to facilite simple parallelism and caching. Joblib is oriented towards efficiently working with numpy arrays, such as through use of *memory mapping*. See *Parallelism* for more information.

label indicator matrix

multilabel indicator matrix

multilabel indicator matrices The format used to represent multilabel data, where each row of a 2d array or sparse matrix corresponds to a sample, each column corresponds to a class, and each element is 1 if the sample is labeled with the class and 0 if not.

leakage

data leakage A problem in cross validation where generalization performance can be over-estimated since knowledge of the test data was inadvertently included in training a model. This is a risk, for instance, when applying a *transformer* to the entirety of a dataset rather than each training portion in a cross validation split.

We aim to provide interfaces (such as `pipeline` and `model_selection`) that shield the user from data leakage.

memmapping

memory map

memory mapping A memory efficiency strategy that keeps data on disk rather than copying it into main memory. Memory maps can be created for arrays that can be read, written, or both, using `numpy.memmap`. When using *joblib* to parallelize operations in Scikit-learn, it may automatically memmap large arrays to reduce memory duplication overhead in multiprocessing.

missing values Most Scikit-learn estimators do not work with missing values. When they do (e.g. in *`impute.SimpleImputer`*), NaN is the preferred representation of missing values in float arrays. If the array has integer dtype, NaN cannot be represented. For this reason, we support specifying another `missing_values` value when *imputation* or learning can be performed in integer space. *Unlabeled data* is a special case of missing values in the *target*.

`n_features` The number of *features*.

`n_outputs` The number of *outputs* in the *target*.

`n_samples` The number of *samples*.

`n_targets` Synonym for *n_outputs*.

narrative docs

narrative documentation An alias for *User Guide*, i.e. documentation written in `doc/modules/`. Unlike the *API reference* provided through docstrings, the User Guide aims to:

- group tools provided by Scikit-learn together thematically or in terms of usage;
- motivate why someone would use each particular tool, often through comparison;
- provide both intuitive and technical descriptions of tools;
- provide or link to *examples* of using key features of a tool.

np A shorthand for Numpy due to the conventional import statement:

```
import numpy as np
```

online learning Where a model is iteratively updated by receiving each batch of ground truth *targets* soon after making predictions on corresponding batch of data. Intrinsically, the model must be usable for prediction after each batch. See *partial_fit*.

out-of-core An efficiency strategy where not all the data is stored in main memory at once, usually by performing learning on batches of data. See *partial_fit*.

outputs Individual scalar/categorical variables per sample in the *target*. For example, in multilabel classification each possible label corresponds to a binary output. Also called *responses*, *tasks* or *targets*. See *multiclass multioutput* and *continuous multioutput*.

pair A tuple of length two.

parameter

parameters

param

params We mostly use *parameter* to refer to the aspects of an estimator that can be specified in its construction. For example, `max_depth` and `random_state` are parameters of `RandomForestClassifier`. Parameters to an estimator's constructor are stored unmodified as attributes on the estimator instance, and conventionally start with an alphabetic character and end with an alphanumeric character. Each estimator's constructor parameters are described in the estimator's docstring.

We do not use parameters in the statistical sense, where parameters are values that specify a model and can be estimated from data. What we call parameters might be what statisticians call hyperparameters to the model: aspects for configuring model structure that are often not directly learnt from data. However, our parameters are also used to prescribe modeling operations that do not affect the learnt model, such as *n_jobs* for controlling parallelism.

When talking about the parameters of a *meta-estimator*, we may also be including the parameters of the estimators wrapped by the meta-estimator. Ordinarily, these nested parameters are denoted by using a *double underscore* (`__`) to separate between the estimator-as-parameter and its parameter. Thus `clf = BaggingClassifier(base_estimator=DecisionTreeClassifier(max_depth=3))` has a deep parameter `base_estimator__max_depth` with value `3`, which is accessible with `clf.base_estimator.max_depth` or `clf.get_params()['base_estimator__max_depth']`.

The list of parameters and their current values can be retrieved from an *estimator instance* using its *get_params* method.

Between construction and fitting, parameters may be modified using *set_params*. To enable this, parameters are not ordinarily validated or altered when the estimator is constructed, or when each parameter is set. Parameter validation is performed when *fit* is called.

Common parameters are listed *below*.

pairwise metric

pairwise metrics In its broad sense, a pairwise metric defines a function for measuring similarity or dissimilarity between two samples (with each ordinarily represented as a *feature vector*). We particularly provide implementations of distance metrics (as well as improper metrics like Cosine Distance) through *metrics.pairwise_distances*, and of kernel functions (a constrained class of similarity functions) in `metrics.pairwise_kernels`. These can compute pairwise distance matrices that are symmetric and hence store data redundantly.

See also *precomputed* and *metric*.

Note that for most distance metrics, we rely on implementations from `scipy.spatial.distance`, but may reimplement for efficiency in our context. The `neighbors` module also duplicates some metric implementations for integration with efficient binary tree search data structures.

pd A shorthand for Pandas due to the conventional import statement:

```
import pandas as pd
```

precomputed Where algorithms rely on *pairwise metrics*, and can be computed from pairwise metrics alone, we often allow the user to specify that the *X* provided is already in the pairwise (dis)similarity space, rather than in a feature space. That is, when passed to *fit*, it is a square, symmetric matrix, with each vector indicating (dis)similarity to every sample, and when passed to prediction/transformation methods, each row corresponds to a testing sample and each column to a training sample.

Use of precomputed X is usually indicated by setting a `metric`, `affinity` or `kernel` parameter to the string 'precomputed'. An estimator should mark itself as being *_pairwise* if this is the case.

rectangular Data that can be represented as a matrix with *samples* on the first axis and a fixed, finite set of *features* on the second is called rectangular.

This term excludes samples with non-vectorial structure, such as text, an image of arbitrary size, a time series of arbitrary length, a set of vectors, etc. The purpose of a *vectorizer* is to produce rectangular forms of such data.

sample

samples We usually use this term as a noun to indicate a single feature vector. Elsewhere a sample is called an instance, data point, or observation. `n_samples` indicates the number of samples in a dataset, being the number of rows in a data array *X*.

sample property

sample properties A sample property is data for each sample (e.g. an array of length n_samples) passed to an estimator method or a similar function, alongside but distinct from the *features* (`X`) and *target* (`y`). The most prominent example is *sample_weight*; see others at *Data and sample properties*.

As of version 0.19 we do not have a consistent approach to handling sample properties and their routing in *meta-estimators*, though a `fit_params` parameter is often used.

scikit-learn-contrib A venue for publishing Scikit-learn-compatible libraries that are broadly authorized by the core developers and the contrib community, but not maintained by the core developer team. See https://scikit-learn-contrib.github.io.

scikit-learn enhancement proposals

SLEP

SLEPs Changes to the API principles and changes to dependencies or supported versions happen via a *SLEP* and follows the decision-making process outlined in *Scikit-learn governance and decision-making*. For all votes, a proposal must have been made public and discussed before the vote. Such proposal must be a consolidated document, in the form of a 'Scikit-Learn Enhancement Proposal' (SLEP), rather than a long discussion on an issue. A SLEP must be submitted as a pull-request to enhancement proposals using the SLEP template.

semi-supervised

semi-supervised learning

semisupervised Learning where the expected prediction (label or ground truth) is only available for some samples provided as training data when *fitting* the model. We conventionally apply the label `-1` to *unlabeled* samples in semi-supervised classification.

sparse matrix

sparse graph A representation of two-dimensional numeric data that is more memory efficient the corresponding dense numpy array where almost all elements are zero. We use the `scipy.sparse` framework, which provides several underlying sparse data representations, or *formats*. Some formats are more efficient than others for particular tasks, and when a particular format provides especial benefit, we try to document this fact in Scikit-learn parameter descriptions.

Some sparse matrix formats (notably CSR, CSC, COO and LIL) distinguish between *implicit* and *explicit* zeros. Explicit zeros are stored (i.e. they consume memory in a `data` array) in the data structure, while implicit zeros correspond to every element not otherwise defined in explicit storage.

Two semantics for sparse matrices are used in Scikit-learn:

matrix semantics The sparse matrix is interpreted as an array with implicit and explicit zeros being interpreted as the number 0. This is the interpretation most often adopted, e.g. when sparse matrices are used for feature matrices or *multilabel indicator matrices*.

graph semantics As with `scipy.sparse.csgraph`, explicit zeros are interpreted as the number 0, but implicit zeros indicate a masked or absent value, such as the absence of an edge between two vertices of a graph, where an explicit value indicates an edge's weight. This interpretation is adopted to represent connectivity in clustering, in representations of nearest neighborhoods (e.g. *`neighbors.kneighbors_graph`*), and for precomputed distance representation where only distances in the neighborhood of each point are required.

When working with sparse matrices, we assume that it is sparse for a good reason, and avoid writing code that densifies a user-provided sparse matrix, instead maintaining sparsity or raising an error if not possible (i.e. if an estimator does not / cannot support sparse matrices).

supervised

supervised learning Learning where the expected prediction (label or ground truth) is available for each sample when *fitting* the model, provided as *y*. This is the approach taken in a *classifier* or *regressor* among other estimators.

target

targets The *dependent variable* in *supervised* (and *semisupervised*) learning, passed as *y* to an estimator's *fit* method. Also known as *dependent variable*, *outcome variable*, *response variable*, *ground truth* or *label*. Scikit-learn works with targets that have minimal structure: a class from a finite set, a finite real-valued number, multiple classes, or multiple numbers. See *Target Types*.

transduction

transductive A transductive (contrasted with *inductive*) machine learning method is designed to model a specific dataset, but not to apply that model to unseen data. Examples include *`manifold.TSNE`*, *`cluster.AgglomerativeClustering`* and *`neighbors.LocalOutlierFactor`*.

unlabeled

unlabeled data Samples with an unknown ground truth when fitting; equivalently, *missing values* in the *target*. See also *semisupervised* and *unsupervised* learning.

unsupervised

unsupervised learning Learning where the expected prediction (label or ground truth) is not available for each sample when *fitting* the model, as in *clusterers* and *outlier detectors*. Unsupervised estimators ignore any *y* passed to *fit*.

5.2 Class APIs and Estimator Types

classifier

classifiers A *supervised* (or *semi-supervised*) *predictor* with a finite set of discrete possible output values.

A classifier supports modeling some of *binary*, *multiclass*, *multilabel*, or *multiclass multioutput* targets. Within scikit-learn, all classifiers support multi-class classification, defaulting to using a one-vs-rest strategy over the binary classification problem.

Classifiers must store a *classes_* attribute after fitting, and usually inherit from `base.ClassifierMixin`, which sets their *_estimator_type* attribute.

A classifier can be distinguished from other estimators with `is_classifier`.

A classifier must implement:

- *fit*
- *predict*
- *score*

It may also be appropriate to implement *decision_function*, *predict_proba* and *predict_log_proba*.

clusterer

clusterers A *unsupervised predictor* with a finite set of discrete output values.

A clusterer usually stores *labels_* after fitting, and must do so if it is *transductive*.

A clusterer must implement:

- *fit*
- *fit_predict* if *transductive*
- *predict* if *inductive*

density estimator TODO

estimator

estimators An object which manages the estimation and decoding of a model. The model is estimated as a deterministic function of:

- *parameters* provided in object construction or with *set_params*;
- the global `numpy.random` random state if the estimator's *random_state* parameter is set to None; and
- any data or *sample properties* passed to the most recent call to *fit*, *fit_transform* or *fit_predict*, or data similarly passed in a sequence of calls to *partial_fit*.

The estimated model is stored in public and private *attributes* on the estimator instance, facilitating decoding through prediction and transformation methods.

Estimators must provide a *fit* method, and should provide *set_params* and *get_params*, although these are usually provided by inheritance from `base.BaseEstimator`.

The core functionality of some estimators may also be available as a *function*.

feature extractor

feature extractors A *transformer* which takes input where each sample is not represented as an *array-like* object of fixed length, and produces an *array-like* object of *features* for each sample (and thus a 2-dimensional array-like for a set of samples). In other words, it (lossily) maps a non-rectangular data representation into *rectangular* data.

Feature extractors must implement at least:

- *fit*
- *transform*
- *get_feature_names*

meta-estimator

meta-estimators

metaestimator

metaestimators An *estimator* which takes another estimator as a parameter. Examples include `pipeline.Pipeline`, `model_selection.GridSearchCV`, `feature_selection.SelectFromModel` and `ensemble.BaggingClassifier`.

In a meta-estimator's *fit* method, any contained estimators should be *cloned* before they are fit (although FIXME: Pipeline and FeatureUnion do not do this currently). An exception to this is that an estimator may explicitly document that it accepts a prefitted estimator (e.g. using `prefit=True` in `feature_selection.SelectFromModel`). One known issue with this is that the prefitted estimator will lose its model if the meta-estimator is cloned. A meta-estimator should have `fit` called before prediction, even if all contained estimators are prefitted.

In cases where a meta-estimator's primary behaviors (e.g. *predict* or *transform* implementation) are functions of prediction/transformation methods of the provided *base estimator* (or multiple base estimators), a meta-estimator should provide at least the standard methods provided by the base estimator. It may not be possible to identify which methods are provided by the underlying estimator until the meta-estimator has been *fitted* (see also *duck typing*), for which `utils.metaestimators.if_delegate_has_method` may help. It should also provide (or modify) the *estimator tags* and *classes_* attribute provided by the base estimator.

Meta-estimators should be careful to validate data as minimally as possible before passing it to an underlying estimator. This saves computation time, and may, for instance, allow the underlying estimator to easily work with data that is not *rectangular*.

outlier detector

outlier detectors An *unsupervised* binary *predictor* which models the distinction between core and outlying samples.

Outlier detectors must implement:

- *fit*
- *fit_predict* if *transductive*
- *predict* if *inductive*

Inductive outlier detectors may also implement *decision_function* to give a normalized inlier score where outliers have score below 0. *score_samples* may provide an unnormalized score per sample.

predictor

predictors An *estimator* supporting *predict* and/or *fit_predict*. This encompasses *classifier*, *regressor*, *outlier detector* and *clusterer*.

In statistics, "predictors" refers to *features*.

regressor

regressors A *supervised* (or *semi-supervised*) *predictor* with *continuous* output values.

Regressors usually inherit from `base.RegressorMixin`, which sets their *_estimator_type* attribute.

A regressor can be distinguished from other estimators with `is_regressor`.

A regressor must implement:

- *fit*
- *predict*
- *score*

transformer

transformers An estimator supporting *transform* and/or *fit_transform*. A purely *transductive* transformer, such as `manifold.TSNE`, may not implement `transform`.

vectorizer

vectorizers See *feature extractor*.

There are further APIs specifically related to a small family of estimators, such as:

cross-validation splitter

CV splitter

cross-validation generator A non-estimator family of classes used to split a dataset into a sequence of train and test portions (see *Cross-validation: evaluating estimator performance*), by providing *split* and *get_n_splits* methods. Note that unlike estimators, these do not have *fit* methods and do not provide *set_params* or *get_params*. Parameter validation may be performed in `__init__`.

cross-validation estimator An estimator that has built-in cross-validation capabilities to automatically select the best hyper-parameters (see the *User Guide*). Some example of cross-validation estimators are `ElasticNetCV` and `LogisticRegressionCV`. Cross-validation estimators are named `EstimatorCV` and tend to be roughly equivalent to `GridSearchCV(Estimator(), ...)`. The advantage of using a cross-validation estimator over the canonical *Estimator* class along with *grid search* is that they can take advantage of warm-starting by reusing precomputed results in the previous steps of the cross-validation process. This generally leads to speed improvements. An exception is the `RidgeCV` class, which can instead perform efficient Leave-One-Out CV.

scorer A non-estimator callable object which evaluates an estimator on given test data, returning a number. Unlike *evaluation metrics*, a greater returned number must correspond with a *better* score. See *The scoring parameter: defining model evaluation rules*.

Further examples:

- `neighbors.DistanceMetric`
- `gaussian_process.kernels.Kernel`
- `tree.Criterion`

5.3 Target Types

binary A classification problem consisting of two classes. A binary target may represented as for a *multiclass* problem but with only two labels. A binary decision function is represented as a 1d array.

Semantically, one class is often considered the "positive" class. Unless otherwise specified (e.g. using *pos_label* in *evaluation metrics*), we consider the class label with the greater value (numerically or lexicographically) as the positive class: of labels [0, 1], 1 is the positive class; of [1, 2], 2 is the positive class; of ['no', 'yes'], 'yes' is the positive class; of ['no', 'YES'], 'no' is the positive class. This affects the output of *decision_function*, for instance.

Note that a dataset sampled from a multiclass `y` or a continuous `y` may appear to be binary.

`type_of_target` will return 'binary' for binary input, or a similar array with only a single class present.

continuous A regression problem where each sample's target is a finite floating point number, represented as a 1-dimensional array of floats (or sometimes ints).

type_of_target will return 'continuous' for continuous input, but if the data is all integers, it will be identified as 'multiclass'.

continuous multioutput

multioutput continuous A regression problem where each sample's target consists of `n_outputs` *outputs*, each one a finite floating point number, for a fixed int `n_outputs > 1` in a particular dataset.

Continuous multioutput targets are represented as multiple *continuous* targets, horizontally stacked into an array of shape `(n_samples, n_outputs)`.

type_of_target will return 'continuous-multioutput' for continuous multioutput input, but if the data is all integers, it will be identified as 'multiclass-multioutput'.

multiclass A classification problem consisting of more than two classes. A multiclass target may be represented as a 1-dimensional array of strings or integers. A 2d column vector of integers (i.e. a single output in *multioutput* terms) is also accepted.

We do not officially support other orderable, hashable objects as class labels, even if estimators may happen to work when given classification targets of such type.

For semi-supervised classification, *unlabeled* samples should have the special label -1 in `y`.

Within sckit-learn, all estimators supporting binary classification also support multiclass classification, using One-vs-Rest by default.

A *preprocessing.LabelEncoder* helps to canonicalize multiclass targets as integers.

type_of_target will return 'multiclass' for multiclass input. The user may also want to handle 'binary' input identically to 'multiclass'.

multiclass multioutput

multioutput multiclass A classification problem where each sample's target consists of `n_outputs` *outputs*, each a class label, for a fixed int `n_outputs > 1` in a particular dataset. Each output has a fixed set of available classes, and each sample is labelled with a class for each output. An output may be binary or multiclass, and in the case where all outputs are binary, the target is *multilabel*.

Multiclass multioutput targets are represented as multiple *multiclass* targets, horizontally stacked into an array of shape `(n_samples, n_outputs)`.

XXX: For simplicity, we may not always support string class labels for multiclass multioutput, and integer class labels should be used.

`multioutput` provides estimators which estimate multi-output problems using multiple single-output estimators. This may not fully account for dependencies among the different outputs, which methods natively handling the multioutput case (e.g. decision trees, nearest neighbors, neural networks) may do better.

type_of_target will return 'multiclass-multioutput' for multiclass multioutput input.

multilabel A *multiclass multioutput* target where each output is *binary*. This may be represented as a 2d (dense) array or sparse matrix of integers, such that each column is a separate binary target, where positive labels are indicated with 1 and negative labels are usually -1 or 0. Sparse multilabel targets are not supported everywhere that dense multilabel targets are supported.

Semantically, a multilabel target can be thought of as a set of labels for each sample. While not used internally, *preprocessing.MultiLabelBinarizer* is provided as a utility to convert from a list of sets representation to a 2d array or sparse matrix. One-hot encoding a multiclass target with *preprocessing.LabelBinarizer* turns it into a multilabel problem.

type_of_target will return 'multilabel-indicator' for multilabel input, whether sparse or dense.

multioutput

multi-output A target where each sample has multiple classification/regression labels. See *multiclass multioutput* and *continuous multioutput*. We do not currently support modelling mixed classification and regression targets.

5.4 Methods

`decision_function` In a fitted *classifier* or *outlier detector*, predicts a "soft" score for each sample in relation to each class, rather than the "hard" categorical prediction produced by *predict*. Its input is usually only some observed data, *X*.

If the estimator was not already *fitted*, calling this method should raise a `exceptions.NotFittedError`.

Output conventions:

binary classification A 1-dimensional array, where values strictly greater than zero indicate the positive class (i.e. the last class in *classes_*).

multiclass classification A 2-dimensional array, where the row-wise arg-maximum is the predicted class. Columns are ordered according to *classes_*.

multilabel classification Scikit-learn is inconsistent in its representation of multilabel decision functions. Some estimators represent it like multiclass multioutput, i.e. a list of 2d arrays, each with two columns. Others represent it with a single 2d array, whose columns correspond to the individual binary classification decisions. The latter representation is ambiguously identical to the multiclass classification format, though its semantics differ: it should be interpreted, like in the binary case, by thresholding at 0.

TODO: This gist highlights the use of the different formats for multilabel.

multioutput classification A list of 2d arrays, corresponding to each multiclass decision function.

outlier detection A 1-dimensional array, where a value greater than or equal to zero indicates an inlier.

`fit` The `fit` method is provided on every estimator. It usually takes some *samples* `X`, *targets* `y` if the model is supervised, and potentially other *sample properties* such as *sample_weight*. It should:

- clear any prior *attributes* stored on the estimator, unless *warm_start* is used;
- validate and interpret any *parameters*, ideally raising an error if invalid;
- validate the input data;
- estimate and store model attributes from the estimated parameters and provided data; and
- return the now *fitted* estimator to facilitate method chaining.

Target Types describes possible formats for `y`.

`fit_predict` Used especially for *unsupervised*, *transductive* estimators, this fits the model and returns the predictions (similar to *predict*) on the training data. In clusterers, these predictions are also stored in the *labels_* attribute, and the output of `.fit_predict(X)` is usually equivalent to `.fit(X).predict(X)`. The parameters to `fit_predict` are the same as those to `fit`.

`fit_transform` A method on *transformers* which fits the estimator and returns the transformed training data. It takes parameters as in *fit* and its output should have the same shape as calling `.fit(X, ...).transform(X)`. There are nonetheless rare cases where `.fit_transform(X, ...)` and `.fit(X, ...).transform(X)` do not return the same value, wherein training data needs to be handled differently (due to model blending in stacked ensembles, for instance; such cases should be clearly documented). *Transductive* transformers may also provide `fit_transform` but not *transform*.

One reason to implement `fit_transform` is that performing `fit` and `transform` separately would be less efficient than together. *base.TransformerMixin* provides a default implementation, providing a consistent interface across transformers where `fit_transform` is or is not specialised.

In *inductive* learning – where the goal is to learn a generalised model that can be applied to new data – users should be careful not to apply `fit_transform` to the entirety of a dataset (i.e. training and test data together) before further modelling, as this results in *data leakage*.

get_feature_names Primarily for *feature extractors*, but also used for other transformers to provide string names for each column in the output of the estimator's *transform* method. It outputs a list of strings, and may take a list of strings as input, corresponding to the names of input columns from which output column names can be generated. By default input features are named x0, x1, ...

get_n_splits On a *CV splitter* (not an estimator), returns the number of elements one would get if iterating through the return value of *split* given the same parameters. Takes the same parameters as split.

get_params Gets all *parameters*, and their values, that can be set using *set_params*. A parameter `deep` can be used, when set to False to only return those parameters not including __, i.e. not due to indirection via contained estimators.

Most estimators adopt the definition from *base.BaseEstimator*, which simply adopts the parameters defined for `__init__`. *pipeline.Pipeline*, among others, reimplements `get_params` to declare the estimators named in its `steps` parameters as themselves being parameters.

partial_fit Facilitates fitting an estimator in an online fashion. Unlike `fit`, repeatedly calling `partial_fit` does not clear the model, but updates it with respect to the data provided. The portion of data provided to `partial_fit` may be called a mini-batch. Each mini-batch must be of consistent shape, etc. In iterative estimators, `partial_fit` often only performs a single iteration.

`partial_fit` may also be used for *out-of-core* learning, although usually limited to the case where learning can be performed online, i.e. the model is usable after each `partial_fit` and there is no separate processing needed to finalize the model. *cluster.Birch* introduces the convention that calling `partial_fit(X)` will produce a model that is not finalized, but the model can be finalized by calling `partial_fit()` i.e. without passing a further mini-batch.

Generally, estimator parameters should not be modified between calls to `partial_fit`, although `partial_fit` should validate them as well as the new mini-batch of data. In contrast, `warm_start` is used to repeatedly fit the same estimator with the same data but varying parameters.

Like `fit`, `partial_fit` should return the estimator object.

To clear the model, a new estimator should be constructed, for instance with *base.clone*.

NOTE: Using `partial_fit` after `fit` results in undefined behavior.

predict Makes a prediction for each sample, usually only taking *X* as input (but see under regressor output conventions below). In a *classifier* or *regressor*, this prediction is in the same target space used in fitting (e.g. one of {'red', 'amber', 'green'} if the `y` in fitting consisted of these strings). Despite this, even when `y` passed to *fit* is a list or other array-like, the output of `predict` should always be an array or sparse matrix. In a *clusterer* or *outlier detector* the prediction is an integer.

If the estimator was not already *fitted*, calling this method should raise a *exceptions.NotFittedError*.

Output conventions:

classifier An array of shape `(n_samples,)` `(n_samples, n_outputs)`. *Multilabel* data may be represented as a sparse matrix if a sparse matrix was used in fitting. Each element should be one of the values in the classifier's *classes_* attribute.

clusterer An array of shape `(n_samples,)` where each value is from 0 to `n_clusters - 1` if the corresponding sample is clustered, and -1 if the sample is not clustered, as in *cluster.dbscan*.

outlier detector An array of shape `(n_samples,)` where each value is -1 for an outlier and 1 otherwise.

regressor A numeric array of shape `(n_samples,)`, usually float64. Some regressors have extra options in their `predict` method, allowing them to return standard deviation (`return_std=True`) or covariance (`return_cov=True`) relative to the predicted value. In this case, the return value is a tuple of arrays corresponding to (prediction mean, std, cov) as required.

predict_log_proba The natural logarithm of the output of *predict_proba*, provided to facilitate numerical stability.

predict_proba A method in *classifiers* and *clusterers* that are able to return probability estimates for each class/cluster. Its input is usually only some observed data, *X*.

If the estimator was not already *fitted*, calling this method should raise a `exceptions.NotFittedError`.

Output conventions are like those for *decision_function* except in the *binary* classification case, where one column is output for each class (while `decision_function` outputs a 1d array). For binary and multiclass predictions, each row should add to 1.

Like other methods, `predict_proba` should only be present when the estimator can make probabilistic predictions (see *duck typing*). This means that the presence of the method may depend on estimator parameters (e.g. in `linear_model.SGDClassifier`) or training data (e.g. in `model_selection.GridSearchCV`) and may only appear after fitting.

score A method on an estimator, usually a *predictor*, which evaluates its predictions on a given dataset, and returns a single numerical score. A greater return value should indicate better predictions; accuracy is used for classifiers and R^2 for regressors by default.

If the estimator was not already *fitted*, calling this method should raise a `exceptions.NotFittedError`.

Some estimators implement a custom, estimator-specific score function, often the likelihood of the data under the model.

score_samples TODO

If the estimator was not already *fitted*, calling this method should raise a `exceptions.NotFittedError`.

set_params Available in any estimator, takes keyword arguments corresponding to keys in *get_params*. Each is provided a new value to assign such that calling `get_params` after `set_params` will reflect the changed *parameters*. Most estimators use the implementation in `base.BaseEstimator`, which handles nested parameters and otherwise sets the parameter as an attribute on the estimator. The method is overridden in `pipeline.Pipeline` and related estimators.

split On a *CV splitter* (not an estimator), this method accepts parameters (*X*, *y*, *groups*), where all may be optional, and returns an iterator over `(train_idx, test_idx)` pairs. Each of {train,test}_idx is a 1d integer array, with values from 0 from `X.shape[0] - 1` of any length, such that no values appear in both some `train_idx` and its corresponding `test_idx`.

transform In a *transformer*, transforms the input, usually only *X*, into some transformed space (conventionally notated as *Xt*). Output is an array or sparse matrix of length *n_samples* and with number of columns fixed after *fitting*.

If the estimator was not already *fitted*, calling this method should raise a `exceptions.NotFittedError`.

5.5 Parameters

These common parameter names, specifically used in estimator construction (see concept *parameter*), sometimes also appear as parameters of functions or non-estimator constructors.

class_weight Used to specify sample weights when fitting classifiers as a function of the *target* class. Where *sample_weight* is also supported and given, it is multiplied by the `class_weight` contribution. Similarly, where `class_weight` is used in a *multioutput* (including *multilabel*) tasks, the weights are multiplied across outputs (i.e. columns of `y`).

By default all samples have equal weight such that classes are effectively weighted by their their prevalence in the training data. This could be achieved explicitly with `class_weight={label1: 1, label2: 1, ...}` for all class labels.

More generally, `class_weight` is specified as a dict mapping class labels to weights (`{class_label: weight}`), such that each sample of the named class is given that weight.

`class_weight='balanced'` can be used to give all classes equal weight by giving each sample a weight inversely related to its class's prevalence in the training data: `n_samples / (n_classes * np.bincount(y))`. Class weights will be used differently depending on the algorithm: for linear models (such as linear SVM or logistic regression), the class weights will alter the loss function by weighting the loss of each sample by its class weight. For tree-based algorithms, the class weights will be used for reweighting the splitting criterion. **Note** however that this rebalancing does not take the weight of samples in each class into account.

For multioutput classification, a list of dicts is used to specify weights for each output. For example, for four-class multilabel classification weights should be `[{0: 1, 1: 1}, {0: 1, 1: 5}, {0: 1, 1: 1}, {0: 1, 1: 1}]` instead of `[{1:1}, {2:5}, {3:1}, {4:1}]`.

The `class_weight` parameter is validated and interpreted with `utils.compute_class_weight`.

cv Determines a cross validation splitting strategy, as used in cross-validation based routines. `cv` is also available in estimators such as *`multioutput.ClassifierChain`* or *`calibration.CalibratedClassifierCV`* which use the predictions of one estimator as training data for another, to not overfit the training supervision.

Possible inputs for `cv` are usually:

- An integer, specifying the number of folds in K-fold cross validation. K-fold will be stratified over classes if the estimator is a classifier (determined by *`base.is_classifier`*) and the *targets* may represent a binary or multiclass (but not multioutput) classification problem (determined by *`utils.multiclass.type_of_target`*).
- A *cross-validation splitter* instance. Refer to the *User Guide* for splitters available within Scikit-learn.
- An iterable yielding train/test splits.

With some exceptions (especially where not using cross validation at all is an option), the default is 5-fold.

`cv` values are validated and interpreted with `utils.check_cv`.

kernel TODO

max_iter For estimators involving iterative optimization, this determines the maximum number of iterations to be performed in *fit*. If `max_iter` iterations are run without convergence, a *`exceptions.ConvergenceWarning`* should be raised. Note that the interpretation of "a single iteration" is inconsistent across estimators: some, but not all, use it to mean a single epoch (i.e. a pass over every sample in the data).

FIXME perhaps we should have some common tests about the relationship between ConvergenceWarning and max_iter.

memory Some estimators make use of `joblib.Memory` to store partial solutions during fitting. Thus when `fit` is called again, those partial solutions have been memoized and can be reused.

A `memory` parameter can be specified as a string with a path to a directory, or a `joblib.Memory` instance (or an object with a similar interface, i.e. a `cache` method) can be used.

`memory` values are validated and interpreted with *`utils.validation.check_memory`*.

metric As a parameter, this is the scheme for determining the distance between two data points. See *metrics.pairwise_distances*. In practice, for some algorithms, an improper distance metric (one that does not obey the triangle inequality, such as Cosine Distance) may be used.

XXX: hierarchical clustering uses `affinity` with this meaning.

We also use *metric* to refer to *evaluation metrics*, but avoid using this sense as a parameter name.

n_components The number of features which a *transformer* should transform the input into. See *components_* for the special case of affine projection.

n_iter_no_change Number of iterations with no improvement to wait before stopping the iterative procedure. This is also known as a *patience* parameter. It is typically used with *early stopping* to avoid stopping too early.

n_jobs This parameter is used to specify how many concurrent processes or threads should be used for routines that are parallelized with *joblib*.

`n_jobs` is an integer, specifying the maximum number of concurrently running workers. If 1 is given, no joblib parallelism is used at all, which is useful for debugging. If set to -1, all CPUs are used. For `n_jobs` below -1, (n_cpus + 1 + n_jobs) are used. For example with `n_jobs=-2`, all CPUs but one are used.

`n_jobs` is `None` by default, which means *unset*; it will generally be interpreted as `n_jobs=1`, unless the current `joblib.Parallel` backend context specifies otherwise.

For more details on the use of `joblib` and its interactions with scikit-learn, please refer to our *parallelism notes*.

pos_label Value with which positive labels must be encoded in binary classification problems in which the positive class is not assumed. This value is typically required to compute asymmetric evaluation metrics such as precision and recall.

random_state Whenever randomization is part of a Scikit-learn algorithm, a `random_state` parameter may be provided to control the random number generator used. Note that the mere presence of `random_state` doesn't mean that randomization is always used, as it may be dependent on another parameter, e.g. `shuffle`, being set.

`random_state`'s value may be:

None (default) Use the global random state from `numpy.random`.

An integer Use a new random number generator seeded by the given integer. To make a randomized algorithm deterministic (i.e. running it multiple times will produce the same result), an arbitrary integer `random_state` can be used. However, it may be worthwhile checking that your results are stable across a number of different distinct random seeds. Popular integer random seeds are 0 and 42.

A `numpy.random.RandomState` instance Use the provided random state, only affecting other users of the same random state instance. Calling fit multiple times will reuse the same instance, and will produce different results.

utils.check_random_state is used internally to validate the input `random_state` and return a `RandomState` instance.

scoring Specifies the score function to be maximized (usually by *cross validation*), or – in some cases – multiple score functions to be reported. The score function can be a string accepted by *metrics.get_scorer* or a callable *scorer*, not to be confused with an *evaluation metric*, as the latter have a more diverse API. `scoring` may also be set to None, in which case the estimator's *score* method is used. See *The scoring parameter: defining model evaluation rules* in the User Guide.

Where multiple metrics can be evaluated, `scoring` may be given either as a list of unique strings or a dict with names as keys and callables as values. Note that this does *not* specify which score function is to be maximised, and another parameter such as `refit` may be used for this purpose.

The `scoring` parameter is validated and interpreted using *metrics.check_scoring*.

verbose Logging is not handled very consistently in Scikit-learn at present, but when it is provided as an option, the `verbose` parameter is usually available to choose no logging (set to False). Any True value should enable some logging, but larger integers (e.g. above 10) may be needed for full verbosity. Verbose logs are usually printed to Standard Output. Estimators should not produce any output on Standard Output with the default `verbose` setting.

warm_start When fitting an estimator repeatedly on the same dataset, but for multiple parameter values (such as to find the value maximizing performance as in *grid search*), it may be possible to reuse aspects of the model learnt from the previous parameter value, saving time. When `warm_start` is true, the existing *fitted* model *attributes* are used to initialise the new model in a subsequent call to *fit*.

Note that this is only applicable for some models and some parameters, and even some orders of parameter values. For example, `warm_start` may be used when building random forests to add more trees to the forest (increasing `n_estimators`) but not to reduce their number.

partial_fit also retains the model between calls, but differs: with `warm_start` the parameters change and the data is (more-or-less) constant across calls to `fit`; with `partial_fit`, the mini-batch of data changes and model parameters stay fixed.

There are cases where you want to use `warm_start` to fit on different, but closely related data. For example, one may initially fit to a subset of the data, then fine-tune the parameter search on the full dataset. For classification, all data in a sequence of `warm_start` calls to `fit` must include samples from each class.

5.6 Attributes

See concept *attribute*.

classes_ A list of class labels known to the *classifier*, mapping each label to a numerical index used in the model representation our output. For instance, the array output from *predict_proba* has columns aligned with `classes_`. For *multi-output* classifiers, `classes_` should be a list of lists, with one class listing for each output. For each output, the classes should be sorted (numerically, or lexicographically for strings).

`classes_` and the mapping to indices is often managed with *`preprocessing.LabelEncoder`*.

components_ An affine transformation matrix of shape `(n_components, n_features)` used in many linear *transformers* where *n_components* is the number of output features and *n_features* is the number of input features.

See also *components_* which is a similar attribute for linear predictors.

coef_ The weight/coefficient matrix of a generalised linear model *predictor*, of shape `(n_features,)` for binary classification and single-output regression, `(n_classes, n_features)` for multiclass classification and `(n_targets, n_features)` for multi-output regression. Note this does not include the intercept (or bias) term, which is stored in `intercept_`.

When available, `feature_importances_` is not usually provided as well, but can be calculated as the norm of each feature's entry in `coef_`.

See also *components_* which is a similar attribute for linear transformers.

embedding_ An embedding of the training data in *manifold learning* estimators, with shape `(n_samples, n_components)`, identical to the output of *fit_transform*. See also *labels_*.

n_iter_ The number of iterations actually performed when fitting an iterative estimator that may stop upon convergence. See also *max_iter*.

feature_importances_ A vector of shape `(n_features,)` available in some *predictors* to provide a relative measure of the importance of each feature in the predictions of the model.

labels_ A vector containing a cluster label for each sample of the training data in *clusterers*, identical to the output of *fit_predict*. See also *embedding_*.

5.7 Data and sample properties

See concept *sample property*.

groups Used in cross validation routines to identify samples which are correlated. Each value is an identifier such that, in a supporting *CV splitter*, samples from some `groups` value may not appear in both a training set and its corresponding test set. See *Cross-validation iterators for grouped data.*.

sample_weight A relative weight for each sample. Intuitively, if all weights are integers, a weighted model or score should be equivalent to that calculated when repeating the sample the number of times specified in the weight. Weights may be specified as floats, so that sample weights are usually equivalent up to a constant positive scaling factor.

FIXME Is this interpretation always the case in practice? We have no common tests.

Some estimators, such as decision trees, support negative weights. FIXME: This feature or its absence may not be tested or documented in many estimators.

This is not entirely the case where other parameters of the model consider the number of samples in a region, as with `min_samples` in *`cluster.DBSCAN`*. In this case, a count of samples becomes to a sum of their weights.

In classification, sample weights can also be specified as a function of class with the *class_weight* estimator *parameter*.

X Denotes data that is observed at training and prediction time, used as independent variables in learning. The notation is uppercase to denote that it is ordinarily a matrix (see *rectangular*). When a matrix, each sample may be represented by a *feature* vector, or a vector of *precomputed* (dis)similarity with each training sample. `X` may also not be a matrix, and may require a *feature extractor* or a *pairwise metric* to turn it into one before learning a model.

Xt Shorthand for "transformed *X*".

y

Y Denotes data that may be observed at training time as the dependent variable in learning, but which is unavailable at prediction time, and is usually the *target* of prediction. The notation may be uppercase to denote that it is a matrix, representing *multi-output* targets, for instance; but usually we use `y` and sometimes do so even when multiple outputs are assumed.

EXAMPLES

6.1 Miscellaneous examples

Miscellaneous and introductory examples for scikit-learn.

Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.1.1 Compact estimator representations

This example illustrates the use of the print_changed_only global parameter.

Setting print_changed_only to True will alternate the representation of estimators to only show the parameters that have been set to non-default values. This can be used to have more compact representations.

Out:

```
Default representation:
LogisticRegression(penalty='l1')

With changed_only option:
LogisticRegression(penalty='l1')
```

```
print(__doc__)

from sklearn.linear_model import LogisticRegression
from sklearn import set_config

lr = LogisticRegression(penalty='l1')
print('Default representation:')
print(lr)
# LogisticRegression(C=1.0, class_weight=None, dual=False, fit_intercept=True,
#                    intercept_scaling=1, l1_ratio=None, max_iter=100,
#                    multi_class='auto', n_jobs=None, penalty='l1',
#                    random_state=None, solver='warn', tol=0.0001, verbose=0,
#                    warm_start=False)
```

(continues on next page)

(continued from previous page)

```
set_config(print_changed_only=True)
print('\nWith changed_only option:')
print(lr)
# LogisticRegression(penalty='l1')
```

Total running time of the script: (0 minutes 0.097 seconds)

Estimated memory usage: 8 MB

Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.1.2 ROC Curve with Visualization API

Scikit-learn defines a simple API for creating visualizations for machine learning. The key features of this API is to allow for quick plotting and visual adjustments without recalculation. In this example, we will demonstrate how to use the visualization API by comparing ROC curves.

```
print(__doc__)
```

Load Data and Train a SVC

First, we load the wine dataset and convert it to a binary classification problem. Then, we train a support vector classifier on a training dataset.

```
import matplotlib.pyplot as plt
from sklearn.svm import SVC
from sklearn.ensemble import RandomForestClassifier
from sklearn.metrics import plot_roc_curve
from sklearn.datasets import load_wine
from sklearn.model_selection import train_test_split

X, y = load_wine(return_X_y=True)
y = y == 2

X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=42)
svc = SVC(random_state=42)
svc.fit(X_train, y_train)
```

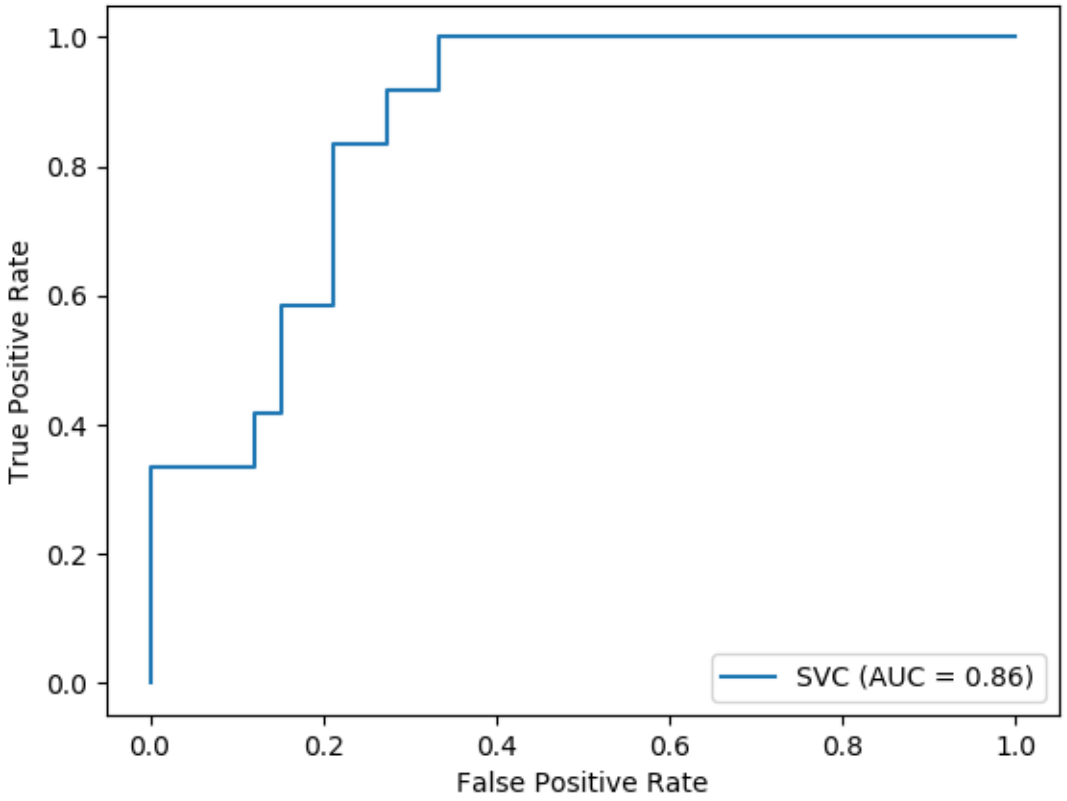
Out:

```
SVC(random_state=42)
```

Plotting the ROC Curve

Next, we plot the ROC curve with a single call to *sklearn.metrics.plot_roc_curve*. The returned `svc_disp` object allows us to continue using the already computed ROC curve for the SVC in future plots.

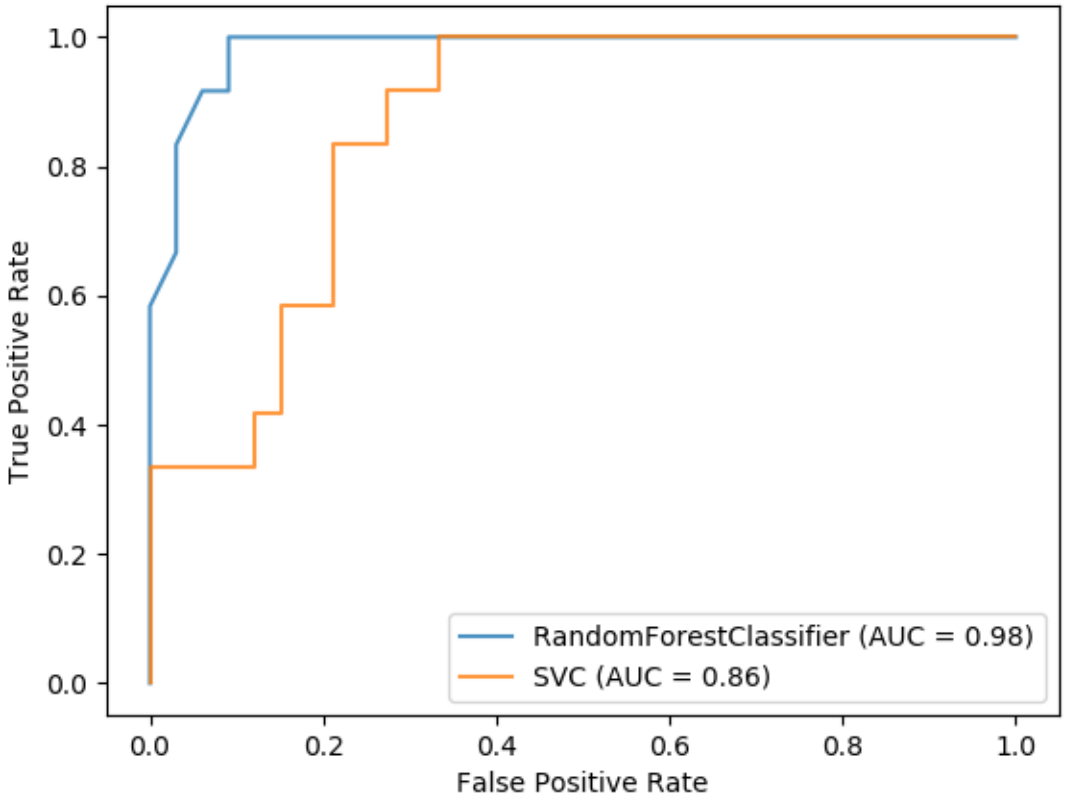
```
svc_disp = plot_roc_curve(svc, X_test, y_test)
plt.show()
```



Training a Random Forest and Plotting the ROC Curve

We train a random forest classifier and create a plot comparing it to the SVC ROC curve. Notice how `svc_disp` uses *`plot`* to plot the SVC ROC curve without recomputing the values of the roc curve itself. Furthermore, we pass `alpha=0.8` to the plot functions to adjust the alpha values of the curves.

```
rfc = RandomForestClassifier(n_estimators=10, random_state=42)
rfc.fit(X_train, y_train)
ax = plt.gca()
rfc_disp = plot_roc_curve(rfc, X_test, y_test, ax=ax, alpha=0.8)
svc_disp.plot(ax=ax, alpha=0.8)
plt.show()
```



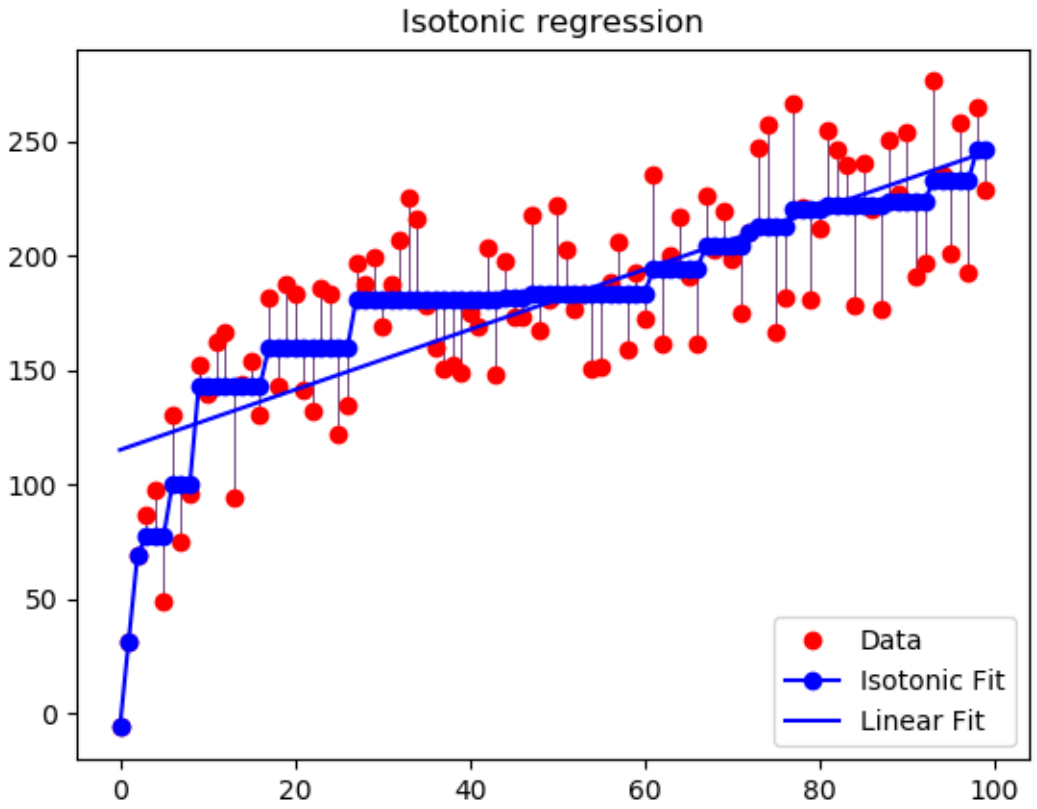
Total running time of the script: (0 minutes 0.567 seconds)

Estimated memory usage: 12 MB

Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.1.3 Isotonic Regression

An illustration of the isotonic regression on generated data. The isotonic regression finds a non-decreasing approximation of a function while minimizing the mean squared error on the training data. The benefit of such a model is that it does not assume any form for the target function such as linearity. For comparison a linear regression is also presented.



```
print(__doc__)

6.1.4 Advanced Plotting With Partial Dependence

The *plot_partial_dependence* function returns a *PartialDependenceDisplay* object that can be used for plotting without needing to recalculate the partial dependence. In this example, we show how to plot partial dependence plots and how to quickly customize the plot with the visualization API.

Note: See also *ROC Curve with Visualization API*

```
print(__doc__)

import pandas as pd
import matplotlib.pyplot as plt
from sklearn.datasets import load_boston
from sklearn.neural_network import MLPRegressor
from sklearn.preprocessing import StandardScaler
from sklearn.pipeline import make_pipeline
from sklearn.tree import DecisionTreeRegressor
from sklearn.inspection import plot_partial_dependence
```

Train models on the boston housing price dataset

First, we train a decision tree and a multi-layer perceptron on the boston housing price dataset.

```
boston = load_boston()
X = pd.DataFrame(boston.data, columns=boston.feature_names)
y = boston.target

tree = DecisionTreeRegressor()
mlp = make_pipeline(StandardScaler(),
                    MLPRegressor(hidden_layer_sizes=(100, 100),
                                 tol=1e-2, max_iter=500, random_state=0))
tree.fit(X, y)
mlp.fit(X, y)
```

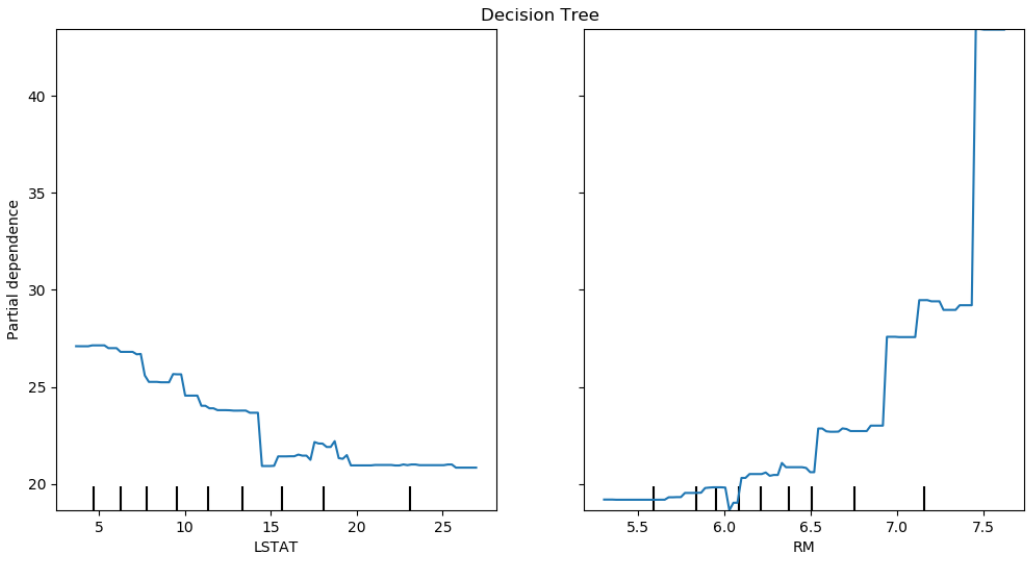
Out:

```
Pipeline(steps=[('standardscaler', StandardScaler()),
                ('mlpregressor',
                 MLPRegressor(hidden_layer_sizes=(100, 100), max_iter=500,
                              random_state=0, tol=0.01))])
```

Plotting partial dependence for two features

We plot partial dependence curves for features "LSTAT" and "RM" for the decision tree. With two features, *plot_partial_dependence* expects to plot two curves. Here the plot function place a grid of two plots using the space defined by `ax` .

```
fig, ax = plt.subplots(figsize=(12, 6))
ax.set_title("Decision Tree")
tree_disp = plot_partial_dependence(tree, X, ["LSTAT", "RM"], ax=ax)
```

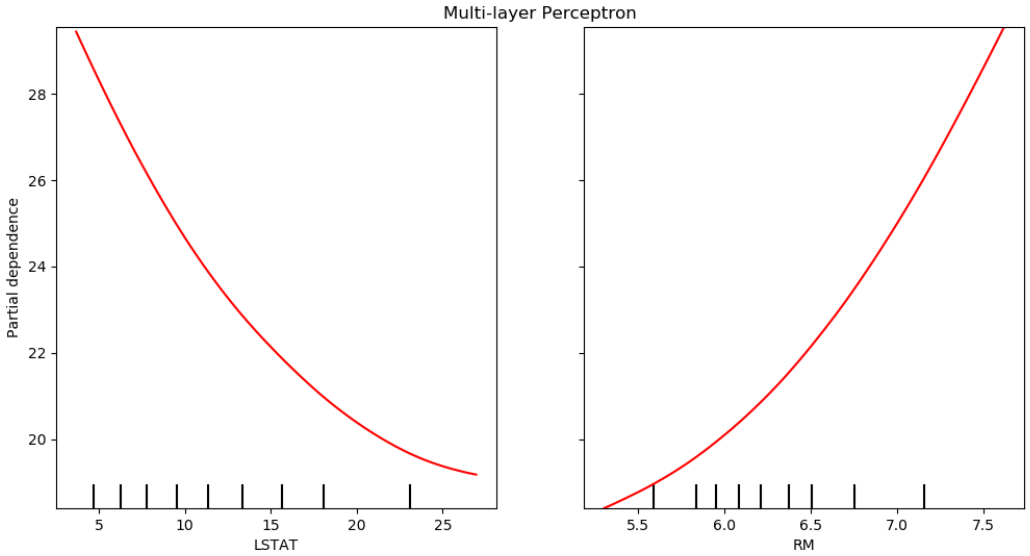


Out:

```
/home/circleci/project/sklearn/tree/_classes.py:1233: FutureWarning: the classes_␣
↪attribute is to be deprecated from version 0.22 and will be removed in 0.24.
  warnings.warn(msg, FutureWarning)
```

The partial depdendence curves can be plotted for the multi-layer perceptron. In this case, `line_kw` is passed to *`plot_partial_dependence`* to change the color of the curve.

```
fig, ax = plt.subplots(figsize=(12, 6))
ax.set_title("Multi-layer Perceptron")
mlp_disp = plot_partial_dependence(mlp, X, ["LSTAT", "RM"], ax=ax,
                                   line_kw={"c": "red"})
```

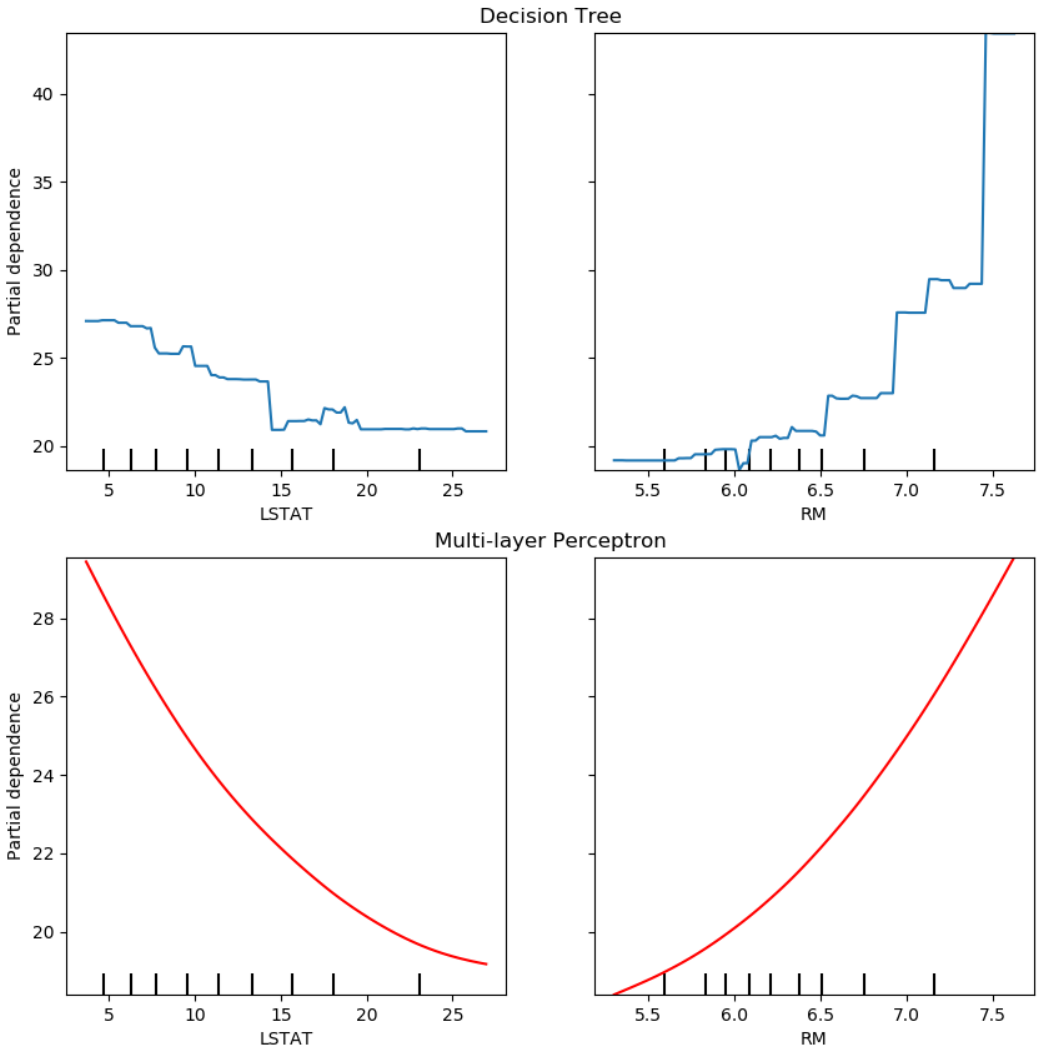


Plotting partial dependence of the two models together

The `tree_disp` and `mlp_disp` *`PartialDependenceDisplay`* objects contain all the computed information needed to recreate the partial dependence curves. This means we can easily create additional plots without needing to recompute the curves.

One way to plot the curves is to place them in the same figure, with the curves of each model on each row. First, we create a figure with two axes within two rows and one column. The two axes are passed to the *`plot`* functions of `tree_disp` and `mlp_disp`. The given axes will be used by the plotting function to draw the partial dependence. The resulting plot places the decision tree partial dependence curves in the first row of the multi-layer perceptron in the second row.

```
fig, (ax1, ax2) = plt.subplots(2, 1, figsize=(10, 10))
tree_disp.plot(ax=ax1)
ax1.set_title("Decision Tree")
mlp_disp.plot(ax=ax2, line_kw={"c": "red"})
ax2.set_title("Multi-layer Perceptron")
```



Out:

```
Text(0.5, 1.0, 'Multi-layer Perceptron')
```

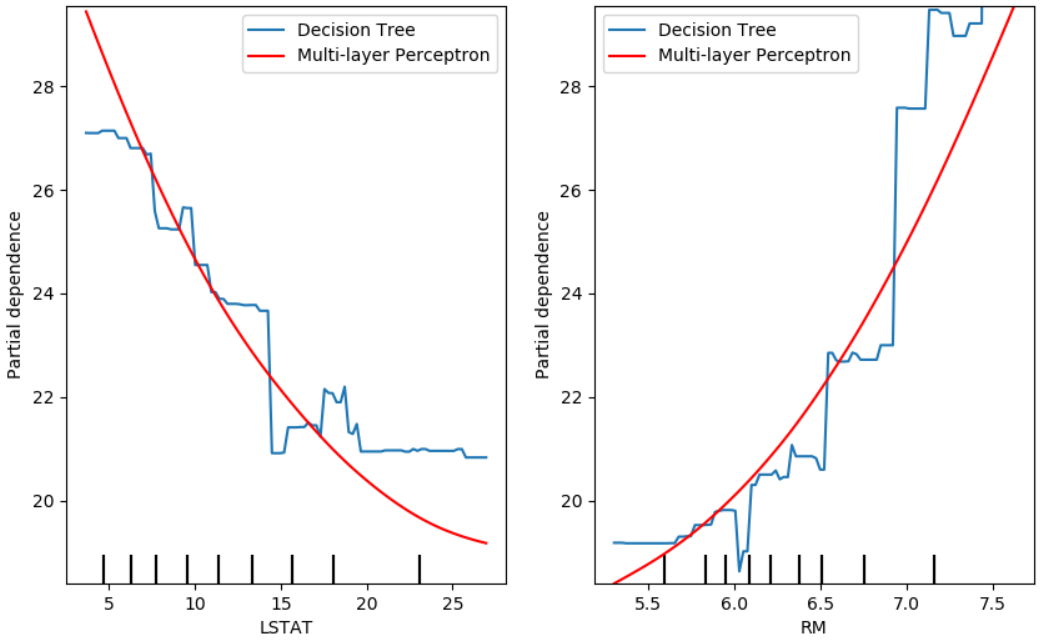
Another way to compare the curves is to plot them on top of each other. Here, we create a figure with one row and two columns. The axes are passed into the *plot* function as a list, which will plot the partial dependence curves of each model on the same axes. The length of the axes list must be equal to the number of plots drawn.

```
# Sets this image as the thumbnail for sphinx gallery
# sphinx_gallery_thumbnail_number = 4
fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(10, 6))
tree_disp.plot(ax=[ax1, ax2], line_kw={"label": "Decision Tree"})
mlp_disp.plot(ax=[ax1, ax2], line_kw={"label": "Multi-layer Perceptron",
                                      "c": "red"})
```

(continues on next page)

(continued from previous page)

```
ax1.legend()
ax2.legend()
```

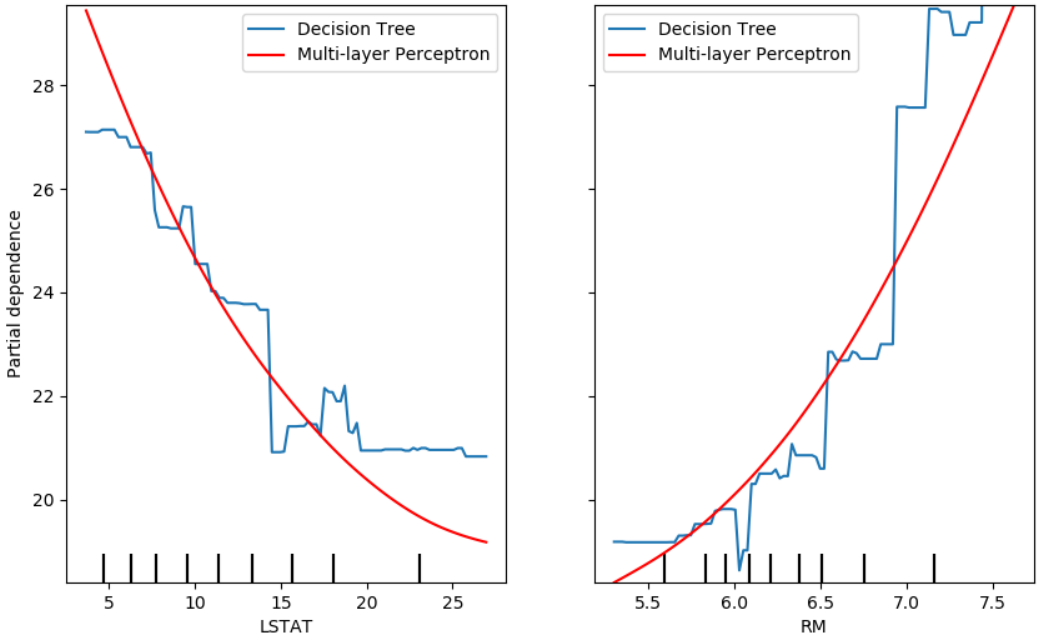


Out:

```
<matplotlib.legend.Legend object at 0x7ffa2778ec70>
```

`tree_disp.axes_` is a numpy array container the axes used to draw the partial dependence plots. This can be passed to `mlp_disp` to have the same affect of drawing the plots on top of each other. Furthermore, the `mlp_disp.figure_` stores the figure, which allows for resizing the figure after calling `plot`. In this case `tree_disp.axes_` has two dimensions, thus `plot` will only show the y label and y ticks on the left most plot.

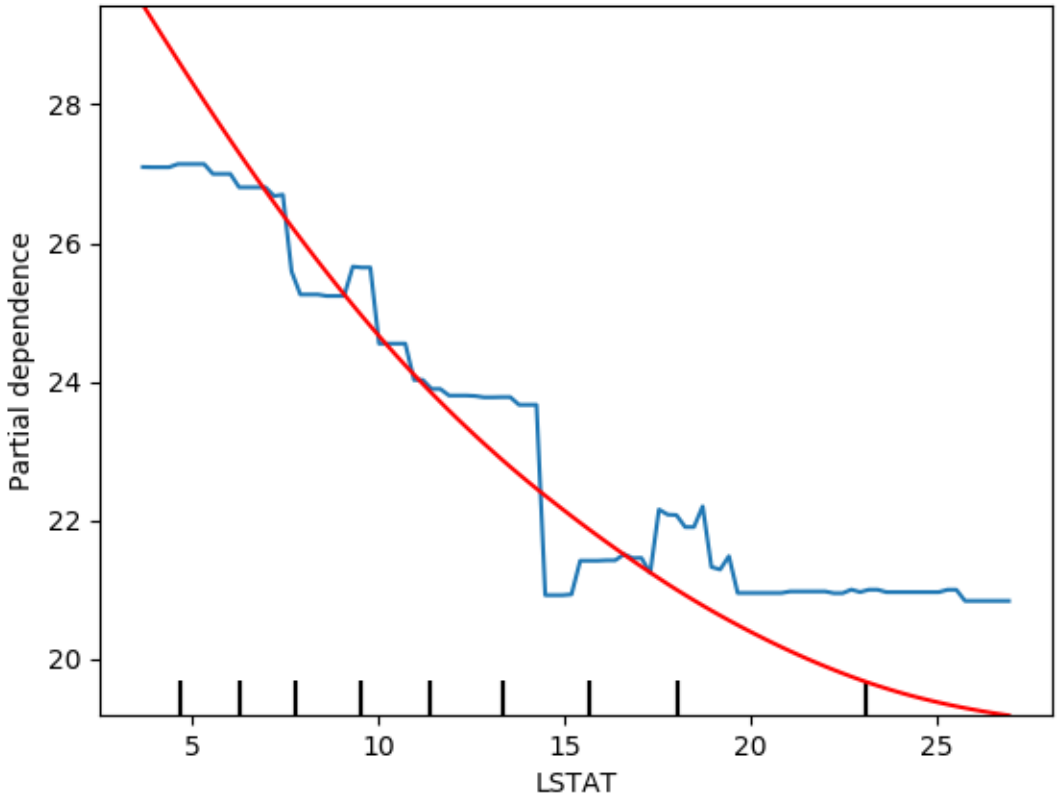
```
tree_disp.plot(line_kw={"label": "Decision Tree"})
mlp_disp.plot(line_kw={"label": "Multi-layer Perceptron", "c": "red"},
              ax=tree_disp.axes_)
tree_disp.figure_.set_size_inches(10, 6)
tree_disp.axes_[0, 0].legend()
tree_disp.axes_[0, 1].legend()
plt.show()
```



Plotting partial dependence for one feature

Here, we plot the partial dependence curves for a single feature, "LSTAT", on the same axes. In this case, `tree_disp.axes_` is passed into the second plot function.

```
tree_disp = plot_partial_dependence(tree, X, ["LSTAT"])
mlp_disp = plot_partial_dependence(mlp, X, ["LSTAT"],
                                   ax=tree_disp.axes_, line_kw={"c": "red"})
```



Out:

```
/home/circleci/project/sklearn/tree/_classes.py:1233: FutureWarning: the classes_
↪attribute is to be deprecated from version 0.22 and will be removed in 0.24.
  warnings.warn(msg, FutureWarning)
```

Total running time of the script: (0 minutes 3.668 seconds)

Estimated memory usage: 47 MB

Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.1.5 Face completion with a multi-output estimators

This example shows the use of multi-output estimator to complete images. The goal is to predict the lower half of a face given its upper half.

The first column of images shows true faces. The next columns illustrate how extremely randomized trees, k nearest neighbors, linear regression and ridge regression complete the lower half of those faces.

```
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt

from sklearn.datasets import fetch_olivetti_faces
from sklearn.utils.validation import check_random_state

from sklearn.ensemble import ExtraTreesRegressor
```

(continues on next page)

(continued from previous page)

```
from sklearn.neighbors import KNeighborsRegressor
from sklearn.linear_model import LinearRegression
from sklearn.linear_model import RidgeCV

# Load the faces datasets
data, targets = fetch_olivetti_faces(return_X_y=True)

plt.show()
```

Total running time of the script: (0 minutes 2.393 seconds)

Estimated memory usage: 263 MB

Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.1.6 Multilabel classification

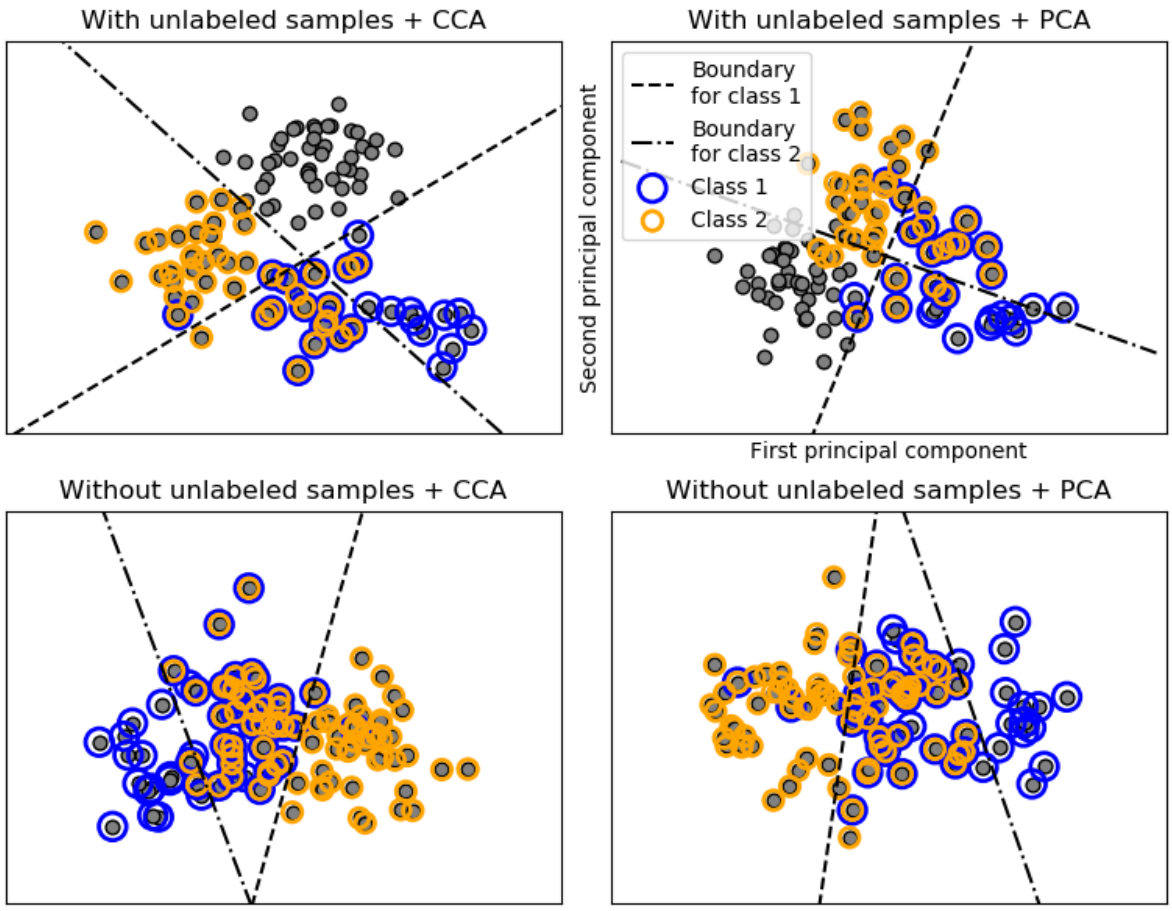
This example simulates a multi-label document classification problem. The dataset is generated randomly based on the following process:

- pick the number of labels: n ~ Poisson(n_labels)
- n times, choose a class c: c ~ Multinomial(theta)
- pick the document length: k ~ Poisson(length)
- k times, choose a word: w ~ Multinomial(theta_c)

In the above process, rejection sampling is used to make sure that n is more than 2, and that the document length is never zero. Likewise, we reject classes which have already been chosen. The documents that are assigned to both classes are plotted surrounded by two colored circles.

The classification is performed by projecting to the first two principal components found by PCA and CCA for visualisation purposes, followed by using the *sklearn.multiclass.OneVsRestClassifier* metaclassifier using two SVCs with linear kernels to learn a discriminative model for each class. Note that PCA is used to perform an unsupervised dimensionality reduction, while CCA is used to perform a supervised one.

Note: in the plot, "unlabeled samples" does not mean that we don't know the labels (as in semi-supervised learning) but that the samples simply do *not* have a label.



```
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt

from sklearn.datasets import make_multilabel_classification
from sklearn.multiclass import OneVsRestClassifier
from sklearn.svm import SVC
from sklearn.decomposition import PCA
from sklearn.cross_decomposition import CCA

6.1.7 Comparing anomaly detection algorithms for outlier detection on toy datasets

This example shows characteristics of different anomaly detection algorithms on 2D datasets. Datasets contain one or two modes (regions of high density) to illustrate the ability of algorithms to cope with multimodal data.

For each dataset, 15% of samples are generated as random uniform noise. This proportion is the value given to the nu parameter of the OneClassSVM and the contamination parameter of the other outlier detection algorithms. Decision boundaries between inliers and outliers are displayed in black except for Local Outlier Factor (LOF) as it has no predict method to be applied on new data when it is used for outlier detection.

The `sklearn.svm.OneClassSVM` is known to be sensitive to outliers and thus does not perform very well for outlier detection. This estimator is best suited for novelty detection when the training set is not contaminated by outliers. That said, outlier detection in high-dimension, or without any assumptions on the distribution of the inlying data is very challenging, and a One-class SVM might give useful results in these situations depending on the value of its hyperparameters.

`sklearn.covariance.EllipticEnvelope` assumes the data is Gaussian and learns an ellipse. It thus degrades when the data is not unimodal. Notice however that this estimator is robust to outliers.

`sklearn.ensemble.IsolationForest` and `sklearn.neighbors.LocalOutlierFactor` seem to perform reasonably well for multi-modal data sets. The advantage of `sklearn.neighbors.LocalOutlierFactor` over the other estimators is shown for the third data set, where the two modes have different densities. This advantage is explained by the local aspect of LOF, meaning that it only compares the score of abnormality of one sample with the scores of its neighbors.

Finally, for the last data set, it is hard to say that one sample is more abnormal than another sample as they are uniformly distributed in a hypercube. Except for the `sklearn.svm.OneClassSVM` which overfits a little, all estimators present decent solutions for this situation. In such a case, it would be wise to look more closely at the scores of abnormality of the samples as a good estimator should assign similar scores to all the samples.

While these examples give some intuition about the algorithms, this intuition might not apply to very high dimensional data.

Finally, note that parameters of the models have been here handpicked but that in practice they need to be adjusted. In the absence of labelled data, the problem is completely unsupervised so model selection can be a challenge.

6.1.8 The Johnson-Lindenstrauss bound for embedding with random projections

The Johnson-Lindenstrauss lemma states that any high dimensional dataset can be randomly projected into a lower dimensional Euclidean space while controlling the distortion in the pairwise distances.

```
print(__doc__)

import sys
from time import time
import numpy as np
import matplotlib
import matplotlib.pyplot as plt
from distutils.version import LooseVersion
from sklearn.random_projection import johnson_lindenstrauss_min_dim
```

(continues on next page)

(continued from previous page)

```
from sklearn.random_projection import SparseRandomProjection
from sklearn.datasets import fetch_20newsgroups_vectorized
from sklearn.datasets import load_digits
from sklearn.metrics.pairwise import euclidean_distances

# `normed` is being deprecated in favor of `density` in histograms
if LooseVersion(matplotlib.__version__) >= '2.1':
    density_param = {'density': True}
else:
    density_param = {'normed': True}
```

Theoretical bounds

The distortion introduced by a random projection `p` is asserted by the fact that `p` is defining an eps-embedding with good probability as defined by:

$$(1 - eps)\|u - v\|^2 < \|p(u) - p(v)\|^2 < (1 + eps)\|u - v\|^2$$

Where u and v are any rows taken from a dataset of shape [n_samples, n_features] and p is a projection by a random Gaussian N(0, 1) matrix with shape [n_components, n_features] (or a sparse Achlioptas matrix).

The minimum number of components to guarantees the eps-embedding is given by:

$$n\_components >= 4log(n\_samples)/(eps^2/2 - eps^3/3)$$

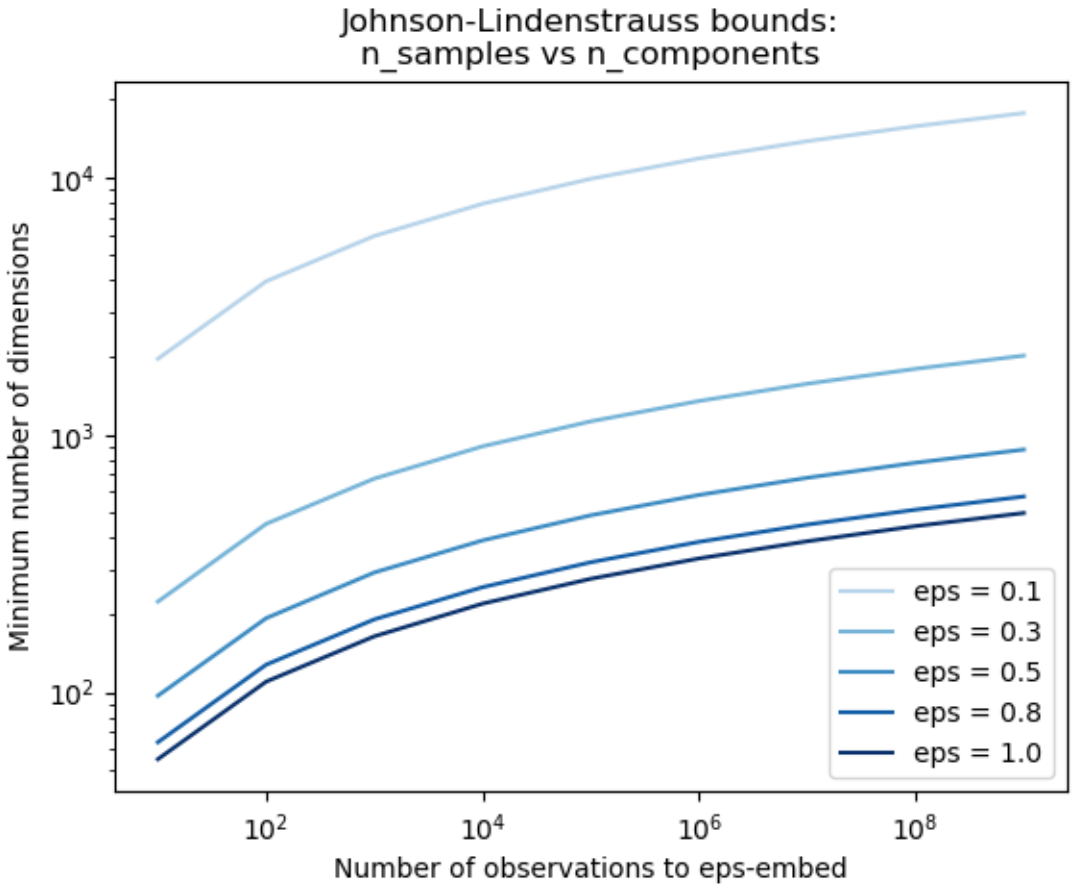
The first plot shows that with an increasing number of samples `n_samples`, the minimal number of dimensions `n_components` increased logarithmically in order to guarantee an `eps`-embedding.

```
# range of admissible distortions
eps_range = np.linspace(0.1, 0.99, 5)
colors = plt.cm.Blues(np.linspace(0.3, 1.0, len(eps_range)))

# range of number of samples (observation) to embed
n_samples_range = np.logspace(1, 9, 9)

plt.figure()
for eps, color in zip(eps_range, colors):
    min_n_components = johnson_lindenstrauss_min_dim(n_samples_range, eps=eps)
    plt.loglog(n_samples_range, min_n_components, color=color)

plt.legend(["eps = %0.1f" % eps for eps in eps_range], loc="lower right")
plt.xlabel("Number of observations to eps-embed")
plt.ylabel("Minimum number of dimensions")
plt.title("Johnson-Lindenstrauss bounds:\nn_samples vs n_components")
plt.show()
```



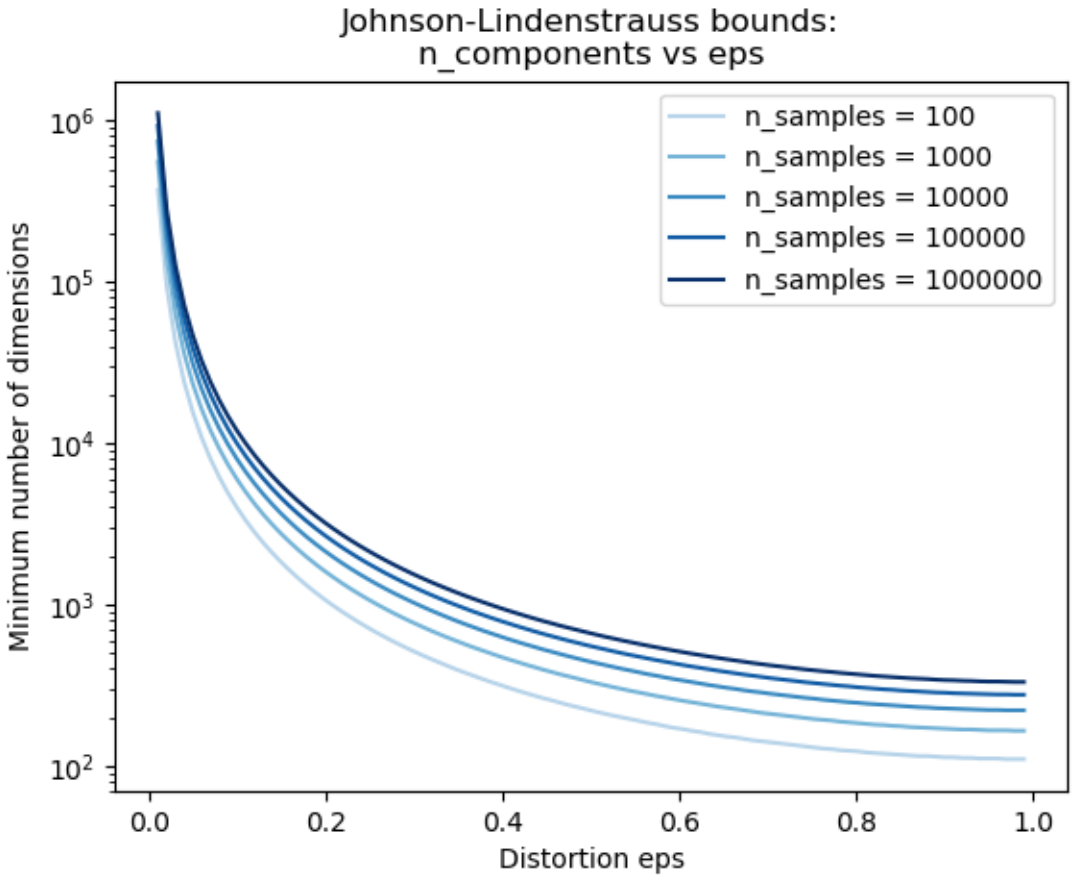
The second plot shows that an increase of the admissible distortion `eps` allows to reduce drastically the minimal number of dimensions `n_components` for a given number of samples `n_samples`

```
# range of admissible distortions
eps_range = np.linspace(0.01, 0.99, 100)

# range of number of samples (observation) to embed
n_samples_range = np.logspace(2, 6, 5)
colors = plt.cm.Blues(np.linspace(0.3, 1.0, len(n_samples_range)))

plt.figure()
for n_samples, color in zip(n_samples_range, colors):
    min_n_components = johnson_lindenstrauss_min_dim(n_samples, eps=eps_range)
    plt.semilogy(eps_range, min_n_components, color=color)

plt.legend(["n_samples = %d" % n for n in n_samples_range], loc="upper right")
plt.xlabel("Distortion eps")
plt.ylabel("Minimum number of dimensions")
plt.title("Johnson-Lindenstrauss bounds:\nn_components vs eps")
plt.show()
```



Empirical validation

We validate the above bounds on the 20 newsgroups text document (TF-IDF word frequencies) dataset or on the digits dataset:

- for the 20 newsgroups dataset some 500 documents with 100k features in total are projected using a sparse random matrix to smaller euclidean spaces with various values for the target number of dimensions `n_components`.
- for the digits dataset, some 8x8 gray level pixels data for 500 handwritten digits pictures are randomly projected to spaces for various larger number of dimensions `n_components`.

The default dataset is the 20 newsgroups dataset. To run the example on the digits dataset, pass the `--use-digits-dataset` command line argument to this script.

```
if '--use-digits-dataset' in sys.argv:
    data = load_digits().data[:500]
else:
    data = fetch_20newsgroups_vectorized().data[:500]
```

For each value of `n_components`, we plot:

- 2D distribution of sample pairs with pairwise distances in original and projected spaces as x and y axis respectively.
- 1D histogram of the ratio of those distances (projected / original).

```
n_samples, n_features = data.shape
print("Embedding %d samples with dim %d using various random projections"
      % (n_samples, n_features))

n_components_range = np.array([300, 1000, 10000])
dists = euclidean_distances(data, squared=True).ravel()

# select only non-identical samples pairs
nonzero = dists != 0
dists = dists[nonzero]

for n_components in n_components_range:
    t0 = time()
    rp = SparseRandomProjection(n_components=n_components)
    projected_data = rp.fit_transform(data)
    print("Projected %d samples from %d to %d in %0.3fs"
          % (n_samples, n_features, n_components, time() - t0))
    if hasattr(rp, 'components_'):
        n_bytes = rp.components_.data.nbytes
        n_bytes += rp.components_.indices.nbytes
        print("Random matrix with size: %0.3fMB" % (n_bytes / 1e6))

    projected_dists = euclidean_distances(
        projected_data, squared=True).ravel()[nonzero]

    plt.figure()
    min_dist = min(projected_dists.min(), dists.min())
    max_dist = max(projected_dists.max(), dists.max())
    plt.hexbin(dists, projected_dists, gridsize=100, cmap=plt.cm.PuBu,
               extent=[min_dist, max_dist, min_dist, max_dist])

Embedding 500 samples with dim 130107 using various random projections
Projected 500 samples from 130107 to 300 in 0.632s
Random matrix with size: 1.296MB
Mean distances rate: 1.00 (0.19)
Projected 500 samples from 130107 to 1000 in 2.118s
Random matrix with size: 4.328MB
Mean distances rate: 1.00 (0.10)
Projected 500 samples from 130107 to 10000 in 22.211s
Random matrix with size: 43.315MB
Mean distances rate: 1.03 (0.04)
```

We can see that for low values of `n_components` the distribution is wide with many distorted pairs and a skewed distribution (due to the hard limit of zero ratio on the left as distances are always positives) while for larger values of n_components the distortion is controlled and the distances are well preserved by the random projection.

Remarks

According to the JL lemma, projecting 500 samples without too much distortion will require at least several thousands dimensions, irrespective of the number of features of the original dataset.

Hence using random projections on the digits dataset which only has 64 features in the input space does not make sense: it does not allow for dimensionality reduction in this case.

On the twenty newsgroups on the other hand the dimensionality can be decreased from 56436 down to 10000 while reasonably preserving pairwise distances.

6.1.9 Comparison of kernel ridge regression and SVR

Both kernel ridge regression (KRR) and SVR learn a non-linear function by employing the kernel trick, i.e., they learn a linear function in the space induced by the respective kernel which corresponds to a non-linear function in the original space. They differ in the loss functions (ridge versus epsilon-insensitive loss). In contrast to SVR, fitting a KRR can be done in closed-form and is typically faster for medium-sized datasets. On the other hand, the learned model is non-sparse and thus slower than SVR at prediction-time.

This example illustrates both methods on an artificial dataset, which consists of a sinusoidal target function and strong noise added to every fifth datapoint. The first figure compares the learned model of KRR and SVR when both complexity/regularization and bandwidth of the RBF kernel are optimized using grid-search. The learned functions are very similar; however, fitting KRR is approx. seven times faster than fitting SVR (both with grid-search). However, prediction of 100000 target values is more than tree times faster with SVR since it has learned a sparse model using only approx. 1/3 of the 100 training datapoints as support vectors.

The next figure compares the time for fitting and prediction of KRR and SVR for different sizes of the training set. Fitting KRR is faster than SVR for medium- sized training sets (less than 1000 samples); however, for larger training sets SVR scales better. With regard to prediction time, SVR is faster than KRR for all sizes of the training set because of the learned sparse solution. Note that the degree of sparsity and thus the prediction time depends on the parameters epsilon and C of the SVR.

6.1.10 Explicit feature map approximation for RBF kernels

An example illustrating the approximation of the feature map of an RBF kernel.

It shows how to use *RBFSampler* and *Nystroem* to approximate the feature map of an RBF kernel for classification with an SVM on the digits dataset. Results using a linear SVM in the original space, a linear SVM using the approximate mappings and using a kernelized SVM are compared. Timings and accuracy for varying amounts of Monte Carlo samplings (in the case of *RBFSampler*, which uses random Fourier features) and different sized subsets of the training set (for *Nystroem*) for the approximate mapping are shown.

Please note that the dataset here is not large enough to show the benefits of kernel approximation, as the exact SVM is still reasonably fast.

Sampling more dimensions clearly leads to better classification results, but comes at a greater cost. This means there is a tradeoff between runtime and accuracy, given by the parameter n_components. Note that solving the Linear SVM and also the approximate kernel SVM could be greatly accelerated by using stochastic gradient descent via *sklearn.linear_model.SGDClassifier*. This is not easily possible for the case of the kernelized SVM.

Timing and accuracy plots

To apply an classifier on this data, we need to flatten the image, to turn the data in a (samples, feature) matrix:

```
n_samples = len(digits.data)
data = digits.data / 16.
data -= data.mean(axis=0)

# We learn the digits on the first half of the digits

Decision Surfaces of RBF Kernel SVM and Linear SVM

The second plot visualized the decision surfaces of the RBF kernel SVM and the linear SVM with approximate kernel maps. The plot shows decision surfaces of the classifiers projected onto the first two principal components of the data. This visualization should be taken with a grain of salt since it is just an interesting slice through the decision surface in 64 dimensions. In particular note that a datapoint (represented as a dot) does not necessarily be classified into the region it is lying in, since it will not lie on the plane that the first two principal components span. The usage of *RBFSampler* and *Nystroem* is described in detail in *Kernel Approximation*.

```
# visualize the decision surface, projected down to the first
# two principal components of the dataset
pca = PCA(n_components=8).fit(data_train)

X = pca.transform(data_train)

# Generate grid along first two principal components
multiples = np.arange(-2, 2, 0.1)
# steps along first component
first = multiples[:, np.newaxis] * pca.components_[0, :]
# steps along second component
second = multiples[:, np.newaxis] * pca.components_[1, :]
# combine
grid = first[np.newaxis, :, :] + second[:, np.newaxis, :]
flat_grid = grid.reshape(-1, data.shape[1])

# title for the plots
titles = ['SVC with rbf kernel',
          'SVC (linear kernel)\n with Fourier rbf feature map\n'
          'n_components=100',
          'SVC (linear kernel)\n with Nystroem rbf feature map\n'
          'n_components=100']

6.2 Biclustering

Examples concerning the `sklearn.cluster.bicluster` module.

Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.2.1 A demo of the Spectral Co-Clustering algorithm

This example demonstrates how to generate a dataset and bicluster it using the Spectral Co-Clustering algorithm.

The dataset is generated using the `make_biclusters` function, which creates a matrix of small values and implants bicluster with large values. The rows and columns are then shuffled and passed to the Spectral Co-Clustering algorithm. Rearranging the shuffled matrix to make biclusters contiguous shows how accurately the algorithm found the biclusters.

6.2.2 A demo of the Spectral Biclustering algorithm

This example demonstrates how to generate a checkerboard dataset and bicluster it using the Spectral Biclustering algorithm.

The data is generated with the `make_checkerboard` function, then shuffled and passed to the Spectral Biclustering algorithm. The rows and columns of the shuffled matrix are rearranged to show the biclusters found by the algorithm.

The outer product of the row and column label vectors shows a representation of the checkerboard structure.

6.2.3 Biclustering documents with the Spectral Co-clustering algorithm

This example demonstrates the Spectral Co-clustering algorithm on the twenty newsgroups dataset. The 'comp.os.ms-windows.misc' category is excluded because it contains many posts containing nothing but data.

The TF-IDF vectorized posts form a word frequency matrix, which is then biclustered using Dhillon's Spectral Co-Clustering algorithm. The resulting document-word biclusters indicate subsets words used more often in those subsets documents.

For a few of the best biclusters, its most common document categories and its ten most important words get printed. The best biclusters are determined by their normalized cut. The best words are determined by comparing their sums inside and outside the bicluster.

For comparison, the documents are also clustered using MiniBatchKMeans. The document clusters derived from the biclusters achieve a better V-measure than clusters found by MiniBatchKMeans.

Out:

6.3 Calibration

Examples illustrating the calibration of predicted probabilities of classifiers.

Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.3.1 Comparison of Calibration of Classifiers

Well calibrated classifiers are probabilistic classifiers for which the output of the predict_proba method can be directly interpreted as a confidence level. For instance a well calibrated (binary) classifier should classify the samples such that among the samples to which it gave a predict_proba value close to 0.8, approx. 80% actually belong to the positive class.

LogisticRegression returns well calibrated predictions as it directly optimizes log-loss. In contrast, the other methods return biased probabilities, with different biases per method:

- GaussianNaiveBayes tends to push probabilities to 0 or 1 (note the counts in the histograms). This is mainly because it makes the assumption that features are conditionally independent given the class, which is not the case in this dataset which contains 2 redundant features.
- RandomForestClassifier shows the opposite behavior: the histograms show peaks at approx. 0.2 and 0.9 probability, while probabilities close to 0 or 1 are very rare. An explanation for this is given by Niculescu-Mizil and Caruana[1]: "Methods such as bagging and random forests that average predictions from a base set of models can have difficulty making predictions near 0 and 1 because variance in the underlying base models will bias predictions that should be near zero or one away from these values. Because predictions are restricted to the interval [0,1], errors caused by variance tend to be one- sided near zero and one. For example, if a model should predict p = 0 for a case, the only way bagging can achieve this is if all bagged trees predict zero. If we add noise to the trees that bagging is averaging over, this noise will cause some trees to predict values larger than 0 for this case, thus moving the average prediction of the bagged ensemble away from 0. We observe this effect most strongly with random forests because the base-level trees trained with random forests have relatively high variance due to feature subsetting." As a result, the calibration curve shows a characteristic sigmoid shape, indicating that the classifier could trust its "intuition" more and return probabilities closer to 0 or 1 typically.
- Support Vector Classification (SVC) shows an even more sigmoid curve as the RandomForestClassifier, which is typical for maximum-margin methods (compare Niculescu-Mizil and Caruana[1]), which focus on hard samples that are close to the decision boundary (the support vectors).

6.3.2 Probability Calibration curves

When performing classification one often wants to predict not only the class label, but also the associated probability. This probability gives some kind of confidence on the prediction. This example demonstrates how to display how well calibrated the predicted probabilities are and how to calibrate an uncalibrated classifier.

The experiment is performed on an artificial dataset for binary classification with 100,000 samples (1,000 of them are used for model fitting) with 20 features. Of the 20 features, only 2 are informative and 10 are redundant. The first figure shows the estimated probabilities obtained with logistic regression, Gaussian naive Bayes, and Gaussian naive Bayes with both isotonic calibration and sigmoid calibration. The calibration performance is evaluated with Brier score, reported in the legend (the smaller the better). One can observe here that logistic regression is well calibrated while raw Gaussian naive Bayes performs very badly. This is because of the redundant features which violate the assumption of feature-independence and result in an overly confident classifier, which is indicated by the typical transposed-sigmoid curve.

Calibration of the probabilities of Gaussian naive Bayes with isotonic regression can fix this issue as can be seen from the nearly diagonal calibration curve. Sigmoid calibration also improves the brier score slightly, albeit not as strongly as the non-parametric isotonic regression. This can be attributed to the fact that we have plenty of calibration data such that the greater flexibility of the non-parametric model can be exploited.

The second figure shows the calibration curve of a linear support-vector classifier (LinearSVC). LinearSVC shows the opposite behavior as Gaussian naive Bayes: the calibration curve has a sigmoid curve, which is typical for an under-confident classifier. In the case of LinearSVC, this is caused by the margin property of the hinge loss, which lets the model focus on hard samples that are close to the decision boundary (the support vectors).

Both kinds of calibration can fix this issue and yield nearly identical results. This shows that sigmoid calibration can deal with situations where the calibration curve of the base classifier is sigmoid (e.g., for LinearSVC) but not where it is transposed-sigmoid (e.g., Gaussian naive Bayes).

6.3.3 Probability calibration of classifiers

When performing classification you often want to predict not only the class label, but also the associated probability. This probability gives you some kind of confidence on the prediction. However, not all classifiers provide well-calibrated probabilities, some being over-confident while others being under-confident. Thus, a separate calibration of predicted probabilities is often desirable as a postprocessing. This example illustrates two different methods for this calibration and evaluates the quality of the returned probabilities using Brier's score (see https://en.wikipedia.org/wiki/Brier_score).

Compared are the estimated probability using a Gaussian naive Bayes classifier without calibration, with a sigmoid calibration, and with a non-parametric isotonic calibration. One can observe that only the non-parametric model is able to provide a probability calibration that returns probabilities close to the expected 0.5 for most of the samples belonging to the middle cluster with heterogeneous labels. This results in a significantly improved Brier score.

6.3.4 Probability Calibration for 3-class classification

This example illustrates how sigmoid calibration changes predicted probabilities for a 3-class classification problem. Illustrated is the standard 2-simplex, where the three corners correspond to the three classes. Arrows point from the probability vectors predicted by an uncalibrated classifier to the probability vectors predicted by the same classifier after sigmoid calibration on a hold-out validation set. Colors indicate the true class of an instance (red: class 1, green: class 2, blue: class 3).

The base classifier is a random forest classifier with 25 base estimators (trees). If this classifier is trained on all 800 training datapoints, it is overly confident in its predictions and thus incurs a large log-loss. Calibrating an identical classifier, which was trained on 600 datapoints, with method='sigmoid' on the remaining 200 datapoints reduces the confidence of the predictions, i.e., moves the probability vectors from the edges of the simplex towards the center. This calibration results in a lower log-loss. Note that an alternative would have been to increase the number of base estimators which would have resulted in a similar decrease in log-loss.

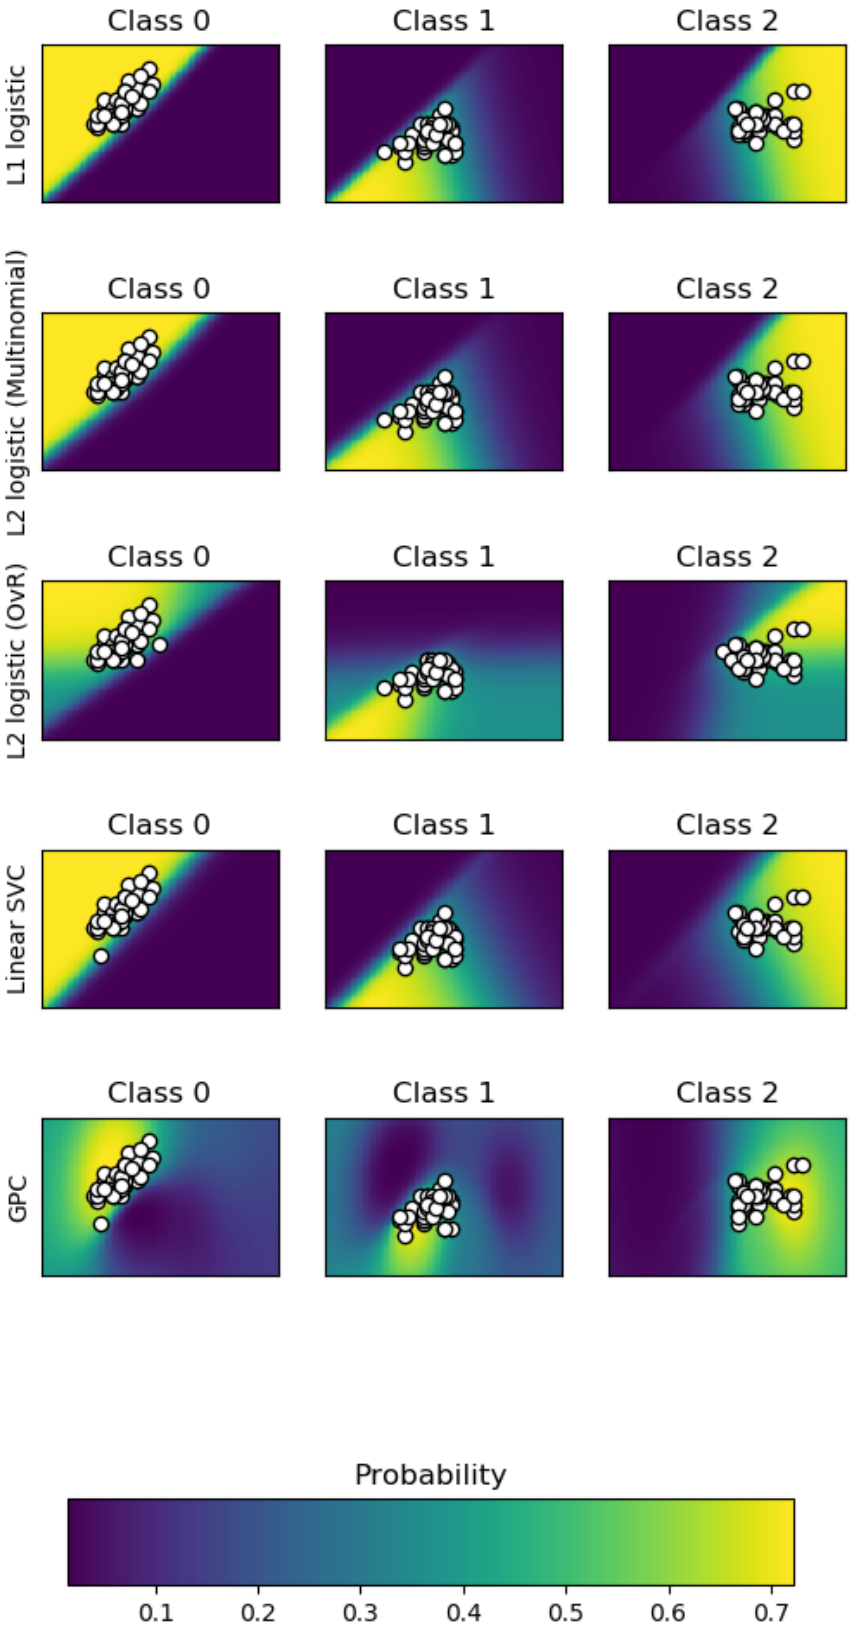
6.4.3 Plot classification probability

Plot the classification probability for different classifiers. We use a 3 class dataset, and we classify it with a Support Vector classifier, L1 and L2 penalized logistic regression with either a One-Vs-Rest or multinomial setting, and Gaussian process classification.

Linear SVC is not a probabilistic classifier by default but it has a built-in calibration option enabled in this example (`probability=True`).

The logistic regression with One-Vs-Rest is not a multiclass classifier out of the box. As a result it has more trouble in separating class 2 and 3 than the other estimators.



Class 0
Class 1
Class 2
L1 logistic
L2 logistic (Multinomial)
L2 logistic (OvR)
Linear SVC
GPC
Probability
0.1
0.2
0.3
0.4
0.5
0.6
0.7

Out:

```
Accuracy (train) for L1 logistic: 82.7%
Accuracy (train) for L2 logistic (Multinomial): 82.7%
Accuracy (train) for L2 logistic (OvR): 79.3%
Accuracy (train) for Linear SVC: 82.0%
Accuracy (train) for GPC: 82.7%
```

```

6.4.4 Classifier comparison

A comparison of a several classifiers in scikit-learn on synthetic datasets. The point of this example is to illustrate the nature of decision boundaries of different classifiers. This should be taken with a grain of salt, as the intuition conveyed by these examples does not necessarily carry over to real datasets.

Particularly in high-dimensional spaces, data can more easily be separated linearly and the simplicity of classifiers such as naive Bayes and linear SVMs might lead to better generalization than is achieved by other classifiers.

The plots show training points in solid colors and testing points semi-transparent. The lower right shows the classification accuracy on the test set.

6.5.4 Demonstration of k-means assumptions

This example is meant to illustrate situations where k-means will produce unintuitive and possibly unexpected clusters. In the first three plots, the input data does not conform to some implicit assumption that k-means makes and undesirable clusters are produced as a result. In the last plot, k-means returns intuitive clusters despite unevenly sized blobs.

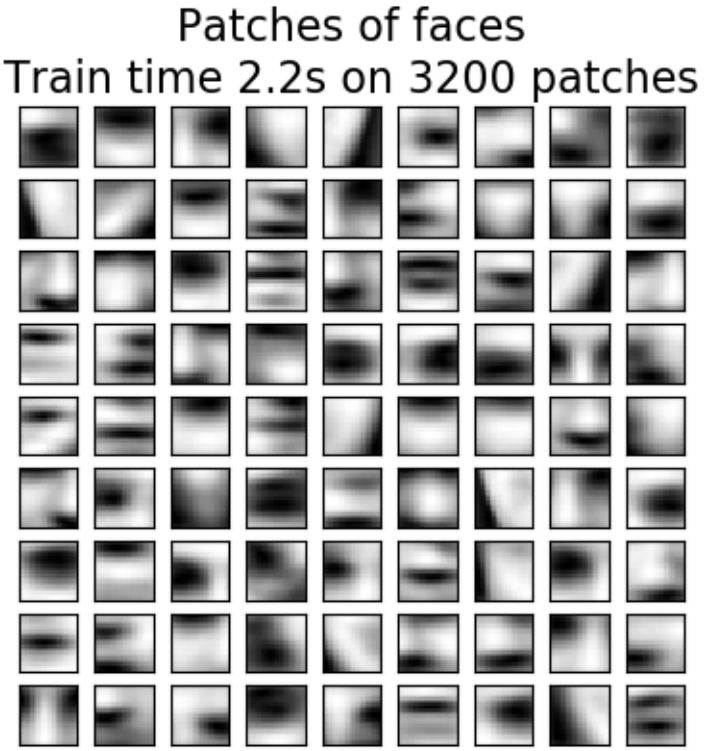
6.5.5 Online learning of a dictionary of parts of faces

This example uses a large dataset of faces to learn a set of 20 x 20 images patches that constitute faces.

From the programming standpoint, it is interesting because it shows how to use the online API of the scikit-learn to process a very large dataset by chunks. The way we proceed is that we load an image at a time and extract randomly 50 patches from this image. Once we have accumulated 500 of these patches (using 10 images), we run the `partial_fit` method of the online KMeans object, MiniBatchKMeans.

The verbose setting on the MiniBatchKMeans enables us to see that some clusters are reassigned during the successive calls to partial-fit. This is because the number of patches that they represent has become too low, and it is better to choose a random new cluster.



Out:

```
Learning the dictionary...
Partial fit of  100 out of 2400

6.5.8 Agglomerative clustering with and without structure

This example shows the effect of imposing a connectivity graph to capture local structure in the data. The graph is simply the graph of 20 nearest neighbors.

Two consequences of imposing a connectivity can be seen. First clustering with a connectivity matrix is much faster.

Second, when using a connectivity matrix, single, average and complete linkage are unstable and tend to create a few clusters that grow very quickly. Indeed, average and complete linkage fight this percolation behavior by considering all the distances between two clusters when merging them (while single linkage exaggerates the behaviour by considering only the shortest distance between clusters). The connectivity graph breaks this mechanism for average and complete linkage, making them resemble the more brittle single linkage. This effect is more pronounced for very sparse graphs (try decreasing the number of neighbors in kneighbors_graph) and with complete linkage. In particular, having a very small number of neighbors in the graph, imposes a geometry that is close to that of single linkage, which is well known to have this percolation instability.

6.5.9 Segmenting the picture of greek coins in regions

This example uses *Spectral clustering* on a graph created from voxel-to-voxel difference on an image to break this image into multiple partly-homogeneous regions.

This procedure (spectral clustering on an image) is an efficient approximate solution for finding normalized graph cuts.

There are two options to assign labels:

- with 'kmeans' spectral clustering will cluster samples in the embedding space using a kmeans algorithm
- whereas 'discrete' will iteratively search for the closest partition space to the embedding space.

6.5.10 Various Agglomerative Clustering on a 2D embedding of digits

An illustration of various linkage option for agglomerative clustering on a 2D embedding of the digits dataset.

The goal of this example is to show intuitively how the metrics behave, and not to find good clusters for the digits. This is why the example works on a 2D embedding.

What this example shows us is the behavior "rich getting richer" of agglomerative clustering that tends to create uneven cluster sizes. This behavior is pronounced for the average linkage strategy, that ends up with a couple of singleton clusters, while in the case of single linkage we get a single central cluster with all other clusters being drawn from noise points around the fringes.

6.5.11 K-means Clustering

The plots display firstly what a K-means algorithm would yield using three clusters. It is then shown what the effect of a bad initialization is on the classification process: By setting n_init to only 1 (default is 10), the amount of times that the algorithm will be run with different centroid seeds is reduced. The next plot displays what using eight clusters would deliver and finally the ground truth.

6.5.12 Spectral clustering for image segmentation

In this example, an image with connected circles is generated and spectral clustering is used to separate the circles.

In these settings, the *Spectral clustering* approach solves the problem know as 'normalized graph cuts': the image is seen as a graph of connected voxels, and the spectral clustering algorithm amounts to choosing graph cuts defining regions while minimizing the ratio of the gradient along the cut, and the volume of the region.

As the algorithm tries to balance the volume (ie balance the region sizes), if we take circles with different sizes, the segmentation fails.

In addition, as there is no useful information in the intensity of the image, or its gradient, we choose to perform the spectral clustering on a graph that is only weakly informed by the gradient. This is close to performing a Voronoi partition of the graph.

In addition, we use the mask of the objects to restrict the graph to the outline of the objects. In this example, we are interested in separating the objects one from the other, and not from the background.

6.5.15 Color Quantization using K-Means

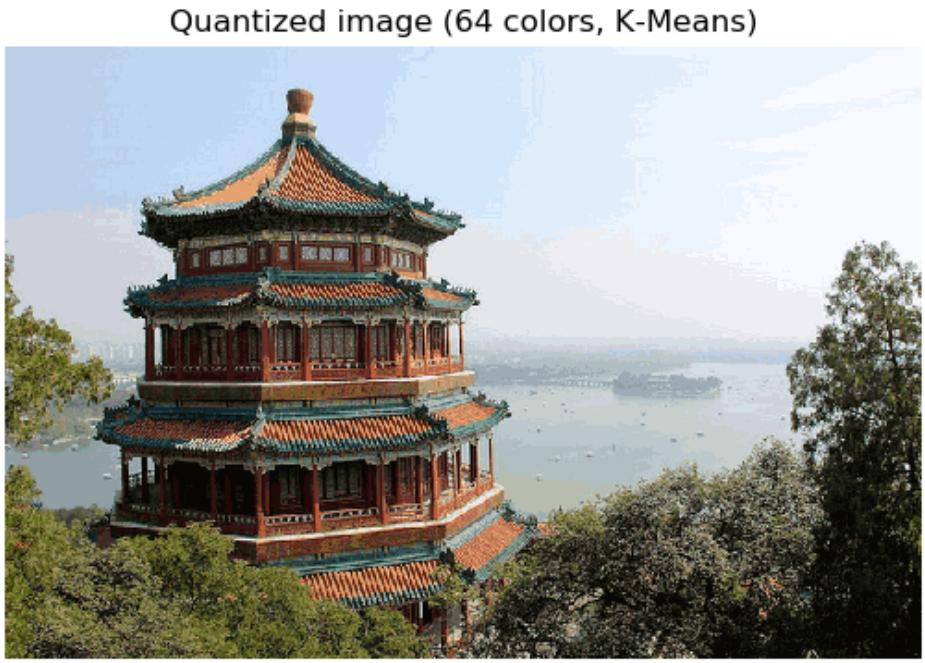
Performs a pixel-wise Vector Quantization (VQ) of an image of the summer palace (China), reducing the number of colors required to show the image from 96,615 unique colors to 64, while preserving the overall appearance quality.

In this example, pixels are represented in a 3D-space and K-means is used to find 64 color clusters. In the image processing literature, the codebook obtained from K-means (the cluster centers) is called the color palette. Using a single byte, up to 256 colors can be addressed, whereas an RGB encoding requires 3 bytes per pixel. The GIF file format, for example, uses such a palette.

For comparison, a quantized image using a random codebook (colors picked up randomly) is also shown.

Original image (96,615 colors)

-



Quantized image (64 colors, K-Means)

6.5.16 Hierarchical clustering: structured vs unstructured ward

Example builds a swiss roll dataset and runs hierarchical clustering on their position.

For more information, see *Hierarchical clustering*.

In a first step, the hierarchical clustering is performed without connectivity constraints on the structure and is solely based on distance, whereas in a second step the clustering is restricted to the k-Nearest Neighbors graph: it's a hierarchical clustering with structure prior.

Some of the clusters learned without connectivity constraints do not respect the structure of the swiss roll and extend across different folds of the manifolds. On the opposite, when opposing connectivity constraints, the clusters form a nice parcellation of the swiss roll.

6.5.17 Agglomerative clustering with different metrics

Demonstrates the effect of different metrics on the hierarchical clustering.

The example is engineered to show the effect of the choice of different metrics. It is applied to waveforms, which can be seen as high-dimensional vector. Indeed, the difference between metrics is usually more pronounced in high dimension (in particular for euclidean and cityblock).

We generate data from three groups of waveforms. Two of the waveforms (waveform 1 and waveform 2) are proportional one to the other. The cosine distance is invariant to a scaling of the data, as a result, it cannot distinguish these two waveforms. Thus even with no noise, clustering using this distance will not separate out waveform 1 and 2.

We add observation noise to these waveforms. We generate very sparse noise: only 6% of the time points contain noise. As a result, the l1 norm of this noise (ie "cityblock" distance) is much smaller than it's l2 norm ("euclidean" distance). This can be seen on the inter-class distance matrices: the values on the diagonal, that characterize the spread of the class, are much bigger for the Euclidean distance than for the cityblock distance.

When we apply clustering to the data, we find that the clustering reflects what was in the distance matrices. Indeed, for the Euclidean distance, the classes are ill-separated because of the noise, and thus the clustering does not separate the waveforms. For the cityblock distance, the separation is good and the waveform classes are recovered. Finally, the cosine distance does not separate at all waveform 1 and 2, thus the clustering puts them in the same cluster.

6.5.18 Inductive Clustering

Clustering can be expensive, especially when our dataset contains millions of datapoints. Many clustering algorithms are not *inductive* and so cannot be directly applied to new data samples without recomputing the clustering, which may be intractable. Instead, we can use clustering to then learn an inductive model with a classifier, which has several benefits:

- it allows the clusters to scale and apply to new data
- unlike re-fitting the clusters to new samples, it makes sure the labelling procedure is consistent over time
- it allows us to use the inferential capabilities of the classifier to describe or explain the clusters

This example illustrates a generic implementation of a meta-estimator which extends clustering by inducing a classifier from the cluster labels.

6.5.19 Demo of OPTICS clustering algorithm

Finds core samples of high density and expands clusters from them. This example uses data that is generated so that the clusters have different densities. The *sklearn.cluster.OPTICS* is first used with its Xi cluster detection method, and then setting specific thresholds on the reachability, which corresponds to *sklearn.cluster.DBSCAN*. We can see that the different clusters of OPTICS's Xi method can be recovered with different choices of thresholds in DBSCAN.

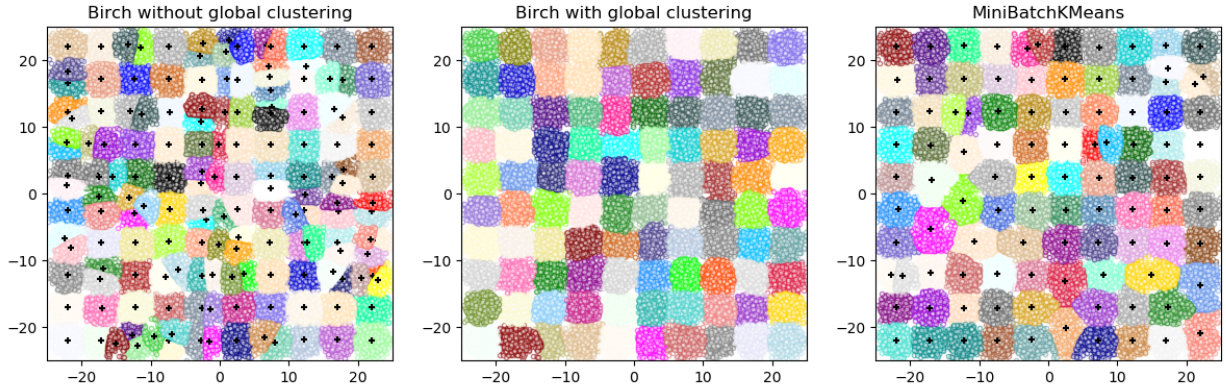
6.5.20 Compare BIRCH and MiniBatchKMeans

This example compares the timing of Birch (with and without the global clustering step) and MiniBatchKMeans on a synthetic dataset having 100,000 samples and 2 features generated using make_blobs.

If `n_clusters` is set to None, the data is reduced from 100,000 samples to a set of 158 clusters. This can be viewed as a preprocessing step before the final (global) clustering step that further reduces these 158 clusters to 100 clusters.



Out:

```
Birch without global clustering as the final step took 2.70 seconds
n_clusters : 158
Birch with global clustering as the final step took 2.85 seconds
n_clusters : 100
Time taken to run MiniBatchKMeans 3.43 seconds
```

```

6.5.21 Empirical evaluation of the impact of k-means initialization

Evaluate the ability of k-means initializations strategies to make the algorithm convergence robust as measured by the relative standard deviation of the inertia of the clustering (i.e. the sum of squared distances to the nearest cluster center).

The first plot shows the best inertia reached for each combination of the model (`KMeans` or `MiniBatchKMeans`) and the init method (`init="random"` or `init="kmeans++"`) for increasing values of the `n_init` parameter that controls the number of initializations.

The second plot demonstrate one single run of the `MiniBatchKMeans` estimator using a `init="random"` and `n_init=1`. This run leads to a bad convergence (local optimum) with estimated centers stuck between ground truth clusters.

The dataset used for evaluation is a 2D grid of isotropic Gaussian clusters widely spaced.

6.5.22 Adjustment for chance in clustering performance evaluation

The following plots demonstrate the impact of the number of clusters and number of samples on various clustering performance evaluation metrics.

Non-adjusted measures such as the V-Measure show a dependency between the number of clusters and the number of samples: the mean V-Measure of random labeling increases significantly as the number of clusters is closer to the total number of samples used to compute the measure.

Adjusted for chance measure such as ARI display some random variations centered around a mean score of 0.0 for any number of samples and clusters.

Only adjusted measures can hence safely be used as a consensus index to evaluate the average stability of clustering algorithms for a given value of k on various overlapping sub-samples of the dataset.

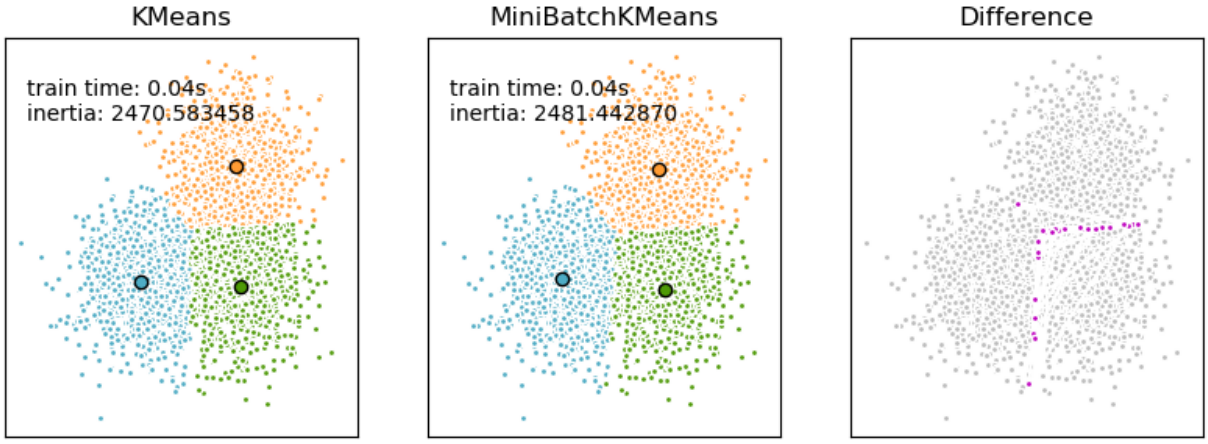
6.5.23 Comparison of the K-Means and MiniBatchKMeans clustering algorithms

We want to compare the performance of the MiniBatchKMeans and KMeans: the MiniBatchKMeans is faster, but gives slightly different results (see *Mini Batch K-Means*).

We will cluster a set of data, first with KMeans and then with MiniBatchKMeans, and plot the results. We will also plot the points that are labelled differently between the two algorithms.



```

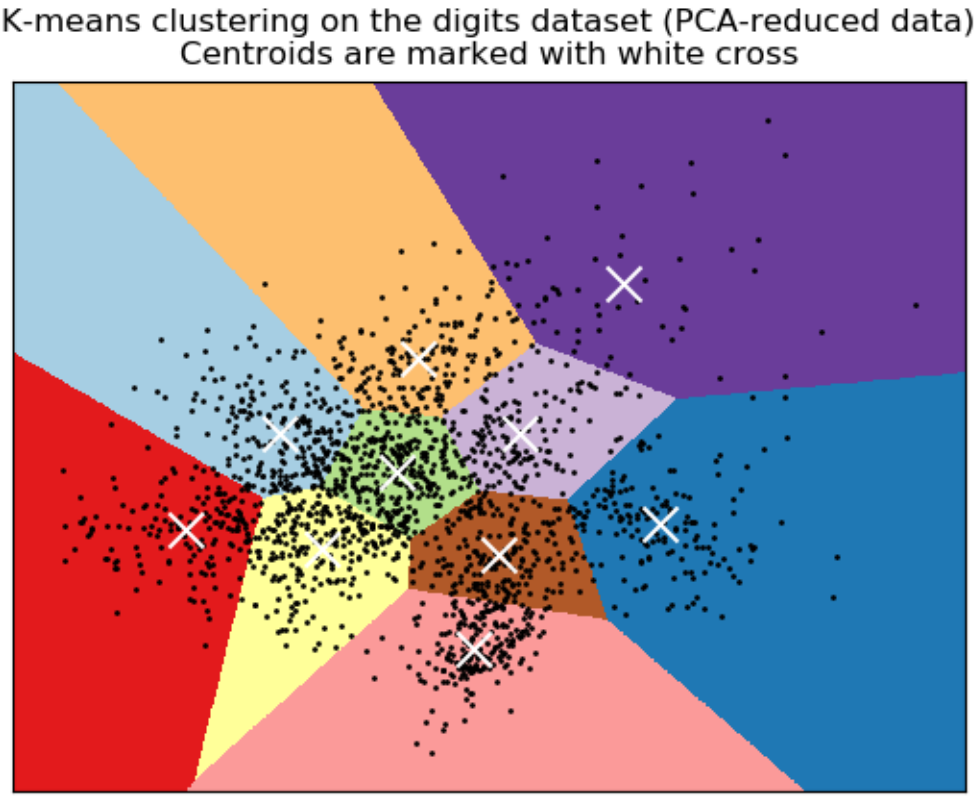
6.5.25 A demo of K-Means clustering on the handwritten digits data

In this example we compare the various initialization strategies for K-means in terms of runtime and quality of the results.

As the ground truth is known here, we also apply different cluster quality metrics to judge the goodness of fit of the cluster labels to the ground truth.

Cluster quality metrics evaluated (see *Clustering performance evaluation* for definitions and discussions of the metrics):

Shorthand	full name
homo	homogeneity score
compl	completeness score
v-meas	V measure
ARI	adjusted Rand index
AMI	adjusted mutual information
silhouette	silhouette coefficient



Out:

6.5.26 Comparing different hierarchical linkage methods on toy datasets

This example shows characteristics of different linkage methods for hierarchical clustering on datasets that are "interesting" but still in 2D.

The main observations to make are:

- single linkage is fast, and can perform well on non-globular data, but it performs poorly in the presence of noise.
- average and complete linkage perform well on cleanly separated globular clusters, but have mixed results otherwise.
- Ward is the most effective method for noisy data.

While these examples give some intuition about the algorithms, this intuition might not apply to very high dimensional data.

6.5.27 Selecting the number of clusters with silhouette analysis on KMeans clustering

Silhouette analysis can be used to study the separation distance between the resulting clusters. The silhouette plot displays a measure of how close each point in one cluster is to points in the neighboring clusters and thus provides a way to assess parameters like number of clusters visually. This measure has a range of [-1, 1].

Silhouette coefficients (as these values are referred to as) near +1 indicate that the sample is far away from the neighboring clusters. A value of 0 indicates that the sample is on or very close to the decision boundary between two neighboring clusters and negative values indicate that those samples might have been assigned to the wrong cluster.

In this example the silhouette analysis is used to choose an optimal value for `n_clusters`. The silhouette plot shows that the `n_clusters` value of 3, 5 and 6 are a bad pick for the given data due to the presence of clusters with below average silhouette scores and also due to wide fluctuations in the size of the silhouette plots. Silhouette analysis is more ambivalent in deciding between 2 and 4.

Also from the thickness of the silhouette plot the cluster size can be visualized. The silhouette plot for cluster 0 when `n_clusters` is equal to 2, is bigger in size owing to the grouping of the 3 sub clusters into one big cluster. However when the `n_clusters` is equal to 4, all the plots are more or less of similar thickness and hence are of similar sizes as can be also verified from the labelled scatter plot on the right.

6.5.28 Comparing different clustering algorithms on toy datasets

This example shows characteristics of different clustering algorithms on datasets that are "interesting" but still in 2D. With the exception of the last dataset, the parameters of each of these dataset-algorithm pairs has been tuned to produce good clustering results. Some algorithms are more sensitive to parameter values than others.

The last dataset is an example of a 'null' situation for clustering: the data is homogeneous, and there is no good clustering. For this example, the null dataset uses the same parameters as the dataset in the row above it, which represents a mismatch in the parameter values and the data structure.

While these examples give some intuition about the algorithms, this intuition might not apply to very high dimensional data.

6.6.1 Ledoit-Wolf vs OAS estimation

The usual covariance maximum likelihood estimate can be regularized using shrinkage. Ledoit and Wolf proposed a close formula to compute the asymptotically optimal shrinkage parameter (minimizing a MSE criterion), yielding the Ledoit-Wolf covariance estimate.

Chen et al. proposed an improvement of the Ledoit-Wolf shrinkage parameter, the OAS coefficient, whose convergence is significantly better under the assumption that the data are Gaussian.

This example, inspired from Chen's publication [1], shows a comparison of the estimated MSE of the LW and OAS methods, using Gaussian distributed data.

[1] "Shrinkage Algorithms for MMSE Covariance Estimation" Chen et al., IEEE Trans. on Sign. Proc., Volume 58, Issue 10, October 2010.

6.6.2 Sparse inverse covariance estimation

Using the GraphicalLasso estimator to learn a covariance and sparse precision from a small number of samples.

To estimate a probabilistic model (e.g. a Gaussian model), estimating the precision matrix, that is the inverse covariance matrix, is as important as estimating the covariance matrix. Indeed a Gaussian model is parametrized by the precision matrix.

To be in favorable recovery conditions, we sample the data from a model with a sparse inverse covariance matrix. In addition, we ensure that the data is not too much correlated (limiting the largest coefficient of the precision matrix) and that there a no small coefficients in the precision matrix that cannot be recovered. In addition, with a small number of observations, it is easier to recover a correlation matrix rather than a covariance, thus we scale the time series.

Here, the number of samples is slightly larger than the number of dimensions, thus the empirical covariance is still invertible. However, as the observations are strongly correlated, the empirical covariance matrix is ill-conditioned and as a result its inverse –the empirical precision matrix– is very far from the ground truth.

If we use l2 shrinkage, as with the Ledoit-Wolf estimator, as the number of samples is small, we need to shrink a lot. As a result, the Ledoit-Wolf precision is fairly close to the ground truth precision, that is not far from being diagonal, but the off-diagonal structure is lost.

The l1-penalized estimator can recover part of this off-diagonal structure. It learns a sparse precision. It is not able to recover the exact sparsity pattern: it detects too many non-zero coefficients. However, the highest non-zero coefficients of the l1 estimated correspond to the non-zero coefficients in the ground truth. Finally, the coefficients of the l1 precision estimate are biased toward zero: because of the penalty, they are all smaller than the corresponding ground truth value, as can be seen on the figure.

Note that, the color range of the precision matrices is tweaked to improve readability of the figure. The full range of values of the empirical precision is not displayed.

The alpha parameter of the GraphicalLasso setting the sparsity of the model is set by internal cross-validation in the GraphicalLassoCV. As can be seen on figure 2, the grid to compute the cross-validation score is iteratively refined in the neighborhood of the maximum.

6.6.3 Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood

When working with covariance estimation, the usual approach is to use a maximum likelihood estimator, such as the `sklearn.covariance.EmpiricalCovariance`. It is unbiased, i.e. it converges to the true (population) covariance when given many observations. However, it can also be beneficial to regularize it, in order to reduce its variance; this, in turn, introduces some bias. This example illustrates the simple regularization used in *Shrunk Covariance* estimators. In particular, it focuses on how to set the amount of regularization, i.e. how to choose the bias-variance trade-off.

Here we compare 3 approaches:

- Setting the parameter by cross-validating the likelihood on three folds according to a grid of potential shrinkage parameters.
- A close formula proposed by Ledoit and Wolf to compute the asymptotically optimal regularization parameter (minimizing a MSE criterion), yielding the `sklearn.covariance.LedoitWolf` covariance estimate.
- An improvement of the Ledoit-Wolf shrinkage, the `sklearn.covariance.OAS`, proposed by Chen et al. Its convergence is significantly better under the assumption that the data are Gaussian, in particular for small samples.

To quantify estimation error, we plot the likelihood of unseen data for different values of the shrinkage parameter. We also show the choices by cross-validation, or with the LedoitWolf and OAS estimates.

Note that the maximum likelihood estimate corresponds to no shrinkage, and thus performs poorly. The Ledoit-Wolf estimate performs really well, as it is close to the optimal and is computational not costly. In this example, the OAS estimate is a bit further away. Interestingly, both approaches outperform cross-validation, which is significantly most computationally costly.

6.6.4 Robust covariance estimation and Mahalanobis distances relevance

An example to show covariance estimation with the Mahalanobis distances on Gaussian distributed data.

For Gaussian distributed data, the distance of an observation x_i to the mode of the distribution can be computed using its Mahalanobis distance: $d_{(\mu,\Sigma)}(x_i)^2 = (x_i - \mu)'\Sigma^{-1}(x_i - \mu)$ where μ and Σ are the location and the covariance of the underlying Gaussian distribution.

In practice, μ and Σ are replaced by some estimates. The usual covariance maximum likelihood estimate is very sensitive to the presence of outliers in the data set and therefor, the corresponding Mahalanobis distances are. One would better have to use a robust estimator of covariance to guarantee that the estimation is resistant to "erroneous" observations in the data set and that the associated Mahalanobis distances accurately reflect the true organisation of the observations.

The Minimum Covariance Determinant estimator is a robust, high-breakdown point (i.e. it can be used to estimate the covariance matrix of highly contaminated datasets, up to $\frac{n_{\text{samples}} - n_{\text{features}} - 1}{2}$ outliers) estimator of covariance. The idea is to find $\frac{n_{\text{samples}} + n_{\text{features}} + 1}{2}$ observations whose empirical covariance has the smallest determinant, yielding a "pure" subset of observations from which to compute standards estimates of location and covariance.

The Minimum Covariance Determinant estimator (MCD) has been introduced by P.J.Rousseuw in [1].

This example illustrates how the Mahalanobis distances are affected by outlying data: observations drawn from a contaminating distribution are not distinguishable from the observations coming from the real, Gaussian distribution that one may want to work with. Using MCD-based Mahalanobis distances, the two populations become distinguishable. Associated applications are outliers detection, observations ranking, clustering, ... For visualization purpose, the cubic root of the Mahalanobis distances are represented in the boxplot, as Wilson and Hilferty suggest [2]

6.6.5 Robust vs Empirical covariance estimate

The usual covariance maximum likelihood estimate is very sensitive to the presence of outliers in the data set. In such a case, it would be better to use a robust estimator of covariance to guarantee that the estimation is resistant to "erroneous" observations in the data set.[1],[2]

Minimum Covariance Determinant Estimator

The Minimum Covariance Determinant estimator is a robust, high-breakdown point (i.e. it can be used to estimate the covariance matrix of highly contaminated datasets, up to $\frac{n_{\text{samples}}-n_{\text{features}}-1}{2}$ outliers) estimator of covariance. The idea is to find $\frac{n_{\text{samples}}+n_{\text{features}}+1}{2}$ observations whose empirical covariance has the smallest determinant, yielding a "pure" subset of observations from which to compute standards estimates of location and covariance. After a correction step aiming at compensating the fact that the estimates were learned from only a portion of the initial data, we end up with robust estimates of the data set location and covariance.

The Minimum Covariance Determinant estimator (MCD) has been introduced by P.J.Rousseuw in[3].

Evaluation

In this example, we compare the estimation errors that are made when using various types of location and covariance estimates on contaminated Gaussian distributed data sets:

- The mean and the empirical covariance of the full dataset, which break down as soon as there are outliers in the data set
- The robust MCD, that has a low error provided $n_{\text{samples}} > 5n_{\text{features}}$
- The mean and the empirical covariance of the observations that are known to be good ones. This can be considered as a "perfect" MCD estimation, so one can trust our implementation by comparing to this case.

6.7 Cross decomposition

Examples concerning the *sklearn.cross_decomposition* module.

Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.7.1 Compare cross decomposition methods

Simple usage of various cross decomposition algorithms: - PLSCanonical - PLSRegression, with multivariate response, a.k.a. PLS2 - PLSRegression, with univariate response, a.k.a. PLS1 - CCA

Given 2 multivariate covarying two-dimensional datasets, X, and Y, PLS extracts the 'directions of covariance', i.e. the components of each datasets that explain the most shared variance between both datasets. This is apparent on the **scatterplot matrix** display: components 1 in dataset X and dataset Y are maximally correlated (points lie around the first diagonal). This is also true for components 2 in both dataset, however, the correlation across datasets for different components is weak: the point cloud is very spherical.

6.8 Dataset examples

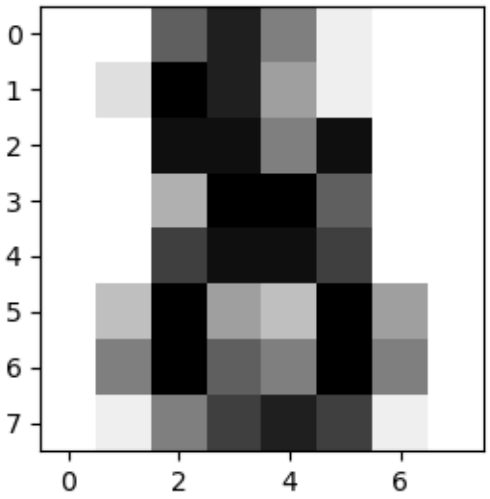
Examples concerning the *sklearn.datasets* module.

Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.8.1 The Digit Dataset

This dataset is made up of 1797 8x8 images. Each image, like the one shown below, is of a hand-written digit. In order to utilize an 8x8 figure like this, we'd have to first transform it into a feature vector with length 64.

See here for more information about this dataset.



```
print(__doc__)

# Code source: Gaël Varoquaux
# Modified for documentation by Jaques Grobler
# License: BSD 3 clause

from sklearn import datasets

import matplotlib.pyplot as plt

#Load the digits dataset
digits = datasets.load_digits()

#Display the first digit
plt.figure(1, figsize=(3, 3))
plt.imshow(digits.images[-1], cmap=plt.cm.gray_r, interpolation='nearest')
plt.show()
```

Total running time of the script: (0 minutes 0.339 seconds)

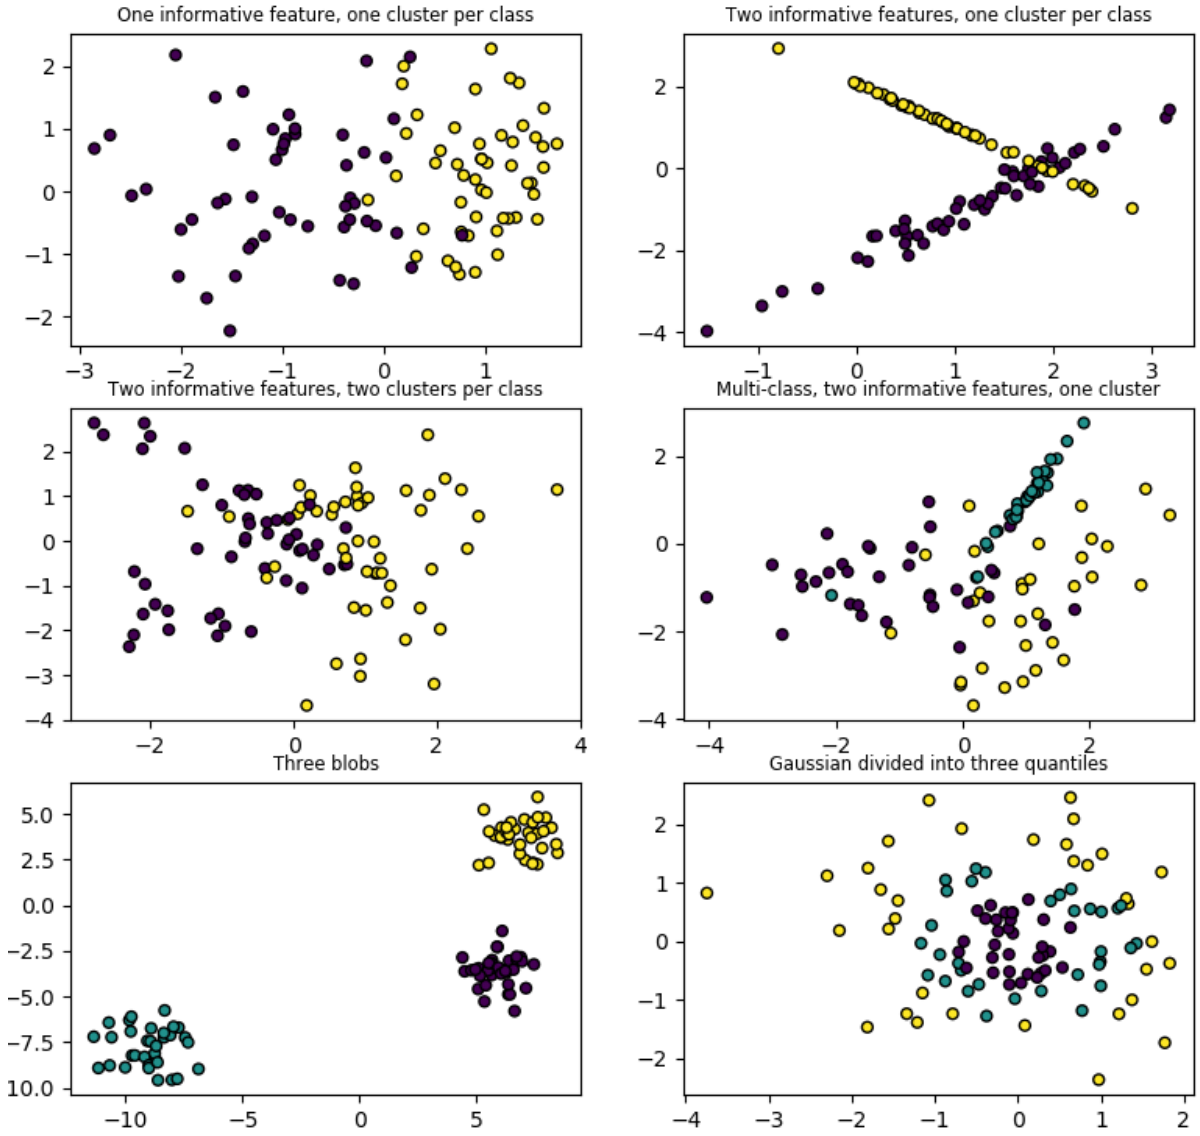
6.8.3 Plot randomly generated classification dataset

Plot several randomly generated 2D classification datasets. This example illustrates the `datasets.make_classification` `datasets.make_blobs` and `datasets.make_gaussian_quantiles` functions.

For `make_classification`, three binary and two multi-class classification datasets are generated, with different numbers of informative features and clusters per class.



```
print(__doc__)

import matplotlib.pyplot as plt

from sklearn.datasets import make_classification
from sklearn.datasets import make_blobs
from sklearn.datasets import make_gaussian_quantiles

plt.figure(figsize=(8, 8))
plt.subplots_adjust(bottom=.05, top=.9, left=.05, right=.95)

plt.subplot(321)
plt.title("One informative feature, one cluster per class", fontsize='small')
X1, Y1 = make_classification(n_features=2, n_redundant=0, n_informative=1,
```

(continues on next page)

(continued from previous page)

```
                               n_clusters_per_class=1)
plt.scatter(X1[:, 0], X1[:, 1], marker='o', c=Y1,
            s=25, edgecolor='k')

plt.subplot(322)
plt.title("Two informative features, one cluster per class", fontsize='small')
X1, Y1 = make_classification(n_features=2, n_redundant=0, n_informative=2,
                               n_clusters_per_class=1)
plt.scatter(X1[:, 0], X1[:, 1], marker='o', c=Y1,
            s=25, edgecolor='k')

plt.subplot(323)
plt.title("Two informative features, two clusters per class",
          fontsize='small')
X2, Y2 = make_classification(n_features=2, n_redundant=0, n_informative=2)
plt.scatter(X2[:, 0], X2[:, 1], marker='o', c=Y2,
            s=25, edgecolor='k')

plt.subplot(324)
plt.title("Multi-class, two informative features, one cluster",
          fontsize='small')
X1, Y1 = make_classification(n_features=2, n_redundant=0, n_informative=2,
                               n_clusters_per_class=1, n_classes=3)
plt.scatter(X1[:, 0], X1[:, 1], marker='o', c=Y1,
            s=25, edgecolor='k')

plt.subplot(325)
plt.title("Three blobs", fontsize='small')
X1, Y1 = make_blobs(n_features=2, centers=3)
plt.scatter(X1[:, 0], X1[:, 1], marker='o', c=Y1,
            s=25, edgecolor='k')

plt.subplot(326)
plt.title("Gaussian divided into three quantiles", fontsize='small')
X1, Y1 = make_gaussian_quantiles(n_features=2, n_classes=3)
plt.scatter(X1[:, 0], X1[:, 1], marker='o', c=Y1,
            s=25, edgecolor='k')

plt.show()
```

6.8.4 Plot randomly generated multilabel dataset

This illustrates the *make_multilabel_classification* dataset generator. Each sample consists of counts of two features (up to 50 in total), which are differently distributed in each of two classes.

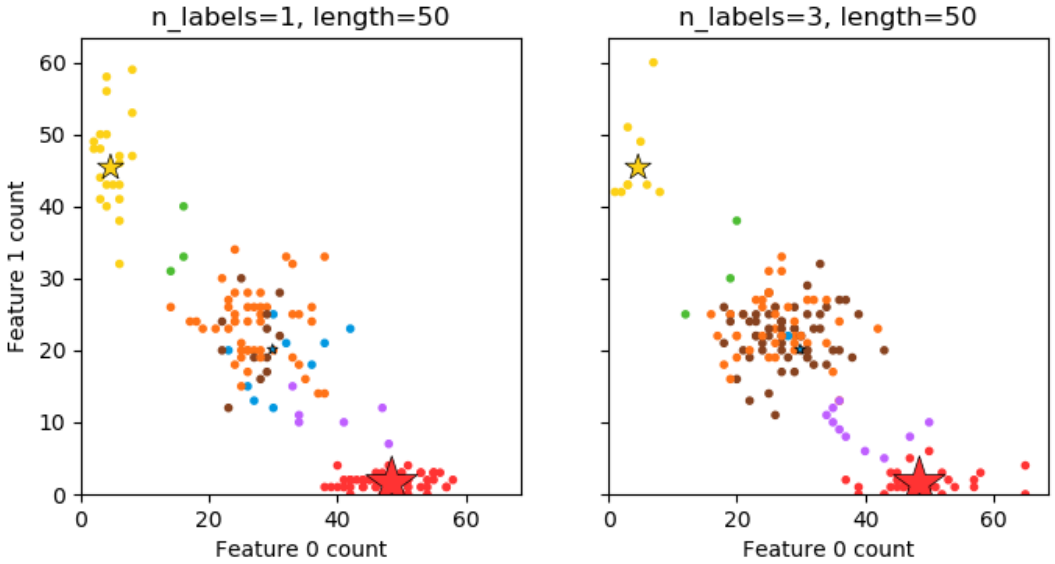
Points are labeled as follows, where Y means the class is present:

1	2	3	Color
Y	N	N	Red
N	Y	N	Blue
N	N	Y	Yellow
Y	Y	N	Purple
Y	N	Y	Orange
Y	Y	N	Green
Y	Y	Y	Brown

A star marks the expected sample for each class; its size reflects the probability of selecting that class label.

The left and right examples highlight the `n_labels` parameter: more of the samples in the right plot have 2 or 3 labels.

Note that this two-dimensional example is very degenerate: generally the number of features would be much greater than the "document length", while here we have much larger documents than vocabulary. Similarly, with `n_classes > n_features`, it is much less likely that a feature distinguishes a particular class.



Out:

```
The data was generated from (random_state=1013):
Class   P(C)    P(w0|C) P(w1|C)
red     0.64    0.97    0.03
blue    0.06    0.60    0.40
yellow  0.30    0.09    0.91
```

```
import numpy as np
import matplotlib.pyplot as plt
```

(continues on next page)

(continued from previous page)

```
from sklearn.datasets import make_multilabel_classification as make_ml_clf

6.9 Decision Trees

Examples concerning the `sklearn.tree` module.

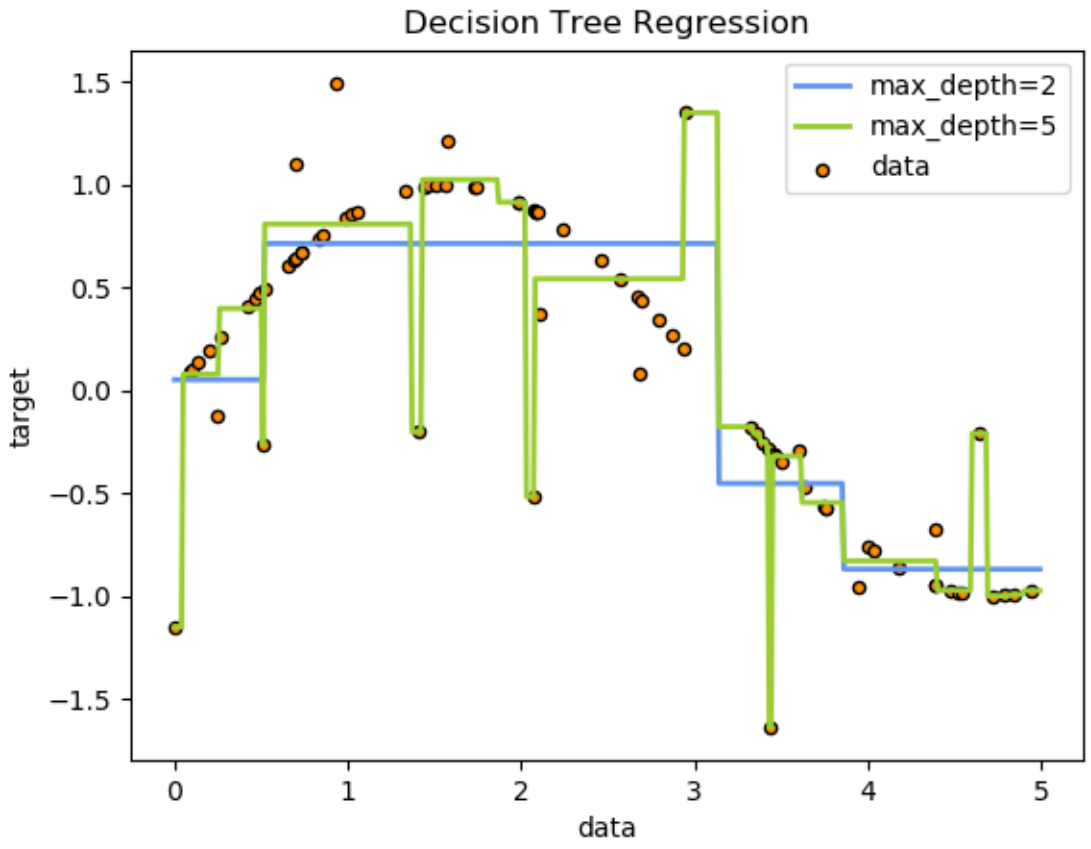
Note: Click *here* to download the full example code or to run this example in your browser via Binder

6.9.1 Decision Tree Regression

A 1D regression with decision tree.

The *decision trees* is used to fit a sine curve with addition noisy observation. As a result, it learns local linear regressions approximating the sine curve.

We can see that if the maximum depth of the tree (controlled by the `max_depth` parameter) is set too high, the decision trees learn too fine details of the training data and learn from the noise, i.e. they overfit.



```
print(__doc__)

# Import the necessary modules and libraries
```

(continues on next page)

(continued from previous page)

```
import numpy as np
from sklearn.tree import DecisionTreeRegressor
import matplotlib.pyplot as plt

# Create a random dataset
rng = np.random.RandomState(1)
X = np.sort(5 * rng.rand(80, 1), axis=0)
y = np.sin(X).ravel()
y[::5] += 3 * (0.5 - rng.rand(16))

# Fit regression model
regr_1 = DecisionTreeRegressor(max_depth=2)
regr_2 = DecisionTreeRegressor(max_depth=5)
regr_1.fit(X, y)
regr_2.fit(X, y)

# Predict
X_test = np.arange(0.0, 5.0, 0.01)[:, np.newaxis]
y_1 = regr_1.predict(X_test)
y_2 = regr_2.predict(X_test)

# Plot the results
plt.figure()
plt.scatter(X, y, s=20, edgecolor="black",
            c="darkorange", label="data")
plt.plot(X_test, y_1, color="cornflowerblue",
         label="max_depth=2", linewidth=2)
plt.plot(X_test, y_2, color="yellowgreen", label="max_depth=5", linewidth=2)

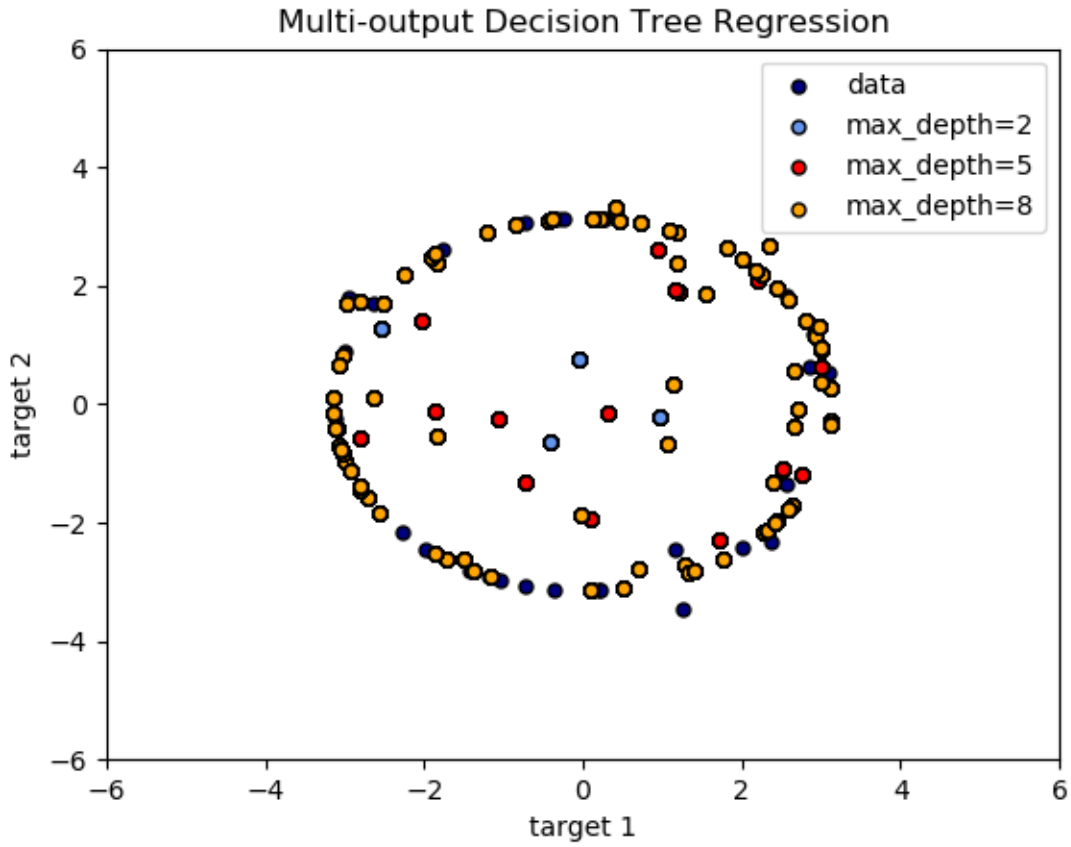
6.9.2 Multi-output Decision Tree Regression

An example to illustrate multi-output regression with decision tree.

The *decision trees* is used to predict simultaneously the noisy x and y observations of a circle given a single underlying feature. As a result, it learns local linear regressions approximating the circle.

We can see that if the maximum depth of the tree (controlled by the `max_depth` parameter) is set too high, the decision trees learn too fine details of the training data and learn from the noise, i.e. they overfit.



```
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt
from sklearn.tree import DecisionTreeRegressor

# Create a random dataset
rng = np.random.RandomState(1)
X = np.sort(200 * rng.rand(100, 1) - 100, axis=0)
y = np.array([np.pi * np.sin(X).ravel(), np.pi * np.cos(X).ravel()]).T
y[::5, :] += (0.5 - rng.rand(20, 2))

# Fit regression model
regr_1 = DecisionTreeRegressor(max_depth=2)
regr_2 = DecisionTreeRegressor(max_depth=5)
regr_3 = DecisionTreeRegressor(max_depth=8)
regr_1.fit(X, y)
regr_2.fit(X, y)
regr_3.fit(X, y)

# Predict
X_test = np.arange(-100.0, 100.0, 0.01)[:, np.newaxis]
y_1 = regr_1.predict(X_test)
y_2 = regr_2.predict(X_test)
y_3 = regr_3.predict(X_test)
```

(continues on next page)

(continued from previous page)

```
# Plot the results
plt.figure()
s = 25
plt.scatter(y[:, 0], y[:, 1], c="navy", s=s,
            edgecolor="black", label="data")
plt.scatter(y_1[:, 0], y_1[:, 1], c="cornflowerblue", s=s,
            edgecolor="black", label="max_depth=2")
plt.scatter(y_2[:, 0], y_2[:, 1], c="red", s=s,
            edgecolor="black", label="max_depth=5")
plt.scatter(y_3[:, 0], y_3[:, 1], c="orange", s=s,
            edgecolor="black", label="max_depth=8")
plt.xlim([-6, 6])
plt.ylim([-6, 6])
plt.xlabel("target 1")
plt.ylabel("target 2")

6.9.3 Plot the decision surface of a decision tree on the iris dataset

Plot the decision surface of a decision tree trained on pairs of features of the iris dataset.

See *decision tree* for more information on the estimator.

For each pair of iris features, the decision tree learns decision boundaries made of combinations of simple thresholding rules inferred from the training samples.

We also show the tree structure of a model built on all of the features.

6.9.4 Post pruning decision trees with cost complexity pruning

The *DecisionTreeClassifier* provides parameters such as `min_samples_leaf` and `max_depth` to prevent a tree from overfiting. Cost complexity pruning provides another option to control the size of a tree. In *DecisionTreeClassifier*, this pruning technique is parameterized by the cost complexity parameter, `ccp_alpha`. Greater values of `ccp_alpha` increase the number of nodes pruned. Here we only show the effect of `ccp_alpha` on regularizing the trees and how to choose a `ccp_alpha` based on validation scores.

See also *Minimal Cost-Complexity Pruning* for details on pruning.

```
print(__doc__)
import matplotlib.pyplot as plt
from sklearn.model_selection import train_test_split
from sklearn.datasets import load_breast_cancer
from sklearn.tree import DecisionTreeClassifier
```

Total impurity of leaves vs effective alphas of pruned tree

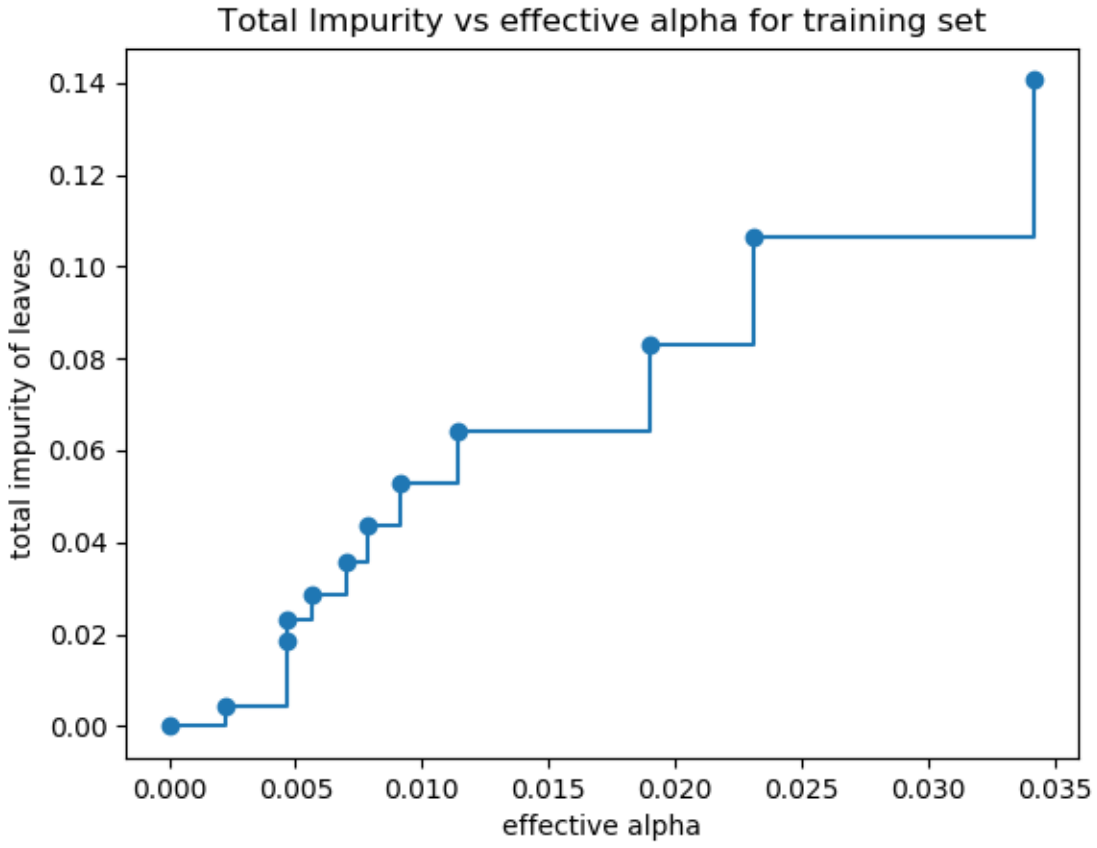
Minimal cost complexity pruning recursively finds the node with the "weakest link". The weakest link is characterized by an effective alpha, where the nodes with the smallest effective alpha are pruned first. To get an idea of what values of `ccp_alpha` could be appropriate, scikit-learn provides *DecisionTreeClassifier.cost_complexity_pruning_path* that returns the effective alphas and the corresponding total leaf impurities at each step of the pruning process. As alpha increases, more of the tree is pruned, which increases the total impurity of its leaves.

```
X, y = load_breast_cancer(return_X_y=True)
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)

clf = DecisionTreeClassifier(random_state=0)
path = clf.cost_complexity_pruning_path(X_train, y_train)
ccp_alphas, impurities = path.ccp_alphas, path.impurities
```

In the following plot, the maximum effective alpha value is removed, because it is the trivial tree with only one node.

```
fig, ax = plt.subplots()
ax.plot(ccp_alphas[:-1], impurities[:-1], marker='o', drawstyle="steps-post")
ax.set_xlabel("effective alpha")
ax.set_ylabel("total impurity of leaves")
ax.set_title("Total Impurity vs effective alpha for training set")
```



Out:

```
Text(0.5, 1.0, 'Total Impurity vs effective alpha for training set')
```

Next, we train a decision tree using the effective alphas. The last value in `ccp_alphas` is the alpha value that prunes the whole tree, leaving the tree, `clfs[-1]`, with one node.

```
clfs = []
for ccp_alpha in ccp_alphas:
    clf = DecisionTreeClassifier(random_state=0, ccp_alpha=ccp_alpha)
    clf.fit(X_train, y_train)
    clfs.append(clf)
print("Number of nodes in the last tree is: {} with ccp_alpha: {}".format(
      clfs[-1].tree_.node_count, ccp_alphas[-1]))
```

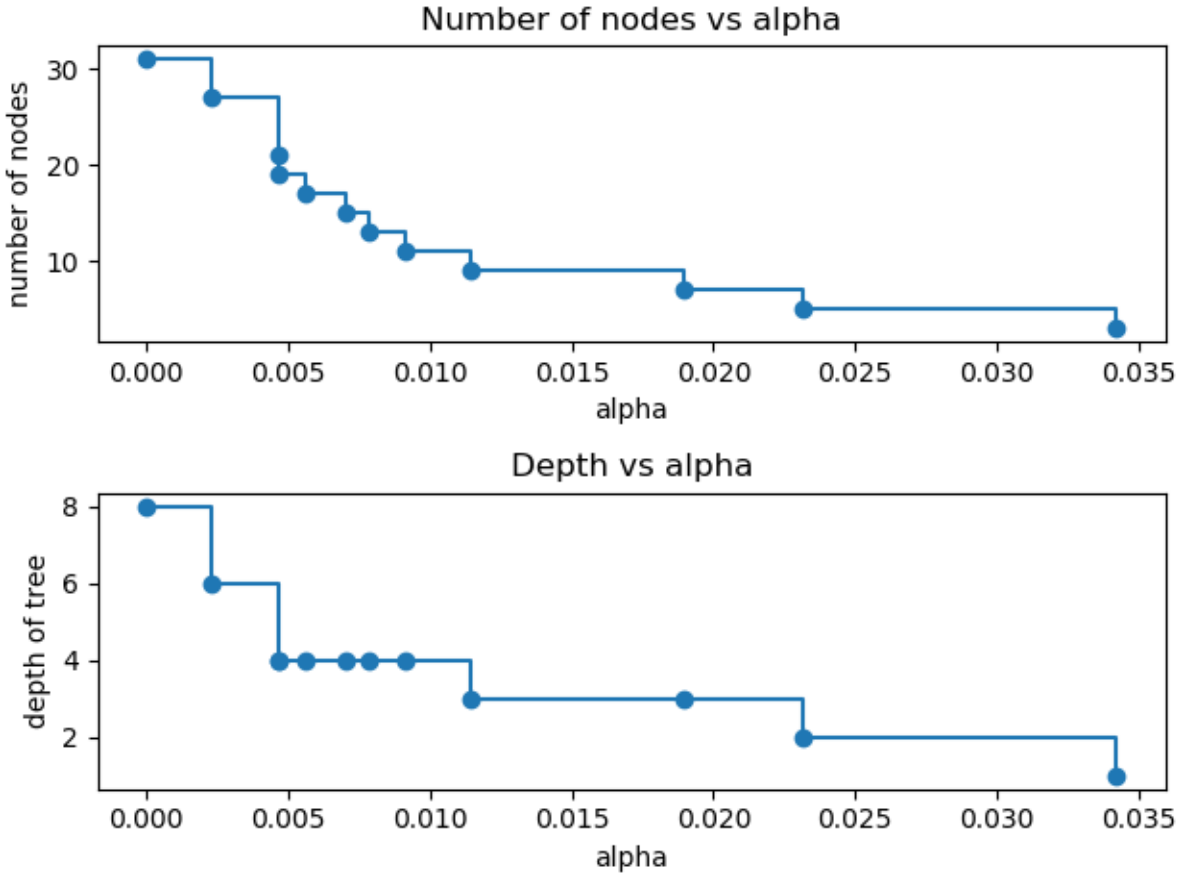
Out:

```
Number of nodes in the last tree is: 1 with ccp_alpha: 0.3272984419327777
```

For the remainder of this example, we remove the last element in `clfs` and `ccp_alphas`, because it is the trivial tree with only one node. Here we show that the number of nodes and tree depth decreases as alpha increases.

```
clfs = clfs[:-1]
ccp_alphas = ccp_alphas[:-1]

node_counts = [clf.tree_.node_count for clf in clfs]
depth = [clf.tree_.max_depth for clf in clfs]
fig, ax = plt.subplots(2, 1)
ax[0].plot(ccp_alphas, node_counts, marker='o', drawstyle="steps-post")
ax[0].set_xlabel("alpha")
ax[0].set_ylabel("number of nodes")
ax[0].set_title("Number of nodes vs alpha")
ax[1].plot(ccp_alphas, depth, marker='o', drawstyle="steps-post")
ax[1].set_xlabel("alpha")
ax[1].set_ylabel("depth of tree")
ax[1].set_title("Depth vs alpha")
fig.tight_layout()
```

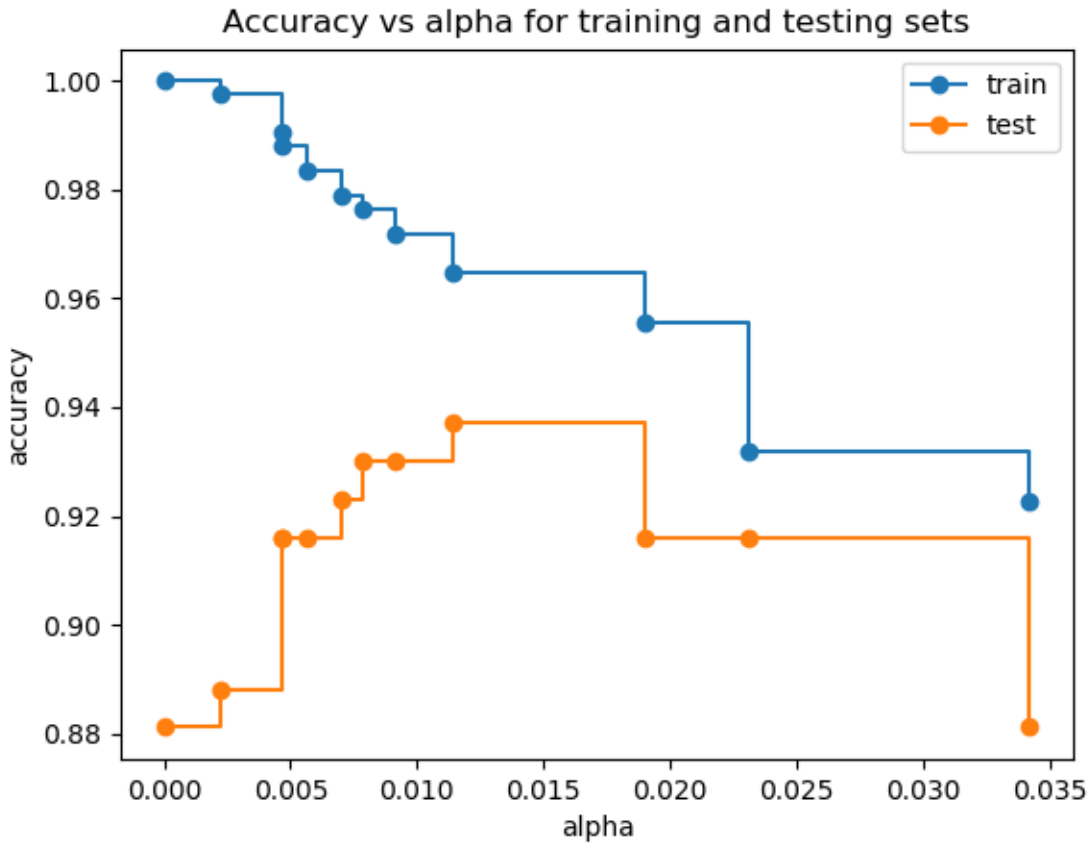


Accuracy vs alpha for training and testing sets

When `ccp_alpha` is set to zero and keeping the other default parameters of *DecisionTreeClassifier*, the tree overfits, leading to a 100% training accuracy and 88% testing accuracy. As alpha increases, more of the tree is pruned, thus creating a decision tree that generalizes better. In this example, setting `ccp_alpha=0.015` maximizes the testing accuracy.

```
train_scores = [clf.score(X_train, y_train) for clf in clfs]
test_scores = [clf.score(X_test, y_test) for clf in clfs]

fig, ax = plt.subplots()
ax.set_xlabel("alpha")
ax.set_ylabel("accuracy")
ax.set_title("Accuracy vs alpha for training and testing sets")
ax.plot(ccp_alphas, train_scores, marker='o', label="train",
        drawstyle="steps-post")
ax.plot(ccp_alphas, test_scores, marker='o', label="test",
        drawstyle="steps-post")
ax.legend()
plt.show()
```



Total running time of the script: (0 minutes 1.627 seconds)

6.9.5 Understanding the decision tree structure

The decision tree structure can be analysed to gain further insight on the relation between the features and the target to predict. In this example, we show how to retrieve:

- the binary tree structure;
- the depth of each node and whether or not it's a leaf;
- the nodes that were reached by a sample using the `decision_path` method;
- the leaf that was reached by a sample using the apply method;
- the rules that were used to predict a sample;
- the decision path shared by a group of samples.

Out:

```
The binary tree structure has 5 nodes and has the following tree structure:
node=0 test node: go to node 1 if X[:, 3] <= 0.800000011920929 else to node 2.
        node=1 leaf node.
        node=2 test node: go to node 3 if X[:, 2] <= 4.950000047683716 else to node 4.
                node=3 leaf node.
                node=4 leaf node.

Rules used to predict sample 0:
decision id node 0 : (X_test[0, 3] (= 2.4) > 0.800000011920929)
decision id node 2 : (X_test[0, 2] (= 5.1) > 4.950000047683716)

The following samples [0, 1] share the node [0 2] in the tree
It is 40.0 % of all nodes.
```

```
import numpy as np

from sklearn.model_selection import train_test_split
from sklearn.datasets import load_iris
from sklearn.tree import DecisionTreeClassifier

iris = load_iris()
X = iris.data
y = iris.target
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)

estimator = DecisionTreeClassifier(max_leaf_nodes=3, random_state=0)
estimator.fit(X_train, y_train)

# The decision estimator has an attribute called tree_  which stores the entire
# tree structure and allows access to low level attributes. The binary tree
# tree_ is represented as a number of parallel arrays. The i-th element of each
# array holds information about the node `i`. Node 0 is the tree's root. NOTE:
# Some of the arrays only apply to either leaves or split nodes, resp. In this
# case the values of nodes of the other type are arbitrary!
#
# Among those arrays, we have:
#   - left_child, id of the left child of the node
#   - right_child, id of the right child of the node
#   - feature, feature used for splitting the node
#   - threshold, threshold value at the node
#

# Using those arrays, we can parse the tree structure:

n_nodes = estimator.tree_.node_count
children_left = estimator.tree_.children_left
children_right = estimator.tree_.children_right
feature = estimator.tree_.feature
threshold = estimator.tree_.threshold

# The tree structure can be traversed to compute various properties such
```

6.10.3 Incremental PCA

Incremental principal component analysis (IPCA) is typically used as a replacement for principal component analysis (PCA) when the dataset to be decomposed is too large to fit in memory. IPCA builds a low-rank approximation for the input data using an amount of memory which is independent of the number of input data samples. It is still dependent on the input data features, but changing the batch size allows for control of memory usage.

This example serves as a visual check that IPCA is able to find a similar projection of the data to PCA (to a sign flip), while only processing a few samples at a time. This can be considered a "toy example", as IPCA is intended for large datasets which do not fit in main memory, requiring incremental approaches.

6.10.4 Comparison of LDA and PCA 2D projection of Iris dataset

The Iris dataset represents 3 kind of Iris flowers (Setosa, Versicolour and Virginica) with 4 attributes: sepal length, sepal width, petal length and petal width.

Principal Component Analysis (PCA) applied to this data identifies the combination of attributes (principal components, or directions in the feature space) that account for the most variance in the data. Here we plot the different samples on the 2 first principal components.

Linear Discriminant Analysis (LDA) tries to identify attributes that account for the most variance *between classes*. In particular, LDA, in contrast to PCA, is a supervised method, using known class labels.

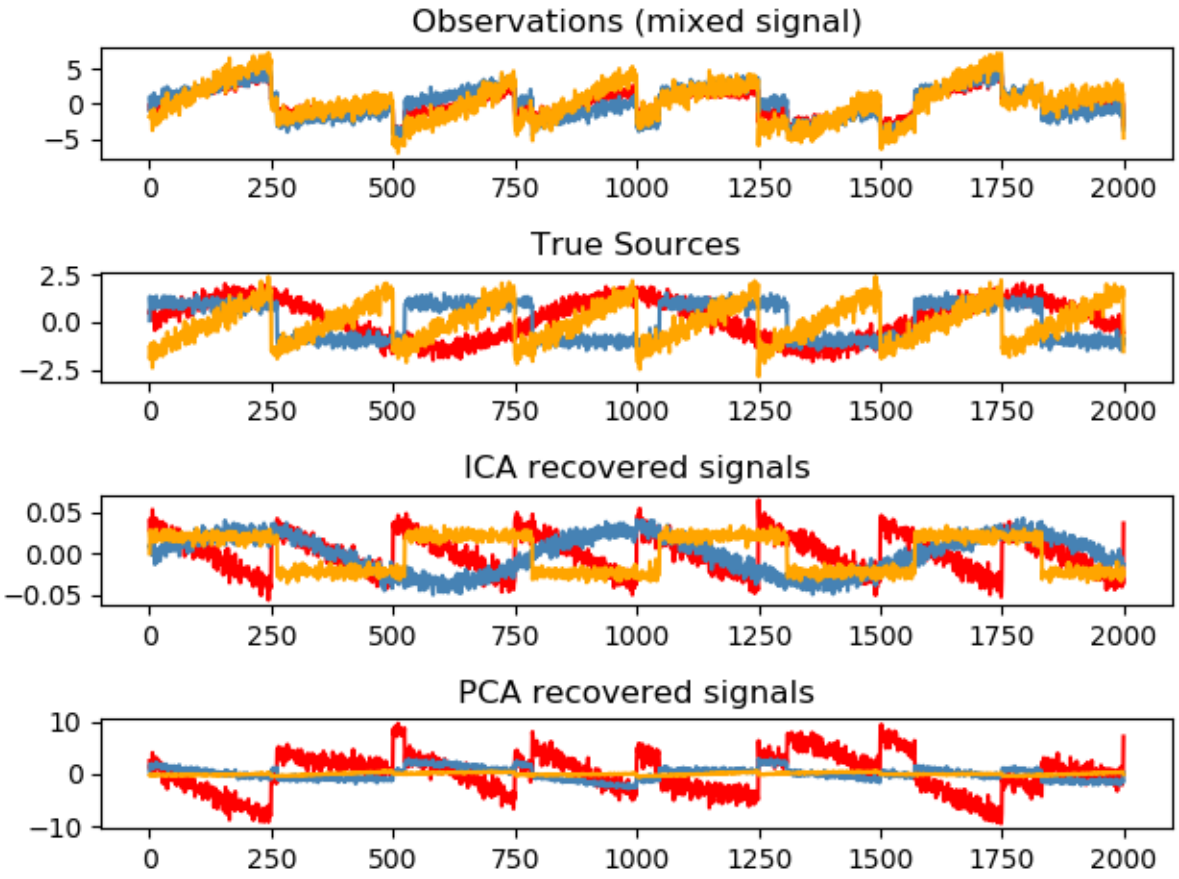
6.10.5 Blind source separation using FastICA

An example of estimating sources from noisy data.

Independent component analysis (ICA) is used to estimate sources given noisy measurements. Imagine 3 instruments playing simultaneously and 3 microphones recording the mixed signals. ICA is used to recover the sources ie. what is played by each instrument. Importantly, PCA fails at recovering our `instruments` since the related signals reflect non-Gaussian processes.



```
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt
from scipy import signal

from sklearn.decomposition import FastICA, PCA

# #############################################################################
# Generate sample data
np.random.seed(0)
n_samples = 2000
time = np.linspace(0, 8, n_samples)

s1 = np.sin(2 * time)  # Signal 1 : sinusoidal signal
s2 = np.sign(np.sin(3 * time))  # Signal 2 : square signal
s3 = signal.sawtooth(2 * np.pi * time)  # Signal 3: saw tooth signal

S = np.c_[s1, s2, s3]
S += 0.2 * np.random.normal(size=S.shape)  # Add noise

S /= S.std(axis=0)  # Standardize data
# Mix data
A = np.array([[1, 1, 1], [0.5, 2, 1.0], [1.5, 1.0, 2.0]])  # Mixing matrix

6.10.7 FastICA on 2D point clouds

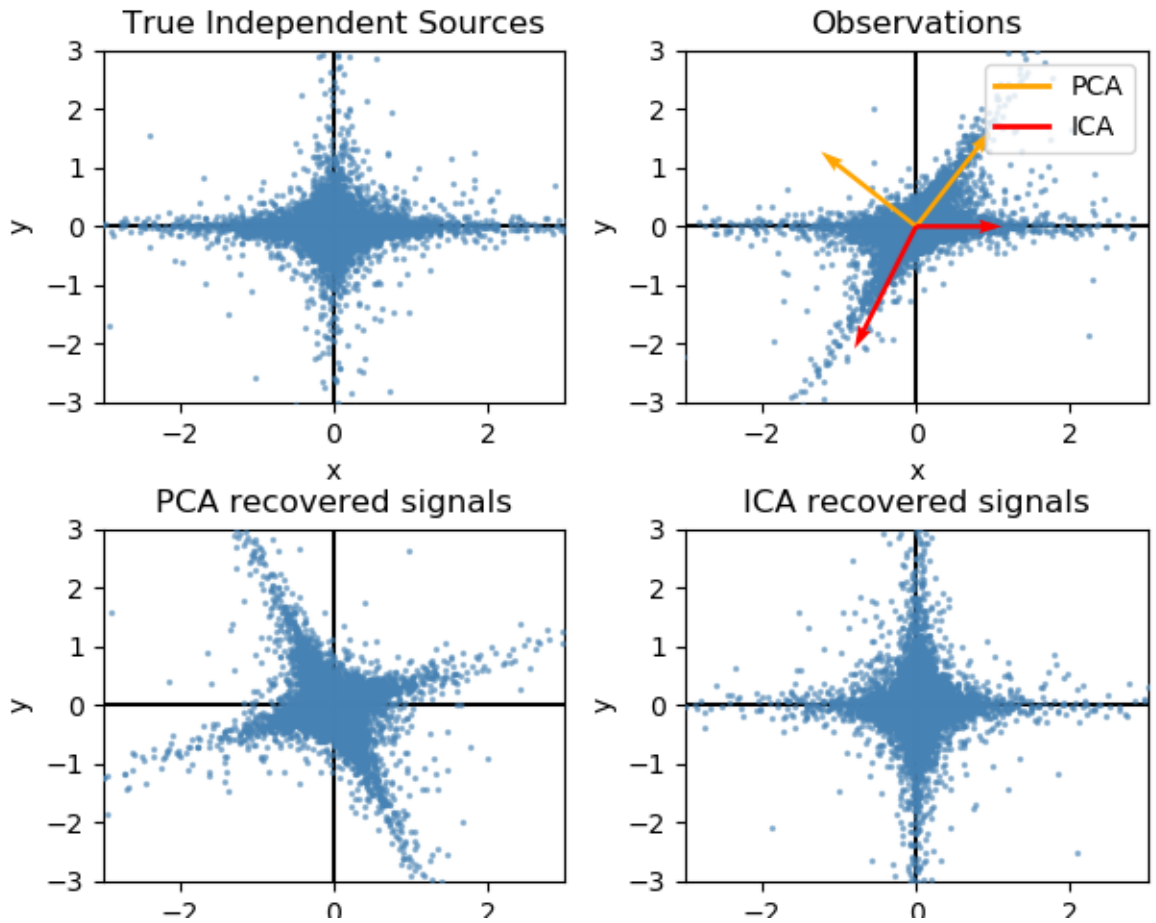
This example illustrates visually in the feature space a comparison by results using two different component analysis techniques.

Independent component analysis (ICA) vs *Principal component analysis (PCA)*.

Representing ICA in the feature space gives the view of 'geometric ICA': ICA is an algorithm that finds directions in the feature space corresponding to projections with high non-Gaussianity. These directions need not be orthogonal in the original feature space, but they are orthogonal in the whitened feature space, in which all directions correspond to the same variance.

PCA, on the other hand, finds orthogonal directions in the raw feature space that correspond to directions accounting for maximum variance.

Here we simulate independent sources using a highly non-Gaussian process, 2 student T with a low number of degrees of freedom (top left figure). We mix them to create observations (top right figure). In this raw observation space, directions identified by PCA are represented by orange vectors. We represent the signal in the PCA space, after whitening by the variance corresponding to the PCA vectors (lower left). Running ICA corresponds to finding a rotation in this space to identify the directions of largest non-Gaussianity (lower right).



```

6.10.9 Model selection with Probabilistic PCA and Factor Analysis (FA)

Probabilistic PCA and Factor Analysis are probabilistic models. The consequence is that the likelihood of new data can be used for model selection and covariance estimation. Here we compare PCA and FA with cross-validation on low rank data corrupted with homoscedastic noise (noise variance is the same for each feature) or heteroscedastic noise (noise variance is the different for each feature). In a second step we compare the model likelihood to the likelihoods obtained from shrinkage covariance estimators.

One can observe that with homoscedastic noise both FA and PCA succeed in recovering the size of the low rank subspace. The likelihood with PCA is higher than FA in this case. However PCA fails and overestimates the rank when heteroscedastic noise is present. Under appropriate circumstances the low rank models are more likely than shrinkage models.

The automatic estimation from Automatic Choice of Dimensionality for PCA. NIPS 2000: 598-604 by Thomas P. Minka is also compared.
