1.1 Installing scikit-learn

There are different ways to install scikit-learn:

- *Install the latest official release.* This is the best approach for most users. It will provide a stable version and pre-built packages are available for most platforms.

- Install the version of scikit-learn provided by your *operating system or Python distribution.* This is a quick option for those who have operating systems or Python distributions that distribute scikit-learn. It might not provide the latest release version.

- *Building the package from source.* This is best for users who want the latest-and-greatest features and aren’t afraid of running brand-new code. This is also needed for users who wish to contribute to the project.

1.1.1 Installing the latest release

Then run:

In order to check your installation you can use

Note that in order to avoid potential conflicts with other packages it is strongly recommended to use a virtual environment, e.g. python3 virtualenv (see python3 virtualenv documentation) or conda environments.

Using an isolated environment makes possible to install a specific version of scikit-learn and its dependencies independently of any previously installed Python packages. In particular under Linux is it discouraged to install pip packages alongside the packages managed by the package manager of the distribution (apt, dnf, pacman . . . ).

Note that you should always remember to activate the environment of your choice prior to running any Python command whenever you start a new terminal session.

If you have not installed NumPy or SciPy yet, you can also install these using conda or pip. When using pip, please ensure that *binary wheels* are used, and NumPy and SciPy are not recompiled from source, which can happen when using particular configurations of operating system and hardware (such as Linux on a Raspberry Pi).

If you must install scikit-learn and its dependencies with pip, you can install it as `scikit-learn[alldeps]`.

Scikit-learn plotting capabilities (i.e., functions start with “plot_” and classes end with “Display”) require Matplotlib. The examples require Matplotlib and some examples require scikit-image, pandas, or seaborn. The minimum version of Scikit-learn dependencies are listed below along with its purpose.
## Dependency

### Warning:
Scikit-learn 0.20 was the last version to support Python 2.7 and Python 3.4. Scikit-learn 0.21 supported Python 3.5-3.7. Scikit-learn 0.22 supported Python 3.5-3.8. Scikit-learn now requires Python 3.6 or newer.

### Note:
For installing on PyPy, PyPy3-v5.10+, Numpy 1.14.0+, and scipy 1.1.0+ are required.

### 1.1.2 Third party distributions of scikit-learn

Some third-party distributions provide versions of scikit-learn integrated with their package-management systems. These can make installation and upgrading much easier for users since the integration includes the ability to automatically install dependencies (numpy, scipy) that scikit-learn requires.

The following is an incomplete list of OS and python distributions that provide their own version of scikit-learn.

#### Arch Linux

Arch Linux’s package is provided through the official repositories as python-scikit-learn for Python. It can be installed by typing the following command:

```
$ sudo pacman -S python-scikit-learn
```
### Debian/Ubuntu

The Debian/Ubuntu package is split into three different packages called `python3-sklearn` (python modules), `python3-sklearn-lib` (low-level implementations and bindings), `python3-sklearn-doc` (documentation). Only the Python 3 version is available in the Debian Buster (the more recent Debian distribution). Packages can be installed using `apt-get`:

```
$ sudo apt-get install python3-sklearn python3-sklearn-lib python3-sklearn-doc
```

### Fedora

The Fedora package is called `python3-scikit-learn` for the python 3 version, the only one available in Fedora 30. It can be installed using `dnf`:

```
$ sudo dnf install python3-scikit-learn
```

### NetBSD

scikit-learn is available via pkgsrc-wip:

http://pkgsrc.se/math/py-scikit-learn

### MacPorts for Mac OSX

The MacPorts package is named `py<XY>-scikits-learn`, where XY denotes the Python version. It can be installed by typing the following command:

```
$ sudo port install py36-scikit-learn
```

### Anaconda and Enthought Deployment Manager for all supported platforms

Anaconda and Enthought Deployment Manager both ship with scikit-learn in addition to a large set of scientific python library for Windows, Mac OSX and Linux.

Anaconda offers scikit-learn as part of its free distribution.

### Intel conda channel

Intel maintains a dedicated conda channel that ships scikit-learn:

```
$ conda install -c intel scikit-learn
```

This version of scikit-learn comes with alternative solvers for some common estimators. Those solvers come from the DAAL C++ library and are optimized for multi-core Intel CPUs.

Note that those solvers are not enabled by default, please refer to the daal4py documentation for more details.

Compatibility with the standard scikit-learn solvers is checked by running the full scikit-learn test suite via automated continuous integration as reported on https://github.com/IntelPython/daal4py.

## 1.1. Installing scikit-learn
WinPython for Windows

The WinPython project distributes scikit-learn as an additional plugin.

1.1.3 Troubleshooting

Error caused by file path length limit on Windows

It can happen that pip fails to install packages when reaching the default path size limit of Windows if Python is installed in a nested location such as the AppData folder structure under the user home directory, for instance:

```
C:\Users\username>C:\Users\username\AppData\Local\Microsoft\WindowsApps\python.exe -m ...
    pip install scikit-learn
Collecting scikit-learn
... Installing collected packages: scikit-learn
ERROR: Could not install packages due to an EnvironmentError: [Errno 2] No such file or directory: 'C:\Users\username\AppData\Local\Packages\...
    →PythonSoftwareFoundation.Python.3.7_qbz5n2kfra8p0\LocalCache\local-packages\...
    →Python37\site-packages\sklearn\datasets\tests\data\openml\292\api-v1-json-...
    →data-list-data_name-australian-limit-2-data_version-1-status-deactivated.json.gz'
```

In this case it is possible to lift that limit in the Windows registry by using the regedit tool:

1. Type “regedit” in the Windows start menu to launch regedit.
2. Go to the Computer\HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem key.
3. Edit the value of the LongPathsEnabled property of that key and set it to 1.
4. Reinstall scikit-learn (ignoring the previous broken installation):

```
pip install --exists-action=i scikit-learn
```

1.2 Frequently Asked Questions

Here we try to give some answers to questions that regularly pop up on the mailing list.

1.2.1 What is the project name (a lot of people get it wrong)?

scikit-learn, but not scikit or SciKit nor sci-kit learn. Also not scikits.learn or scikits-learn, which were previously used.
1.2.2 How do you pronounce the project name?

sy-kit learn. sci stands for science!

1.2.3 Why scikit?

There are multiple scikits, which are scientific toolboxes built around SciPy. You can find a list at https://scikits.appspot.com/scikits. Apart from scikit-learn, another popular one is scikit-image.

1.2.4 How can I contribute to scikit-learn?

See Contributing. Before wanting to add a new algorithm, which is usually a major and lengthy undertaking, it is recommended to start with known issues. Please do not contact the contributors of scikit-learn directly regarding contributing to scikit-learn.

1.2.5 What’s the best way to get help on scikit-learn usage?

For general machine learning questions, please use Cross Validated with the [machine-learning] tag.

For scikit-learn usage questions, please use Stack Overflow with the [scikit-learn] and [python] tags. You can alternatively use the mailing list.

Please make sure to include a minimal reproduction code snippet (ideally shorter than 10 lines) that highlights your problem on a toy dataset (for instance from sklearn.datasets or randomly generated with functions of numpy.random with a fixed random seed). Please remove any line of code that is not necessary to reproduce your problem.

The problem should be reproducible by simply copy-pasting your code snippet in a Python shell with scikit-learn installed. Do not forget to include the import statements.

More guidance to write good reproduction code snippets can be found at:

https://stackoverflow.com/help/mcve

If your problem raises an exception that you do not understand (even after googling it), please make sure to include the full traceback that you obtain when running the reproduction script.

For bug reports or feature requests, please make use of the issue tracker on GitHub.

There is also a scikit-learn Gitter channel where some users and developers might be found.

Please do not email any authors directly to ask for assistance, report bugs, or for any other issue related to scikit-learn.

1.2.6 How should I save, export or deploy estimators for production?

See Model persistence.
1.2.7 How can I create a bunch object?

Bunch objects are sometimes used as an output for functions and methods. They extend dictionaries by enabling values to be accessed by key, `bunch["value_key"]`, or by an attribute, `bunch.value_key`. They should not be used as an input; therefore you almost never need to create a `Bunch` object, unless you are extending the scikit-learn’s API.

1.2.8 How can I load my own datasets into a format usable by scikit-learn?

Generally, scikit-learn works on any numeric data stored as numpy arrays or scipy sparse matrices. Other types that are convertible to numeric arrays such as pandas DataFrame are also acceptable. For more information on loading your data files into these usable data structures, please refer to loading external datasets.

1.2.9 What are the inclusion criteria for new algorithms?

We only consider well-established algorithms for inclusion. A rule of thumb is at least 3 years since publication, 200+ citations, and wide use and usefulness. A technique that provides a clear-cut improvement (e.g. an enhanced data structure or a more efficient approximation technique) on a widely-used method will also be considered for inclusion.

From the algorithms or techniques that meet the above criteria, only those which fit well within the current API of scikit-learn, that is a `fit`, `predict`/`transform` interface and ordinarily having input/output that is a numpy array or sparse matrix, are accepted.

The contributor should support the importance of the proposed addition with research papers and/or implementations in other similar packages, demonstrate its usefulness via common use-cases/applications and corroborate performance improvements, if any, with benchmarks and/or plots. It is expected that the proposed algorithm should outperform the methods that are already implemented in scikit-learn at least in some areas.

Inclusion of a new algorithm speeding up an existing model is easier if:
- it does not introduce new hyper-parameters (as it makes the library more future-proof),
- it is easy to document clearly when the contribution improves the speed and when it does not, for instance “when n_features >> n_samples”,
- benchmarks clearly show a speed up.

Also, note that your implementation need not be in scikit-learn to be used together with scikit-learn tools. You can implement your favorite algorithm in a scikit-learn compatible way, upload it to GitHub and let us know. We will be happy to list it under Related Projects. If you already have a package on GitHub following the scikit-learn API, you may also be interested to look at scikit-learn-contrib.

1.2.10 Why are you so selective on what algorithms you include in scikit-learn?

Code comes with maintenance cost, and we need to balance the amount of code we have with the size of the team (and add to this the fact that complexity scales non-linearly with the number of features). The package relies on core developers using their free time to fix bugs, maintain code and review contributions. Any algorithm that is added needs future attention by the developers, at which point the original author might long have lost interest. See also What are the inclusion criteria for new algorithms?. For a great read about long-term maintenance issues in open-source software, look at the Executive Summary of Roads and Bridges.
1.2.11 Why did you remove HMMs from scikit-learn?

See Will you add graphical models or sequence prediction to scikit-learn?.

1.2.12 Will you add graphical models or sequence prediction to scikit-learn?

Not in the foreseeable future. scikit-learn tries to provide a unified API for the basic tasks in machine learning, with pipelines and meta-algorithms like grid search to tie everything together. The required concepts, APIs, algorithms and expertise required for structured learning are different from what scikit-learn has to offer. If we started doing arbitrary structured learning, we’d need to redesign the whole package and the project would likely collapse under its own weight.

There are two project with API similar to scikit-learn that do structured prediction:

- pystruct handles general structured learning (focuses on SSVMs on arbitrary graph structures with approximate inference; defines the notion of sample as an instance of the graph structure)
- seqlearn handles sequences only (focuses on exact inference; has HMMs, but mostly for the sake of completeness; treats a feature vector as a sample and uses an offset encoding for the dependencies between feature vectors)

1.2.13 Will you add GPU support?

No, or at least not in the near future. The main reason is that GPU support will introduce many software dependencies and introduce platform specific issues. scikit-learn is designed to be easy to install on a wide variety of platforms. Outside of neural networks, GPUs don’t play a large role in machine learning today, and much larger gains in speed can often be achieved by a careful choice of algorithms.

1.2.14 Do you support PyPy?

In case you didn’t know, PyPy is an alternative Python implementation with a built-in just-in-time compiler. Experimental support for PyPy3-v5.10+ has been added, which requires Numpy 1.14.0+, and scipy 1.1.0+.

1.2.15 How do I deal with string data (or trees, graphs...)?

scikit-learn estimators assume you’ll feed them real-valued feature vectors. This assumption is hard-coded in pretty much all of the library. However, you can feed non-numerical inputs to estimators in several ways.

If you have text documents, you can use a term frequency features; see Text feature extraction for the built-in text vectorizers. For more general feature extraction from any kind of data, see Loading features from dicts and Feature hashing.

Another common case is when you have non-numerical data and a custom distance (or similarity) metric on these data. Examples include strings with edit distance (aka. Levenshtein distance; e.g., DNA or RNA sequences). These can be encoded as numbers, but doing so is painful and error-prone. Working with distance metrics on arbitrary data can be done in two ways.

Firstly, many estimators take precomputed distance/similarity matrices, so if the dataset is not too large, you can compute distances for all pairs of inputs. If the dataset is large, you can use feature vectors with only one “feature”, which is an index into a separate data structure, and supply a custom metric function that looks up the actual data in this data structure. E.g., to use DBSCAN with Levenshtein distances:
```python
>>> from leven import levenshtein
>>> import numpy as np
>>> from sklearn.cluster import dbscan

>>> data = ["ACCTCTAGAAG", "ACCTACTAGAAGTT", "GAATATTAGGCCGA"]

>>> def lev_metric(x, y):
...     i, j = int(x[0]), int(y[0])  # extract indices
...     return levenshtein(data[i], data[j])
...

>>> X = np.arange(len(data)).reshape(-1, 1)

>>> X
array([[0],
       [1],
       [2]])

>>> # We need to specify algorithm='brute' as the default assumes
>>> # a continuous feature space.
>>> dbscan(X, metric=lev_metric, eps=5, min_samples=2, algorithm='brute')
...  
... (array([0, 1], array([0, 0, -1])))
```

(This uses the third-party edit distance package `leven`.)

Similar tricks can be used, with some care, for tree kernels, graph kernels, etc.

### 1.2.16 Why do I sometime get a crash/freeze with `n_jobs > 1` under OSX or Linux?

Several scikit-learn tools such as `GridSearchCV` and `cross_val_score` rely internally on Python’s `multiprocessing` module to parallelize execution onto several Python processes by passing `n_jobs > 1` as an argument.

The problem is that Python `multiprocessing` does a `fork` system call without following it with an `exec` system call for performance reasons. Many libraries like (some versions of) Accelerate / vecLib under OSX, (some versions of) MKL, the OpenMP runtime of GCC, nvidia’s Cuda (and probably many others), manage their own internal thread pool. Upon a call to `fork`, the thread pool state in the child process is corrupted: the thread pool believes it has many threads while only the main thread state has been forked. It is possible to change the libraries to make them detect when a fork happens and reinitialize the thread pool in that case: we did that for OpenBLAS (merged upstream in master since 0.2.10) and we contributed a patch to GCC’s OpenMP runtime (not yet reviewed).

But in the end the real culprit is Python’s `multiprocessing` that does `fork` without `exec` to reduce the overhead of starting and using new Python processes for parallel computing. Unfortunately this is a violation of the POSIX standard and therefore some software editors like Apple refuse to consider the lack of fork-safety in Accelerate / vecLib as a bug.

In Python 3.4+ it is now possible to configure `multiprocessing` to use the ‘forkserver’ or ‘spawn’ start methods (instead of the default ‘fork’) to manage the process pools. To work around this issue when using scikit-learn, you can set the `JOBLIB_START_METHOD` environment variable to `forkserver`. However the user should be aware that using the ‘forkserver’ method prevents joblib.Parallel to call function interactively defined in a shell session.

If you have custom code that uses `multiprocessing` directly instead of using it via joblib you can enable the ‘forkserver’ mode globally for your program: Insert the following instructions in your main script:

```python
import multiprocessing

# other imports, custom code, load data, define model...

if __name__ == '__main__':
    multiprocessing.set_start_method('forkserver')
```

(continues on next page)
# call scikit-learn utils with n_jobs > 1 here

You can find more default on the new start methods in the multiprocessing documentation.

## 1.2.17 Why does my job use more cores than specified with n_jobs?

This is because `n_jobs` only controls the number of jobs for routines that are parallelized with `joblib`, but parallel code can come from other sources:

- some routines may be parallelized with OpenMP (for code written in C or Cython).
- scikit-learn relies a lot on numpy, which in turn may rely on numerical libraries like MKL, OpenBLAS or BLIS which can provide parallel implementations.

For more details, please refer to our Parallelism notes.

## 1.2.18 Why is there no support for deep or reinforcement learning / Will there be support for deep or reinforcement learning in scikit-learn?

Deep learning and reinforcement learning both require a rich vocabulary to define an architecture, with deep learning additionally requiring GPUs for efficient computing. However, neither of these fit within the design constraints of scikit-learn; as a result, deep learning and reinforcement learning are currently out of scope for what scikit-learn seeks to achieve.

You can find more information about addition of gpu support at Will you add GPU support?.

Note that scikit-learn currently implements a simple multilayer perceptron in `sklearn.neural_network`. We will only accept bug fixes for this module. If you want to implement more complex deep learning models, please turn to popular deep learning frameworks such as tensorflow, keras and pytorch.

## 1.2.19 Why is my pull request not getting any attention?

The scikit-learn review process takes a significant amount of time, and contributors should not be discouraged by a lack of activity or review on their pull request. We care a lot about getting things right the first time, as maintenance and later change comes at a high cost. We rarely release any “experimental” code, so all of our contributions will be subject to high use immediately and should be of the highest quality possible initially.

Beyond that, scikit-learn is limited in its reviewing bandwidth; many of the reviewers and core developers are working on scikit-learn on their own time. If a review of your pull request comes slowly, it is likely because the reviewers are busy. We ask for your understanding and request that you not close your pull request or discontinue your work solely because of this reason.
1.2.20 How do I set a random_state for an entire execution?

For testing and replicability, it is often important to have the entire execution controlled by a single seed for the pseudo-random number generator used in algorithms that have a randomized component. Scikit-learn does not use its own global random state; whenever a RandomState instance or an integer random seed is not provided as an argument, it relies on the numpy global random state, which can be set using `numpy.random.seed`. For example, to set an execution's numpy global random state to 42, one could execute the following in his or her script:

```python
import numpy as np
np.random.seed(42)
```

However, a global random state is prone to modification by other code during execution. Thus, the only way to ensure replicability is to pass `RandomState` instances everywhere and ensure that both estimators and cross-validation splitters have their `random_state` parameter set.

1.2.21 Why do categorical variables need preprocessing in scikit-learn, compared to other tools?

Most of scikit-learn assumes data is in NumPy arrays or SciPy sparse matrices of a single numeric dtype. These do not explicitly represent categorical variables at present. Thus, unlike R's data.frames or pandas.DataFrame, we require explicit conversion of categorical features to numeric values, as discussed in Encoding categorical features. See also Column Transformer with Mixed Types for an example of working with heterogeneous (e.g. categorical and numeric) data.

1.2.22 Why does Scikit-learn not directly work with, for example, pandas.DataFrame?

The homogeneous NumPy and SciPy data objects currently expected are most efficient to process for most operations. Extensive work would also be needed to support Pandas categorical types. Restricting input to homogeneous types therefore reduces maintenance cost and encourages usage of efficient data structures.

1.2.23 Do you plan to implement transform for target y in a pipeline?

Currently transform only works for features X in a pipeline. There's a long-standing discussion about not being able to transform y in a pipeline. Follow on github issue #4143. Meanwhile check out TransformedTargetRegressor, pipegraph, imbalanced-learn. Note that Scikit-learn solved for the case where y has an invertible transformation applied before training and inverted after prediction. Scikit-learn intends to solve for use cases where y should be transformed at training time and not at test time, for resampling and similar uses, like at imbalanced learn. In general, these use cases can be solved with a custom meta estimator rather than a Pipeline

1.3 Support

There are several ways to get in touch with the developers.
1.3.1 Mailing List

- The main mailing list is scikit-learn.
- There is also a commit list scikit-learn-commits, where updates to the main repository and test failures get notified.

1.3.2 User questions

- Some scikit-learn developers support users on StackOverflow using the [scikit-learn] tag.
- For general theoretical or methodological Machine Learning questions stack exchange is probably a more suitable venue.

In both cases please use a descriptive question in the title field (e.g. no “Please help with scikit-learn!” as this is not a question) and put details on what you tried to achieve, what were the expected results and what you observed instead in the details field.

Code and data snippets are welcome. Minimalistic (up to ~20 lines long) reproduction script very helpful.

Please describe the nature of your data and how you preprocessed it: what is the number of samples, what is the number and type of features (i.d. categorical or numerical) and for supervised learning tasks, what target are you trying to predict: binary, multiclass (1 out of n_classes) or multilabel (k out of n_classes) classification or continuous variable regression.

User questions should not be asked on the bug tracker, as it crowds the list of issues and makes the development of the project harder.

1.3.3 Bug tracker

If you think you’ve encountered a bug, please report it to the issue tracker:

https://github.com/scikit-learn/scikit-learn/issues

Don’t forget to include:

- steps (or better script) to reproduce,
- expected outcome,
- observed outcome or Python (or gdb) tracebacks

To help developers fix your bug faster, please link to a https://gist.github.com holding a standalone minimalistic python script that reproduces your bug and optionally a minimalistic subsample of your dataset (for instance, exported as CSV files using numpy.savetxt).

Note: Gists are Git cloneable repositories and thus you can use Git to push datafiles to them.

Gitter ===

Some developers like to hang out on scikit-learn Gitter room: https://gitter.im/scikit-learn/scikit-learn.
1.3.4 Documentation resources

This documentation is relative to 0.24.dev0. Documentation for other versions can be found here.
Printable pdf documentation for old versions can be found here.

1.4 Related Projects

Projects implementing the scikit-learn estimator API are encouraged to use the scikit-learn-contrib template which facilitates best practices for testing and documenting estimators. The scikit-learn-contrib GitHub organisation also accepts high-quality contributions of repositories conforming to this template.

Below is a list of sister-projects, extensions and domain specific packages.

1.4.1 Interoperability and framework enhancements

These tools adapt scikit-learn for use with other technologies or otherwise enhance the functionality of scikit-learn’s estimators.

Data formats

- Fast svmlight / libsvm file loader Fast and memory-efficient svmlight / libsvm file loader for Python.
- sklearn_pandas bridge for scikit-learn pipelines and pandas data frame with dedicated transformers.
- sklearn_xarray provides compatibility of scikit-learn estimators with xarray data structures.

Auto-ML

- auto-sklearn An automated machine learning toolkit and a drop-in replacement for a scikit-learn estimator
- TPOT An automated machine learning toolkit that optimizes a series of scikit-learn operators to design a machine learning pipeline, including data and feature preprocessors as well as the estimators. Works as a drop-in replacement for a scikit-learn estimator.
- Featuretools A framework to perform automated feature engineering. It can be used for transforming temporal and relational datasets into feature matrices for machine learning.
- Neuraxle A library for building neat pipelines, providing the right abstractions to both ease research, development, and deployment of machine learning applications. Compatible with deep learning frameworks and scikit-learn API, it can stream minibatches, use data checkpoints, build funky pipelines, and serialize models with custom per-step savers.

Experimentation frameworks

- REP Environment for conducting data-driven research in a consistent and reproducible way
- Scikit-Learn Laboratory A command-line wrapper around scikit-learn that makes it easy to run machine learning experiments with multiple learners and large feature sets.

Model inspection and visualisation

- dtreeviz A python library for decision tree visualization and model interpretation.
- eli5 A library for debugging/inspecting machine learning models and explaining their predictions.
- mlxtend Includes model visualization utilities.
- yellowbrick A suite of custom matplotlib visualizers for scikit-learn estimators to support visual feature analysis, model selection, evaluation, and diagnostics.
Model selection

- **scikit-optimize** A library to minimize (very) expensive and noisy black-box functions. It implements several methods for sequential model-based optimization, and includes a replacement for GridSearchCV or RandomizedSearchCV to do cross-validated parameter search using any of these strategies.

- **sklearn-deap** Use evolutionary algorithms instead of gridsearch in scikit-learn.

Model export for production

- **onnxmltools** Serializes many Scikit-learn pipelines to ONNX for interchange and prediction.

- **sklearn2pmml** Serialization of a wide variety of scikit-learn estimators and transformers into PMML with the help of JPMML-SkLearn library.

- **sklearn-porter** Transpiles trained scikit-learn models to C, Java, Javascript and others.

- **treelite** Compiles tree-based ensemble models into C code for minimizing prediction latency.

1.4.2 Other estimators and tasks

Not everything belongs or is mature enough for the central scikit-learn project. The following are projects providing interfaces similar to scikit-learn for additional learning algorithms, infrastructures and tasks.

Structured learning

- **tslearn** A machine learning library for time series that offers tools for pre-processing and feature extraction as well as dedicated models for clustering, classification and regression.

- **sktime** A scikit-learn compatible toolbox for machine learning with time series including time series classification/regression and (supervised/panel) forecasting.

- **HMMLearn** Implementation of hidden markov models that was previously part of scikit-learn.

- **PyStruct** General conditional random fields and structured prediction.

- **pomegranate** Probabilistic modelling for Python, with an emphasis on hidden Markov models.

- **sklearn-crfsuite** Linear-chain conditional random fields (CRFsuite wrapper with sklearn-like API).

Deep neural networks etc.

- **nolearn** A number of wrappers and abstractions around existing neural network libraries

- **keras** Deep Learning library capable of running on top of either TensorFlow or Theano.

- **lasagne** A lightweight library to build and train neural networks in Theano.

- **skorch** A scikit-learn compatible neural network library that wraps PyTorch.

Broad scope

- **mlxtend** Includes a number of additional estimators as well as model visualization utilities.

- **scikit-lego** A number of scikit-learn compatible custom transformers, models and metrics, focusing on solving practical industry tasks.

Other regression and classification

- **xgboost** Optimised gradient boosted decision tree library.

- **ML-Ensemble** Generalized ensemble learning (stacking, blending, subsemble, deep ensembles, etc.).

- **lightning** Fast state-of-the-art linear model solvers (SDCA, AdaGrad, SVRG, SAG, etc…).

- **py-earth** Multivariate adaptive regression splines
- **Kernel Regression** Implementation of Nadaraya-Watson kernel regression with automatic bandwidth selection.

- **gplearn** Genetic Programming for symbolic regression tasks.

- **scikit-multilearn** Multi-label classification with focus on label space manipulation.

- **seglearn** Time series and sequence learning using sliding window segmentation.

- **libOPF** Optimal path forest classifier.

- **fastFM** Fast factorization machine implementation compatible with scikit-learn.

**Decomposition and clustering**

- **lda** Fast implementation of latent Dirichlet allocation in Cython which uses Gibbs sampling to sample from the true posterior distribution. (scikit-learn’s *LatentDirichletAllocation* implementation uses variational inference to sample from a tractable approximation of a topic model’s posterior distribution.)

- **kmodes** k-modes clustering algorithm for categorical data, and several of its variations.

- **hdbscan** HDBSCAN and Robust Single Linkage clustering algorithms for robust variable density clustering.

- **spherecluster** Spherical K-means and mixture of von Mises Fisher clustering routines for data on the unit hypersphere.

**Pre-processing**

- **categorical-encoding** A library of sklearn compatible categorical variable encoders.

- **imbalanced-learn** Various methods to under- and over-sample datasets.

- **Feature-engine** A library of sklearn compatible transformers for missing data imputation, categorical encoding, variable transformation, discretization, outlier handling and more. Feature-engine allows the application of preprocessing steps to selected groups of variables and it is fully compatible with the Scikit-learn Pipeline.

**Topological Data Analysis**

- **giotto-tda** A library for Topological Data Analysis aiming to provide a scikit-learn compatible API. It offers tools to transform data inputs (point clouds, graphs, time series, images) into forms suitable for computations of topological summaries, and components dedicated to extracting sets of scalar features of topological origin, which can be used alongside other feature extraction methods in scikit-learn.

### 1.4.3 Statistical learning with Python

Other packages useful for data analysis and machine learning.

- **Pandas** Tools for working with heterogeneous and columnar data, relational queries, time series and basic statistics.

- **statsmodels** Estimating and analysing statistical models. More focused on statistical tests and less on prediction than scikit-learn.

- **PyMC** Bayesian statistical models and fitting algorithms.

- **Sacred** Tool to help you configure, organize, log and reproduce experiments.

- **Seaborn** Visualization library based on matplotlib. It provides a high-level interface for drawing attractive statistical graphics.
**Recommendation Engine packages**

- **implicit**: Library for implicit feedback datasets.
- **lightfm**: A Python/Cython implementation of a hybrid recommender system.
- **OpenRec**: TensorFlow-based neural-network inspired recommendation algorithms.
- **Spotlight**: Pytorch-based implementation of deep recommender models.
- **Surprise Lib**: Library for explicit feedback datasets.

**Domain specific packages**

- **scikit-image**: Image processing and computer vision in python.
- **Natural language toolkit (nltk)**: Natural language processing and some machine learning.
- **gensim**: A library for topic modelling, document indexing and similarity retrieval
- **NiLearn**: Machine learning for neuro-imaging.
- **AstroML**: Machine learning for astronomy.
- **MSMBuilder**: Machine learning for protein conformational dynamics time series.

### 1.5 About us

#### 1.5.1 History

This project was started in 2007 as a Google Summer of Code project by David Cournapeau. Later that year, Matthieu Brucher started work on this project as part of his thesis.

In 2010 Fabian Pedregosa, Gael Varoquaux, Alexandre Gramfort and Vincent Michel of INRIA took leadership of the project and made the first public release, February the 1st 2010. Since then, several releases have appeared following a ~ 3-month cycle, and a thriving international community has been leading the development.

#### 1.5.2 Governance

The decision making process and governance structure of scikit-learn is laid out in the governance document.

#### 1.5.3 Authors

The following people are currently core contributors to scikit-learn’s development and maintenance:

Please do not email the authors directly to ask for assistance or report issues. Instead, please see What’s the best way to ask questions about scikit-learn in the FAQ.

See also:

_How you can contribute to the project_
1.5.4 Triage Team

The following people are active contributors who also help with triaging issues, PRs, and general maintenance:

1.5.5 Emeritus Core Developers

The following people have been active contributors in the past, but are no longer active in the project:

- Mathieu Blondel
- Matthieu Brucher
- Lars Buitinck
- David Cournapeau
- Noel Dawe
- Shiqiao Du
- Vincent Dubourg
- Edouard Duchesnay
- Alexander Fabisch
- Virgile Fritsch
- Satrajit Ghosh
- Angel Soler Gollonet
- Chris Gorgolewski
- Jaques Grobler
- Brian Holt
- Arnaud Joly
- Thouis (Ray) Jones
- Kyle Kastner
- manoj kumar
- Robert Layton
- Wei Li
- Paolo Losi
- Gilles Louppe
- Vincent Michel
- Jarrod Millman
- Alexandre Passos
- Fabian Pedregosa
- Peter Prettenhofer
- (Venkat) Raghav, Rajagopalan
- Jacob Schreiber
1.5.6 Citing scikit-learn

If you use scikit-learn in a scientific publication, we would appreciate citations to the following paper:

Bibtex entry:

```latex
@article{scikit-learn,
  title={Scikit-learn: Machine Learning in {Python}},
  journal={Journal of Machine Learning Research},
  volume={12},
  pages={2825--2830},
  year={2011}
}
```

If you want to cite scikit-learn for its API or design, you may also want to consider the following paper:

**API design for machine learning software: experiences from the scikit-learn project**, Buitinck et al., 2013.

Bibtex entry:

```latex
@inproceedings{sklearn_api,
  title = {{API} design for machine learning software: experiences from the scikit-learn project},
  author = {Lars Buitinck and Gilles Louppe and Mathieu Blondel and Fabian Pedregosa and Andreas Mueller and Olivier Grisel and Vlad Niculae and Peter Prettenhofer and Alexandre Gramfort and Jaques Grobler and Robert Layton and Jake VanderPlas and Arnaud Joly and Brian Holt andGa{"e}l Varoquaux},
  booktitle = {ECML PKDD Workshop: Languages for Data Mining and Machine Learning},
  year = {2013},
  pages = {108--122},
}
```
1.5.7 Artwork

High quality PNG and SVG logos are available in the doc/logos/ source directory.

1.5.8 Funding

Scikit-Learn is a community driven project, however institutional and private grants help to assure its sustainability. The project would like to thank the following funders.

The Members of the Scikit-Learn Consortium at Inria Foundation fund Olivier Grisel, Guillaume Lemaitre, Jérémie du Boisberranger and Chiara Marmo.

Columbia University funds Andreas Müller since 2016
Andreas Müller received a grant to improve scikit-learn from the Alfred P. Sloan Foundation. This grant supports the position of Nicolas Hug and Thomas J. Fan.

The University of Sydney funds Joel Nothman since July 2017.

Past Sponsors

INRIA actively supports this project. It has provided funding for Fabian Pedregosa (2010-2012), Jaques Grobler (2012-2013) and Olivier Grisel (2013-2017) to work on this project full-time. It also hosts coding sprints and other events.

Paris-Saclay Center for Data Science funded one year for a developer to work on the project full-time (2014-2015), 50% of the time of Guillaume Lemaitre (2016-2017) and 50% of the time of Joris van den Bossche (2017-2018).

Anaconda, Inc funded Adrin Jalali in 2019.

NYU Moore-Sloan Data Science Environment funded Andreas Mueller (2014-2016) to work on this project. The Moore-Sloan Data Science Environment also funds several students to work on the project part-time.

The following students were sponsored by Google to work on scikit-learn through the Google Summer of Code program.

- 2007 - David Cournapeau
- 2011 - Vlad Niculae
- 2012 - Vlad Niculae, Immanuel Bayer.
- 2013 - Kemal Eren, Nicolas Trésegnie
- 2014 - Hamzeh Alsalhi, Issam Laradji, Maheshkya Wijewardena, Manoj Kumar.
- 2015 - Raghav RV, Wei Xue
- 2016 - Nelson Liu, YenChen Lin

The NeuroDebian project providing Debian packaging and contributions is supported by Dr. James V. Haxby (Dartmouth College).

### 1.5.9 Sprints

The International 2019 Paris sprint was kindly hosted by AXA. Also some participants could attend thanks to the support of the Alfred P. Sloan Foundation, the Python Software Foundation (PSF) and the DATAIA Institute.

The 2013 International Paris Sprint was made possible thanks to the support of Télécom Paristech, tinyclues, the French Python Association and the Fonds de la Recherche Scientifique.

The 2011 International Granada sprint was made possible thanks to the support of the PSF and tinyclues.
Donating to the project

If you are interested in donating to the project or to one of our code-sprints, you can use the *Paypal* button below or the *NumFOCUS Donations Page* (if you use the latter, please indicate that you are donating for the scikit-learn project).

All donations will be handled by *NumFOCUS*, a non-profit-organization which is managed by a board of *Scipy community members*. *NumFOCUS*’s mission is to foster scientific computing software, in particular in Python. As a fiscal home of scikit-learn, it ensures that money is available when needed to keep the project funded and available while in compliance with tax regulations.

The received donations for the scikit-learn project mostly will go towards covering travel-expenses for code sprints, as well as towards the organization budget of the project\(^1\).

Notes

1.5.10 Infrastructure support

- We would like to thank *Rackspace* for providing us with a free *Rackspace Cloud* account to automatically build the documentation and the example gallery from for the development version of scikit-learn using [this tool](#).
- We would also like to thank *Microsoft Azure, Travis CI, CircleCI* for free CPU time on their Continuous Integration servers.

1.6 Who is using scikit-learn?

1.6.1 J.P.Morgan

Scikit-learn is an indispensable part of the Python machine learning toolkit at JPMorgan. It is very widely used across all parts of the bank for classification, predictive analytics, and very many other machine learning tasks. Its straightforward API, its breadth of algorithms, and the quality of its documentation combine to make scikit-learn simultaneously very approachable and very powerful.

Stephen Simmons, VP, Athena Research, JPMorgan

**J.P.Morgan**

1.6.2 Spotify

Scikit-learn provides a toolbox with solid implementations of a bunch of state-of-the-art models and makes it easy to plug them into existing applications. We’ve been using it quite a lot for music recommendations at Spotify and I think it’s the most well-designed ML package I’ve seen so far.

Erik Bernhardsson, Engineering Manager Music Discovery & Machine Learning, Spotify

---

\(^1\) Regarding the organization budget, in particular, we might use some of the donated funds to pay for other project expenses such as DNS, hosting or continuous integration services.
1.6.3 Inria

At INRIA, we use scikit-learn to support leading-edge basic research in many teams: Parietal for neuroimaging, Lear for computer vision, Visages for medical image analysis, Privatics for security. The project is a fantastic tool to address difficult applications of machine learning in an academic environment as it is performant and versatile, but all easy-to-use and well documented, which makes it well suited to grad students.

Gaël Varoquaux, research at Parietal

1.6.4 betaworks

Betaworks is a NYC-based startup studio that builds new products, grows companies, and invests in others. Over the past 8 years we’ve launched a handful of social data analytics-driven services, such as Bitly, Chartbeat, digg and Scale Model. Consistently the betaworks data science team uses Scikit-learn for a variety of tasks. From exploratory analysis, to product development, it is an essential part of our toolkit. Recent uses are included in digg’s new video recommender system, and Poncho’s dynamic heuristic subspace clustering.

Gilad Lotan, Chief Data Scientist

1.6.5 Hugging Face

At Hugging Face we’re using NLP and probabilistic models to generate conversational Artificial intelligences that are fun to chat with. Despite using deep neural nets for a few of our NLP tasks, scikit-learn is still the bread-and-butter of our daily machine learning routine. The ease of use and predictability of the interface, as well as the straightforward mathematical explanations that are here when you need them, is the killer feature. We use a variety of scikit-learn models in production and they are also operationally very pleasant to work with.

Julien Chaumond, Chief Technology Officer
1.6.6 Evernote

Building a classifier is typically an iterative process of exploring the data, selecting the features (the attributes of the data believed to be predictive in some way), training the models, and finally evaluating them. For many of these tasks, we relied on the excellent scikit-learn package for Python.

Read more

Mark Ayzenshtat, VP, Augmented Intelligence

1.6.7 Télécom ParisTech

At Telecom ParisTech, scikit-learn is used for hands-on sessions and home assignments in introductory and advanced machine learning courses. The classes are for undergrads and masters students. The great benefit of scikit-learn is its fast learning curve that allows students to quickly start working on interesting and motivating problems.

Alexandre Gramfort, Assistant Professor
1.6.8 Booking.com

At Booking.com, we use machine learning algorithms for many different applications, such as recommending hotels and destinations to our customers, detecting fraudulent reservations, or scheduling our customer service agents. Scikit-learn is one of the tools we use when implementing standard algorithms for prediction tasks. Its API and documentations are excellent and make it easy to use. The scikit-learn developers do a great job of incorporating state of the art implementations and new algorithms into the package. Thus, scikit-learn provides convenient access to a wide spectrum of algorithms, and allows us to readily find the right tool for the right job.

Melanie Mueller, Data Scientist

1.6.9 AWeber

The scikit-learn toolkit is indispensable for the Data Analysis and Management team at AWeber. It allows us to do AWesome stuff we would not otherwise have the time or resources to accomplish. The documentation is excellent, allowing new engineers to quickly evaluate and apply many different algorithms to our data. The text feature extraction utilities are useful when working with the large volume of email content we have at AWeber. The RandomizedPCA implementation, along with Pipelining and FeatureUnions, allows us to develop complex machine learning algorithms efficiently and reliably.

Anyone interested in learning more about how AWeber deploys scikit-learn in a production environment should check out talks from PyData Boston by AWeber’s Michael Becker available at https://github.com/mdbecker/pydata_2013

Michael Becker, Software Engineer, Data Analysis and Management Ninjas

1.6.10 Yhat

The combination of consistent APIs, thorough documentation, and top notch implementation make scikit-learn our favorite machine learning package in Python. scikit-learn makes doing advanced analysis in Python accessible to anyone. At Yhat, we make it easy to integrate these models into your production applications. Thus eliminating the unnecessary dev time encountered productionizing analytical work.

Greg Lamp, Co-founder Yhat
1.6.11 Rangespan

The Python scikit-learn toolkit is a core tool in the data science group at Rangespan. Its large collection of well documented models and algorithms allow our team of data scientists to prototype fast and quickly iterate to find the right solution to our learning problems. We find that scikit-learn is not only the right tool for prototyping, but its careful and well tested implementation give us the confidence to run scikit-learn models in production.

Jurgen Van Gael, Data Science Director at Rangespan Ltd

1.6.12 Birchbox

At Birchbox, we face a range of machine learning problems typical to E-commerce: product recommendation, user clustering, inventory prediction, trends detection, etc. Scikit-learn lets us experiment with many models, especially in the exploration phase of a new project: the data can be passed around in a consistent way; models are easy to save and reuse; updates keep us informed of new developments from the pattern discovery research community. Scikit-learn is an important tool for our team, built the right way in the right language.

Thierry Bertin-Mahieux, Birchbox, Data Scientist

1.6.13 Bestofmedia Group

Scikit-learn is our #1 toolkit for all things machine learning at Bestofmedia. We use it for a variety of tasks (e.g. spam fighting, ad click prediction, various ranking models) thanks to the varied, state-of-the-art algorithm implementations packaged into it. In the lab it accelerates prototyping of complex pipelines. In production I can say it has proven to be robust and efficient enough to be deployed for business critical components.

Eustache Diemert, Lead Scientist Bestofmedia Group
1.6.14 Change.org

At change.org we automate the use of scikit-learn’s RandomForestClassifier in our production systems to drive email targeting that reaches millions of users across the world each week. In the lab, scikit-learn’s ease-of-use, performance, and overall variety of algorithms implemented has proved invaluable in giving us a single reliable source to turn to for our machine-learning needs.

Vijay Ramesh, Software Engineer in Data/science at Change.org

1.6.15 PHIMECA Engineering

At PHIMECA Engineering, we use scikit-learn estimators as surrogates for expensive-to-evaluate numerical models (mostly but not exclusively finite-element mechanical models) for speeding up the intensive post-processing operations involved in our simulation-based decision making framework. Scikit-learn’s fit/predict API together with its efficient cross-validation tools considerably eases the task of selecting the best-fit estimator. We are also using scikit-learn for illustrating concepts in our training sessions. Trainees are always impressed by the ease-of-use of scikit-learn despite the apparent theoretical complexity of machine learning.

Vincent Dubourg, PHIMECA Engineering, PhD Engineer

1.6.16 HowAboutWe

At HowAboutWe, scikit-learn lets us implement a wide array of machine learning techniques in analysis and in production, despite having a small team. We use scikit-learn’s classification algorithms to predict user behavior, enabling us to (for example) estimate the value of leads from a given traffic source early in the lead’s tenure on our site. Also, our users’ profiles consist of primarily unstructured data (answers to open-ended questions), so we use scikit-learn’s feature extraction and dimensionality reduction tools to translate these unstructured data into inputs for our matchmaking system.

Daniel Weitzenfeld, Senior Data Scientist at HowAboutWe
1.6.17 PeerIndex

At PeerIndex we use scientific methodology to build the Influence Graph - a unique dataset that allows us to identify who’s really influential and in which context. To do this, we have to tackle a range of machine learning and predictive modeling problems. Scikit-learn has emerged as our primary tool for developing prototypes and making quick progress. From predicting missing data and classifying tweets to clustering communities of social media users, scikit-learn proved useful in a variety of applications. Its very intuitive interface and excellent compatibility with other python tools makes it an indispensable tool in our daily research efforts.

Ferenc Huszar - Senior Data Scientist at Peerindex

1.6.18 DataRobot

DataRobot is building next generation predictive analytics software to make data scientists more productive, and scikit-learn is an integral part of our system. The variety of machine learning techniques in combination with the solid implementations that scikit-learn offers makes it a one-stop-shopping library for machine learning in Python. Moreover, its consistent API, well-tested code and permissive licensing allow us to use it in a production environment. Scikit-learn has literally saved us years of work we would have had to do ourselves to bring our product to market.

Jeremy Achin, CEO & Co-founder DataRobot Inc.

1.6.19 OkCupid

We’re using scikit-learn at OkCupid to evaluate and improve our matchmaking system. The range of features it has, especially preprocessing utilities, means we can use it for a wide variety of projects, and it’s performant enough to handle the volume of data that we need to sort through. The documentation is really thorough, as well, which makes the library quite easy to use.

David Koh - Senior Data Scientist at OkCupid
1.6.20 Lovely

At Lovely, we strive to deliver the best apartment marketplace, with respect to our users and our listings. From understanding user behavior, improving data quality, and detecting fraud, scikit-learn is a regular tool for gathering insights, predictive modeling and improving our product. The easy-to-read documentation and intuitive architecture of the API makes machine learning both explorable and accessible to a wide range of python developers. I’m constantly recommending that more developers and scientists try scikit-learn.

Simon Frid - Data Scientist, Lead at Lovely

1.6.21 Data Publica

Data Publica builds a new predictive sales tool for commercial and marketing teams called C-Radar. We extensively use scikit-learn to build segmentations of customers through clustering, and to predict future customers based on past partnerships success or failure. We also categorize companies using their website communication thanks to scikit-learn and its machine learning algorithm implementations. Eventually, machine learning makes it possible to detect weak signals that traditional tools cannot see. All these complex tasks are performed in an easy and straightforward way thanks to the great quality of the scikit-learn framework.

Guillaume Lebourgeois & Samuel Charron - Data Scientists at Data Publica

1.6.22 Machinalis

Scikit-learn is the cornerstone of all the machine learning projects carried at Machinalis. It has a consistent API, a wide selection of algorithms and lots of auxiliary tools to deal with the boilerplate. We have used it in production environments on a variety of projects including click-through rate prediction, information extraction, and even counting sheep!

In fact, we use it so much that we’ve started to freeze our common use cases into Python packages, some of them open-sourced, like FeatureForge. Scikit-learn in one word: Awesome.

Rafael Carrascosa, Lead developer
1.6.23 **sólido**

Scikit-learn is helping to drive Moore’s Law, via Sólido. Sólido creates computer-aided design tools used by the majority of top-20 semiconductor companies and fabs, to design the bleeding-edge chips inside smartphones, automobiles, and more. Scikit-learn helps to power Sólido’s algorithms for rare-event estimation, worst-case verification, optimization, and more. At Sólido, we are particularly fond of scikit-learn’s libraries for Gaussian Process models, large-scale regularized linear regression, and classification. Scikit-learn has increased our productivity, because for many ML problems we no longer need to “roll our own” code. *This PyData 2014 talk* has details.

Trent McConaghy, founder, Sólido Design Automation Inc.

1.6.24 **INFONEA**

We employ scikit-learn for rapid prototyping and custom-made Data Science solutions within our in-memory based Business Intelligence Software INFONEA®. As a well-documented and comprehensive collection of state-of-the-art algorithms and pipelining methods, scikit-learn enables us to provide flexible and scalable scientific analysis solutions. Thus, scikit-learn is immensely valuable in realizing a powerful integration of Data Science technology within self-service business analytics.

Thorsten Kranz, Data Scientist, Coma Soft AG.

1.6.25 **Dataiku**

Our software, Data Science Studio (DSS), enables users to create data services that combine ETL with Machine Learning. Our Machine Learning module integrates many scikit-learn algorithms. The scikit-learn library is a perfect integration with DSS because it offers algorithms for virtually all business cases. Our goal is to offer a transparent and flexible tool that makes it easier to optimize time consuming aspects of building a data service, preparing data, and training machine learning algorithms on all types of data.

Florian Douetteau, CEO, Dataiku

1.6.26 **Otto Group**

Here at Otto Group, one of global Big Five B2C online retailers, we are using scikit-learn in all aspects of our daily work from data exploration to development of machine learning application to the productive deployment of those services. It helps us to tackle machine learning problems ranging from e-commerce to logistics. It consistent APIs enabled us to build the *Palladium REST-API framework* around it and continuously deliver scikit-learn based services.

Christian Rammig, Head of Data Science, Otto Group
1.6.27 Zopa

At Zopa, the first ever Peer-to-Peer lending platform, we extensively use scikit-learn to run the business and optimize our users’ experience. It powers our Machine Learning models involved in credit risk, fraud risk, marketing, and pricing, and has been used for originating at least 1 billion GBP worth of Zopa loans. It is very well documented, powerful, and simple to use. We are grateful for the capabilities it has provided, and for allowing us to deliver on our mission of making money simple and fair.

Vlasios Vasileiou, Head of Data Science, Zopa

1.6.28 MARS

Scikit-Learn is integral to the Machine Learning Ecosystem at Mars. Whether we’re designing better recipes for petfood or closely analysing our cocoa supply chain, Scikit-Learn is used as a tool for rapidly prototyping ideas and taking them to production. This allows us to better understand and meet the needs of our consumers worldwide. Scikit-Learn’s feature-rich toolset is easy to use and equips our associates with the capabilities they need to solve the business challenges they face every day.

Michael Fitzke Next Generation Technologies Sr Leader, Mars Inc.

1.7 Release History

Release notes for all scikit-learn releases are linked in this page.

Tip: Subscribe to scikit-learn releases on libraries.io to be notified when new versions are released.

1.7.1 Version 0.24.0

In Development

Legend for changelogs

- [MAJOR FEATURE]: something big that you couldn’t do before.
- [FEATURE]: something that you couldn’t do before.
- [EFFICIENCY]: an existing feature now may not require as much computation or memory.
- [ENHANCEMENT]: a miscellaneous minor improvement.
- [FIX]: something that previously didn’t work as documented – or according to reasonable expectations – should now work.
- [API CHANGE]: you will need to change your code to have the same effect in the future; or a feature will be removed in the future.
Put the changes in their relevant module.

**Changed models**

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- [Fix] `decomposition.KernelPCA` behaviour is now more consistent between 32-bits and 64-bits data when the kernel has small positive eigenvalues.

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

**Changelog**

**sklearn.calibration**

- [Enhancement] Allow `calibration.CalibratedClassifierCV` use with `prefit` `pipeline.Pipeline` where data is not `X` is not array-like, sparse matrix or dataframe at the start. #17546 by Lucy Liu.

**sklearn.cluster**

- [Enhancement] `cluster.AgglomerativeClustering` has a new parameter `compute_distances`. When set to `True`, distances between clusters are computed and stored in the `distances_` attribute even when the parameter `distance_threshold` is not used. This new parameter is useful to produce dendrogram visualizations, but introduces a computational and memory overhead. #17984 by Michael Riedmann, Emilie Delattre, and Francesco Casalegno.

- [Enhancement] `cluster.SpectralClustering` and `cluster.spectral_clustering` have a new keyword argument `verbose`. When set to `True`, additional messages will be displayed which can aid with debugging. #18052 by Sean O. Stalley.

- [API Change] `cluster.MiniBatchKMeans` attributes, `counts_` and `init_size_`, are deprecated and will be removed in 0.26. #17864 by Jérémie du Boisberranger.

**sklearn.compose**

- [Fix] `compose.ColumnTransformer` will skip transformers the column selector is a list of bools that are False. #17616 by Thomas Fan.

- [Fix] `compose.ColumnTransformer` now displays the remainder in the diagram display. #18167 by Thomas Fan.
sklearn.covariance

• [API CHANGE] Deprecated cv_alphas_ in favor of cv_results_['alphas'] and grid_scores_ in favor of split scores in cv_results_ in covariance.GraphicalLassoCV. cv_alphas_ and grid_scores_ will be removed in version 0.26. #16392 by Thomas Fan.

sklearn.cross_decomposition

• [Fix] Fixed a bug in cross_decomposition.PLSSVD which would sometimes return components in the reversed order of importance. #17095 by Nicolas Hug.
• [Fix] Fixed a bug in cross_decomposition.PLSSVD, cross_decomposition.CCA, and cross_decomposition.PLSCanonical, which would lead to incorrect predictions for est. transform(Y) when the training data is single-target. #17095 by Nicolas Hug.
• [API CHANGE] The bounds of the n_components parameter is now restricted:
  - into [1, min(n_samples, n_features, n_targets)], for cross_decomposition.PLSSVD, cross_decomposition.CCA, and cross_decomposition.PLSCanonical.
  - into [1, n_features] or cross_decomposition.PLSRegression. An error will be raised in 0.26. #17095 by Nicolas Hug.
• [API CHANGE] For cross_decomposition.PLSSVD, cross_decomposition.CCA, and cross_decomposition.PLSCanonical, the x_scores_ and y_scores_ attributes were deprecated and will be removed in 0.26. They can be retrieved by calling transform on the training data. The norm_y_weights attribute will also be removed. #17095 by Nicolas Hug.

sklearn.datasets

• [Feature] datasets.fetch_openml now validates md5 checksum of arff files downloaded or cached to ensure data integrity. #14800 by Shashank Singh and Joel Nothman.
• [Enhancement] datasets.fetch_openml now allows argument as_frame to be 'auto', which tries to convert returned data to pandas DataFrame unless data is sparse. #17396 by Jiaxiang.
• [Enhancement] datasets.fetch_covtype now now supports the optional argument as_frame; when it is set to True, the returned Bunch object’s data and frame members are pandas DataFrames, and the target member is a pandas Series. #17491 by Alex Liang.
• [Enhancement] datasets.fetch_kddcup99 now now supports the optional argument as_frame; when it is set to True, the returned Bunch object’s data and frame members are pandas DataFrames, and the target member is a pandas Series. #18280 by Alex Liang and Guillaume Lemaitre.
• [API CHANGE] The default value of as_frame in datasets.fetch_openml is changed from False to ‘auto’. #17610 by Jiaxiang.
sklearn.decomposition

- [Enhancement] `decomposition.FactorAnalysis` now supports the optional argument `rotation`, which can take the value `None`, 'varimax' or 'quartimax'. #11064 by Jona Sassenhagen.

- [Enhancement] `decomposition.NMF` now supports the optional parameter `regularization`, which can take the values `None`, 'components', 'transformation' or 'both', in accordance with `decomposition.NMF.non_negative_factorization`. #17414 by Bharat Raghunathan.

- [Fix] `decomposition.KernelPCA` behaviour is now more consistent between 32-bits and 64-bits data input when the kernel has small positive eigenvalues. Small positive eigenvalues were not correctly discarded for 32-bits data. #18149 by Sylvain Marié.

- [Fix] Fix `decomposition.SparseCoder` such that it follows scikit-learn API and support cloning. The attribute `components_` is deprecated in 0.24 and will be removed in 0.26. This attribute was redundant with the dictionary attribute and constructor parameter. #17679 by Xavier Dupré.

- [Fix] `TruncatedSVD.fit_transform` consistently returns the same as `TruncatedSVD.fit` followed by `TruncatedSVD.transform`. #18528 by Albert Villanova del Moral and Ruifeng Zheng.

sklearn.discriminant_analysis

- [Enhancement] `discriminant_analysis.LinearDiscriminantAnalysis` can now use custom covariance estimate by setting the `covariance_estimator` parameter. #14446 by Hugo Richard.

sklearn.ensemble

- [Feature] `ensemble.HistGradientBoostingRegressor` and `ensemble.HistGradientBoostingClassifier` now support the method `staged_predict`, which allows monitoring of each stage. #16985 by Hao Chun Chang.

- [Efficiency] break cyclic references in the tree nodes used internally in `ensemble.HistGradientBoostingRegressor` and `ensemble.HistGradientBoostingClassifier` to allow for the timely garbage collection of large intermediate datastructures and to improve memory usage in `fit`. #18334 by Olivier Grisel, Nicolas Hug, Thomas Fan and Andreas Müller.

- [Efficiency] Histogram initialization is now done in parallel in `ensemble.HistGradientBoostingRegressor` and `ensemble.HistGradientBoostingClassifier` which results in speed improvement for problems that build a lot of nodes on multicore machines. #18341 by Olivier Grisel, Nicolas Hug, Thomas Fan, and Egor Smirnov.

- [API Change] The parameter `n_classes` is now deprecated in `ensemble.GradientBoostingRegressor` and returns 1. #17702 by Simona Maggio.

- [API Change] Mean absolute error ('mae') is now deprecated for the parameter `criterion` in `ensemble.GradientBoostingRegressor` and `ensemble.GradientBoostingClassifier`. #18326 by Madhura Jayaratne.
sklearn.exceptions

- [API CHANGE] `exceptions.ChangedBehaviorWarning` and `exceptions.NonBLASDotWarning` are deprecated and will be removed in v0.26, #17804 by Adrin Jalali.

sklearn.feature_extraction

- [ENHANCEMENT] `feature_extraction.DictVectorizer` accepts multiple values for one categorical feature. #17367 by Peng Yu and Chiara Marmo.

sklearn.feature_selection

- [FEATURE] Added `feature_selection.SequentialFeatureSelector` which implements forward and backward sequential feature selection. #6545 by Sebastian Raschka and #17159 by Nicolas Hug.
- [FEATURE] A new parameter `importance_getter` was added to `feature_selection.RFE`, `feature_selection.RFECV` and `feature_selection.SelectFromModel`, allowing the user to specify an attribute name/path or a callable for extracting feature importance from the estimator. #15361 by Venkatachalam N.
- [ENHANCEMENT] `feature_selection.RFE` supports the option for the number of `n_features_to_select` to be given as a float representing the percentage of features to select. #17090 by Lisa Schwetlick and Marija Vlajic Wheeler.

sklearn.gaussian_process

- [ENHANCEMENT] A new method `gaussian_process.Kernel._check_bounds_params` is called after fitting a Gaussian Process and raises a `ConvergenceWarning` if the bounds of the hyperparameters are too tight. #12638 by Sylvain Lannuzel.

sklearn.impute

- [FEATURE] `impute.SimpleImputer` now supports a list of strings when `strategy='most_frequent'` or `strategy='constant'`. #17526 by Ayako YAGI and Juan Carlos Alfaro Jiménez.
- [FEATURE] Added method `impute.SimpleImputer.inverse_transform` to revert imputed data to original when instantiated with `add_indicator=True`. #17612 by Srimukh Sripada.
- [Fix] replace the default values in `impute.IterativeImputer` of `min_value` and `max_value` parameters to `-np.inf` and `np.inf`, respectively instead of `None`. However, the behaviour of the class does not change since `None` was defaulting to these values already. #16493 by Darshan N.
- [Fix] `impute.IterativeImputer` will not attempt to set the estimator’s `random_state` attribute, allowing to use it with more external classes. #15636 by David Cortes.
sklearn.inspection

- [FEATURE] `inspection.partial_dependence` and `inspection.plot_partial_dependence` now support calculating and plotting Individual Conditional Expectation (ICE) curves controlled by the `kind` parameter. #16619 by Madhura Jayratne.

- [FEATURE] Add `sample_weight` parameter to `inspection.permutation_importance`. #16906 by Roei Kahny.

sklearn.isotonic

- [FEATURE] Expose fitted attributes `X_thresholds_` and `y_thresholds_` that hold the de-duplicated interpolation thresholds of an `isotonic.IsotonicRegression` instance for model inspection purpose. #16289 by Masashi Kishimoto and Olivier Grisel.

- [ENHANCEMENT] `isotonic.IsotonicRegression` now accepts 2d array with 1 feature as input array. #17379 by Jiaxiang.

sklearn.kernel_approximation

- [FEATURE] Added class `kernel_approximation.PolynomialCountSketch` which implements the Tensor Sketch algorithm for polynomial kernel feature map approximation. #13003 by Daniel López Sánchez.

sklearn.linear_model

- [FEATURE] `linear_model.LinearRegression` now forces coefficients to be all positive when `positive` is set to True. #17578 by Joseph Knox, Nelle Varoquaux and Chiara Marmo.

- [ENHANCEMENT] `linear_model.RidgeCV` now supports finding an optimal regularization value `alpha` for each target separately by setting `alpha_per_target=True`. This is only supported when using the default efficient leave-one-out cross-validation scheme `cv=None`. #6624 by Marijn van Vliet.

- [FIX] Fixes bug in `linear_model.TheilSenRegressor` where `predict` and `score` would fail when `fit_intercept=False` and there was one feature during fitting. #18121 by Thomas Fan.

sklearn.manifold

- [EFFICIENCY] Fixed #10493. Improve Local Linear Embedding (LLE) that raised `MemoryError` exception when used with large inputs. #17997 by Bertrand Maisonneuve.

- [ENHANCEMENT] Add `square_distances` parameter to `manifold.TSNE`, which provides backward compatibility during deprecation of legacy squaring behavior. Distances will be squared by default in 0.26, and this parameter will be removed in 0.28. #17662 by Joshua Newton.

- [FIX] `manifold.MDS` now correctly sets its `_pairwise` attribute. #18278 by Thomas Fan.
sklearn.metrics

- [FEATURE] Added `metrics.det_curve` to compute Detection Error Tradeoff curve classification metric. #10591 by Jeremy Karnowski and Daniel Mohns.

- [FEATURE] Added `metrics.plot_det_curve` and `metrics.DetCurveDisplay` to ease the plot of DET curves. #18176 by Guillaume Lemaitre.

- [FEATURE] Added `metrics.mean_absolute_percentage_error` metric and the associated scorer for regression problems. #10708 fixed with the PR #15007 by Ashutosh Hathidara. The scorer and some practical test cases were taken from PR #10711 by Mohamed Ali Jamaou.

- [FEATURE] `metrics.plot_confusion_matrix` now supports making colorbar optional in the matplotlib plot by setting `colorbar=False`. #17192 by Avi Gupta

- [ENHANCEMENT] Add `sample_weight` parameter to `metrics.median_absolute_error`. #17225 by Lucy Liu.

- [ENHANCEMENT] Add `pos_label` parameter in `metrics.plot_precision_recall_curve` in order to specify the positive class to be used when computing the precision and recall statistics. #17569 by Guillaume Lemaitre.

- [ENHANCEMENT] Add `pos_label` parameter in `metrics.plot_roc_curve` in order to specify the positive class to be used when computing the roc auc statistics. #17651 by Clara Matos.

- [Fix] Fixed a bug in `metrics.classification_report` which was raising AttributeError when called with `output_dict=True` for 0-length values. #17777 by Shubhanshu Mishra.

- [Fix] Fixed a bug in `metrics.jaccard_score` which recommended the `zero_division` parameter when called with no true or predicted samples. #17826 by Richard Decal and Joseph Willard

- [Fix] bug in `metrics.hinge_loss` where error occurs when `y_true` is missing some labels that are provided explicitly in the `labels` parameter. #17935 by Cary Goltermann.

- [Fix] Fix scorers that accept a `pos_label` parameter and compute their metrics from values returned by `decision_function` or `predict_proba`. Previously, they would return erroneous values when `pos_label` was not corresponding to `classifier.classes_[1]`. This is especially important when training classifiers directly with string labeled target classes. ##18114 by Guillaume Lemaitre.

sklearn.model_selection

- [FEATURE] `model_selection.RandomizedSearchCV` and `model_selection.GridSearchCV` now have the method `score_samples` #17478 by Teon Brooks and Mohamed Maskani.

- [Enhancement] `model_selection.TimeSeriesSplit` has two new keyword arguments `test_size` and `gap`. `test_size` allows the out-of-sample time series length to be fixed for all folds. `gap` removes a fixed number of samples between the train and test set on each fold. #13204 by Kyle Kosic.

- [Enhancement] `model_selection.cross_val_score`, `model_selection.cross_validate`, `model_selection.GridSearchCV`, and `model_selection.RandomizedSearchCV` allows estimator to fail scoring and replace the score with `error_score`. If `error_score="raise"`, the error will be raised. #18343 by Guillaume Lemaitre and Devi Sandeep.
• [Fix] Fixed the `len` of `model_selection.ParameterSampler` when all distributions are lists and `n_iter` is more than the number of unique parameter combinations. #18222 by Nicolas Hug.

• [Fix] A fix to raise warning when one or more CV splits of `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` results in non-finite scores. #18266 by Subrat Sahu, Nirvan and Arthur Book.

sklearn.multiclass

• [Fix] A fix to allow `multiclass.OutputCodeClassifier` to accept sparse input data in its `fit` and `predict` methods. The check for validity of the input is now delegated to the base estimator. #17233 by Zolisa Bleki.

• [Enhancement] `multiclass.OneVsOneClassifier` now accepts the inputs with missing values. Hence, estimators which can handle missing values (may be a pipeline with imputation step) can be used as a estimator for multiclass wrappers. #17987 by Venkatachalam N.

sklearn.multioutput

• [Enhancement] `multioutput.MultiOutputClassifier` and `multioutput.MultiOutputRegressor` now accepts the inputs with missing values. Hence, estimators which can handle missing values (may be a pipeline with imputation step, HistGradientBoosting estimators) can be used as a estimator for multiclass wrappers. #17987 by Venkatachalam N.

• [Fix] A fix to accept tuples for the `order` parameter in `multioutput.ClassifierChain`. #18124 by Gus Brocchini and Amanda Dsouza.

sklearn.naive_bayes

• [Enhancement] Adds a parameter `min_categories` to `naive_bayes.CategoricalNB` that allows a minimum number of categories per feature to be specified. This allows categories unseen during training to be accounted for. #16326 by George Armstrong.

• [API Change] The attributes `coef_` and `intercept_` are now deprecated in `naive_bayes.MultinomialNB`, `naive_bayes.ComplementNB`, `naive_bayes.BernoulliNB` and `naive_bayes.CategoricalNB`, and will be removed in v0.26. #17427 by Juan Carlos Alfaro Jiménez.

sklearn.neighbors

• [Efficiency] Speed up `seuclidean`, `wminkowski`, `mahalanobis` and `haversine` metrics in `neighbors.DistanceMetric` by avoiding unexpected GIL acquiring in Cython when setting `n_jobs>1` in `neighbors.KNeighborsClassifier`, `neighbors.KNeighborsRegressor`, `neighbors.RadiusNeighborsClassifier`, `neighbors.RadiusNeighborsRegressor`, `metrics.pairwise_distances` and by validating data out of loops. #17038 by Wenbo Zhao.

• [Efficiency] `neighbors.NeighborsBase` benefits of an improved algorithm = 'auto' heuristic. In addition to the previous set of rules, now, when the number of features exceeds 15, `brute` is selected, assuming the data intrinsic dimensionality is too high for tree-based methods. #17148 by Geoffrey Bolmier.

• [Fix] `neighbors.NearestCentroid` with a numerical `shrink_threshold` will raise a `ValueError` when fitting on data with all constant features. #18370 by Trevor Waite.
sklearn.neural_network

- [Efficiency] Neural net training and prediction are now a little faster. #17603, #17604, #17606, #17608, #17609, #17633, #17661, #17932 by Alex Henrie.

- [Fix] Fix method fit of neural_network.MLPClassifier not iterating to max_iter if warm started. #18269 by Norbert Preining and Guillaume Lemaitre.

sklearn.pipeline

- [Enhancement] References to transformers passed through transformer_weights to pipeline. FeatureUnion that aren’t present in transformer_list will raise a ValueError. #17876 by Cary Goltermann.

- [Fix] A slice of a pipeline.Pipeline now inherits the parameters of the original pipeline (memory and verbose). #18429 by Albert Villanova del Moral and Paweł Biernat.

sklearn.preprocessing

- [Feature] preprocessing.OneHotEncoder now supports missing values by treating them as a category. #17317 by Thomas Fan.

- [Feature] Add a new handle_unknown parameter with a use_encoded_value option, along with a new unknown_value parameter, to preprocessing.OrdinalEncoder to allow unknown categories during transform and set the encoded value of the unknown categories. #17406 by Felix Wick and #18406 by Nicolas Hug.

- [Feature] Add clip parameter to preprocessing.MinMaxScaler, which clips the transformed values of test data to feature_range. #17833 by Yashika Sharma.

- [Feature] Add sample_weight parameter to preprocessing.StandardScaler for when X is dense. Allows setting individual weights for each sample. #18510 and #18447 and #16066 by Maria Telenczuk and Albert Villanova and @panpiort8.

- [Enhancement] Verbose output of model_selection.GridSearchCV has been improved for readability. #16935 by Raghav Rajagopalan and Chiara Marmo.

- [Enhancement] Add unit_variance to preprocessing.RobustScaler, which scales output data such that normally distributed features have a variance of 1. #17193 by Lucy Liu and Mabel Villalba.

- [Enhancement] Add dtype parameter to preprocessing.KBinsDiscretizer. #16335 by Arthur Imbert.
sklearn.svm

sklearn.tree

• [ENHANCEMENT] \texttt{tree.plot_tree} now uses colors from the \texttt{matplotlib} configuration settings. \#17187 by Andreas Müller.

• [API CHANGE] The parameter \texttt{X_idx_sorted} is now deprecated in \texttt{tree.DecisionTreeClassifier.
fit} and \texttt{tree.DecisionTreeRegressor.fit}, and has not effect. \#17614 by Juan Carlos Alfaro Jiménez.

sklearn.utils

• [ENHANCEMENT] Add \texttt{check_methods_sample_order_invariance} to \texttt{check_estimator}, which checks that estimator methods are invariant if applied to the same dataset with different sample order \#17598 by Jason Ngo.

• [Fix] Raise ValueError with clear error message in \texttt{check_array} for sparse DataFrames with mixed types. \#17992 by Thomas J. Fan and Alex Shacked.

• [Fix] Allow serialized tree based models to be unpickled on a machine with different endianness. \#17644 by Qi Zhang.

Miscellaneous

• [ENHANCEMENT] Calls to \texttt{repr} are now faster when \texttt{print_changed_only=True}, especially with meta-
estimators. \#18508 by Nathan C..

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.23, including:

1.7.2 Version 0.23.2

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

• [Fix] \texttt{inertia} attribute of \texttt{cluster.KMeans} and \texttt{cluster.MiniBatchKMeans}.

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)
Changelog

sklearn.cluster

- [Fix] Fixed a bug in `cluster.KMeans` where rounding errors could prevent convergence to be declared when `tol=0`. #17959 by Jérémie du Boisberranger.
- [Fix] Fixed a bug in `cluster.KMeans` and `cluster.MiniBatchKMeans` where the reported inertia was incorrectly weighted by the sample weights. #17848 by Jérémie du Boisberranger.
- [Fix] Fixed a bug in `cluster.MeanShift` with `bin_seeding=True`. When the estimated bandwidth is 0, the behavior is equivalent to `bin_seeding=False`. #17742 by Jeremie du Boisberranger.
- [Fix] Fixed a bug in `cluster.AffinityPropagation`, that gives incorrect clusters when the array dtype is float32. #17995 by Thomaz Santana and Amanda Dsouza.

sklearn.decomposition

- [Fix] Fixed a bug in `decomposition.MiniBatchDictionaryLearning.partial_fit` which should update the dictionary by iterating only once over a mini-batch. #17433 by Chiara Marmo.
- [Fix] Avoid overflows on Windows in `decomposition.IncrementalPCA.partial_fit` for large batch_size and n_samples values. #17985 by Alan Butler and Amanda Dsouza.

sklearn.ensemble

- [Fix] Fixed bug in `ensemble.MultinomialDeviance` where the average of logloss was incorrectly calculated as sum of logloss. #17694 by Markus Rempfler and Tsutomu Kusanagi.

sklearn.feature_extraction

- [Fix] Fixes bug in `feature_extraction.text.CountVectorizer` where sample order invariance was broken when `max_features` was set and features had the same count. #18016 by Thomas Fan, Roman Yurchak, and Joel Nothman.

sklearn.linear_model

- [Fix] `linear_model.lars_path` does not overwrite X when `X_copy=True` and `Gram='auto'`. #17914 by Thomas Fan.
sklearn.manifold

- [Fix] Fixed a bug where `metrics.pairwise_distances` would raise an error if `metric='seuclidean'` and `X` is not type `np.float64`. #15730 by Forrest Koch.

sklearn.metrics

- [Fix] Fixed a bug in `metrics.mean_squared_error` where the average of multiple RMSE values was incorrectly calculated as the root of the average of multiple MSE values. #17309 by Swier Heeres.

sklearn.pipeline

- [Fix] `pipeline.FeatureUnion` raises a deprecation warning when `None` is included in `transformer_list`. #17360 by Thomas Fan.

sklearn.utils

- [Fix] Fix `utils.estimator_checks.check_estimator` so that all test cases support the `binary_only` estimator tag. #17812 by Bruno Charron.

1.7.3 Version 0.23.1

May 18 2020

Changelog

sklearn.cluster

- [Efficiency] `cluster.KMeans` efficiency has been improved for very small datasets. In particular it cannot spawn idle threads any more. #17210 and #17235 by Jeremie du Boisberranger.
- [Fix] Fixed a bug in `cluster.KMeans` where the sample weights provided by the user were modified in place. #17204 by Jeremie du Boisberranger.

Miscellaneous

- [Fix] Fixed a bug in the `repr` of third-party estimators that use a `**kwargs` parameter in their constructor, when `changed_only` is `True` which is now the default. #17205 by Nicolas Hug.
Enforcing keyword-only arguments

In an effort to promote clear and non-ambiguous use of the library, most constructor and function parameters are now expected to be passed as keyword arguments (i.e. using the param=value syntax) instead of positional. To ease the transition, a FutureWarning is raised if a keyword-only parameter is used as positional. In version 0.25, these parameters will be strictly keyword-only, and a TypeError will be raised. #15005 by Joel Nothman, Adrin Jalali, Thomas Fan, and Nicolas Hug. See SLEP009 for more details.

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- [Fix] cluster.KMeans with algorithm="elkan" and algorithm="full".
- [Fix] cluster.Birch
- [Fix] compose.ColumnTransformer.get_feature_names
- [Fix] compose.ColumnTransformer.fit
- [Fix] datasets.make_multilabel_classification
- [Fix] decomposition.PCA with n_components='mle'
- [Enhancement] decomposition.NMF and decomposition.non_negative_factorization with float32 dtype input.
- [Fix] decomposition.KernelPCA.inverse_transform
- [API Change] ensemble.HistGradientBoostingClassifier and ensemble.HistGradientBoostingRegressor
• [Fix] estimator_samples_ in ensemble.BaggingClassifier, ensemble.BaggingRegressor and ensemble.IsolationForest
• [Fix] ensemble.StackingClassifier and ensemble.StackingRegressor with sample_weight
• [Fix] gaussian_process.GaussianProcessRegressor
• [Fix] linear_model.RANSACRegressor with sample_weight.
• [Fix] linear_model.RidgeClassifierCV
• [Fix] metrics.mean_squared_error with squared and multioutput='raw_values'.
• [Fix] metrics.mutual_info_score with negative scores.
• [Fix] metrics.confusion_matrix with zero length y_true and y_pred
• [Fix] neural_network.MLPClassifier
• [Fix] preprocessing.Normalizer with norm='max'

Details are listed in the changelog below.
(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

Changelog

sklearn.cluster

• [Efficiency] cluster.Birch implementation of the predict method avoids high memory footprint by calculating the distances matrix using a chunked scheme. #16149 by Jeremie du Boisberranger and Alex Shacked.
• [Efficiency] [Major Feature] The critical parts of cluster.KMeans have a more optimized implementation. Parallelism is now over the data instead of over initializations allowing better scalability. #11950 by Jeremie du Boisberranger.
• [Enhancement] cluster.KMeans now supports sparse data when solver = "elkan". #11950 by Jeremie du Boisberranger.
• [Enhancement] cluster.AgglomerativeClustering has a faster and more memory efficient implementation of single linkage clustering. #11514 by Leland McInnes.
• [Fix] cluster.KMeans with algorithm="elkan" now converges with tol=0 as with the default algorithm="full". #16075 by Erich Schubert.
• [Fix] Fixed a bug in cluster.Birch where the n_clusters parameter could not have a np.int64 type. #16484 by Jeremie du Boisberranger.
• [Fix] cluster.AgglomerativeClustering add specific error when distance matrix is not square and affinity=precomputed. #16257 by Simona Maggio.
• [API CHANGE] The \texttt{n\_jobs} parameter of \texttt{cluster.KMeans}, \texttt{cluster.SpectralCoclustering} and \texttt{cluster.SpectralBiclustering} is deprecated. They now use OpenMP based parallelism. For more details on how to control the number of threads, please refer to our \textit{Parallelism} notes. \#11950 by Jeremie du Boisberranger.

• [API CHANGE] The \texttt{precompute\_distances} parameter of \texttt{cluster.KMeans} is deprecated. It has no effect. \#11950 by Jeremie du Boisberranger.

• [API CHANGE] The \texttt{random\_state} parameter has been added to \texttt{cluster.AffinityPropagation}. \#16801 by @rcwoolston and Chiara Marmo.

\texttt{sklearn.compose}

• [EFFICIENCY] \texttt{compose.ColumnTransformer} is now faster when working with dataframes and strings are used to specific subsets of data for transformers. \#16431 by Thomas Fan.

• [ENHANCEMENT] \texttt{compose.ColumnTransformer} method \texttt{get\_feature\_names} now supports \textquote{passthrough} columns, with the feature name being either the column name for a dataframe, or \textquote{xi} for column index \texttt{i}. \#14048 by Lewis Ball.

• [Fix] \texttt{compose.ColumnTransformer} method \texttt{get\_feature\_names} now returns correct results when one of the transformer steps applies on an empty list of columns \#15963 by Roman Yurchak.

• [Fix] \texttt{compose.ColumnTransformer.fit} will error when selecting a column name that is not unique in the dataframe. \#16431 by Thomas Fan.

\texttt{sklearn.datasets}

• [EFFICIENCY] \texttt{datasets.fetch\_openml} has reduced memory usage because it no longer stores the full dataset text stream in memory. \#16084 by Joel Nothman.

• [Feature] \texttt{datasets.fetch\_california\_housing} now supports heterogeneous data using pandas by setting \texttt{as\_frame=True}. \#15950 by Stephanie Andrews and Reshama Shaikh.

• [Feature] embedded dataset loaders \texttt{load\_breast\_cancer}, \texttt{load\_diabetes}, \texttt{load\_digits}, \texttt{load\_iris}, \texttt{load\_linnerud} and \texttt{load\_wine} now support loading as a pandas DataFrame by setting \texttt{as\_frame=True}. \#15980 by @wconnell and Reshama Shaikh.

• [Enhancement] Added \texttt{return\_centers} parameter in \texttt{datasets.make\_blobs}, which can be used to return centers for each cluster. \#15709 by @shivamgargsy and Venkatachalam N.

• [Enhancement] Functions \texttt{datasets.make\_circles} and \texttt{datasets.make\_moons} now accept two-element tuple. \#15707 by Maciej J Mikulski.

• [Fix] \texttt{datasets.make\_multilabel\_classification} now generates \texttt{ValueError} for arguments \texttt{n\_classes < 1 OR length < 1}. \#16006 by Rushabh Vasani.

• [API Change] The \texttt{StreamHandler} was removed from \texttt{sklearn.logger} to avoid double logging of messages in common cases where a handler is attached to the root logger, and to follow the Python logging documentation recommendation for libraries to leave the log message handling to users and application code. \#16451 by Christoph Deil.
**sklearn.decomposition**

- **[Enhancement]** `decomposition.NMF` and `decomposition.non_negative_factorization` now preserves float32 dtype. #16280 by Jeremie du Boisberranger.

- **[Enhancement]** `TruncatedSVD.transform` is now faster on given sparse `csc` matrices. #16837 by @wornbb.

- **[Fix]** `decomposition.PCA` with a float `n_components` parameter, will exclusively choose the components that explain the variance greater than `n_components`. #15669 by Krishna Chaitanya

- **[Fix]** `decomposition.PCA` with `n_components='mle'` now correctly handles small eigenvalues, and does not infer 0 as the correct number of components. #16224 by Lisa Schwetlick, and Gelavizh Ahmadi and Marija Vlajic Wheeler and #16841 by Nicolas Hug.

- **[Fix]** `decomposition.KernelPCA` method `inverse_transform` now applies the correct inverse transform to the transformed data. #16655 by Lewis Ball.

- **[Fix]** Fixed bug that was causing `decomposition.KernelPCA` to sometimes raise invalid value encountered in multiply during fit. #16718 by Gui Miotto.

- **[Feature]** Added `n_components_` attribute to `decomposition.SparsePCA` and `decomposition.MiniBatchSparsePCA`. #16981 by Mateusz Górski.

**sklearn.ensemble**

- **[Feature]** Early stopping in `ensemble.HistGradientBoostingClassifier` and `ensemble.HistGradientBoostingRegressor` is now determined with a new `early_stopping` parameter instead of `n_iter_no_change`. Default value is ‘auto’, which enables early stopping if there are at least 10,000 samples in the training set. #14516 by Johann Faouzi.

- **[Major Feature]** `ensemble.HistGradientBoostingClassifier` and `ensemble.HistGradientBoostingRegressor` now support monotonic constraints, useful when features are supposed to have a positive/negative effect on the target. #15582 by Nicolas Hug.

- **[API Change]** Fixed a bug in `ensemble.HistGradientBoostingClassifier` and `ensemble.HistGradientBoostingRegressor` that would not respect the `max_leaf_nodes` parameter if the criteria was reached at the same time as the `max_depth` criteria. #16183 by Nicolas Hug.

- **[Fix]** Changed the convention for `max_depth` parameter of `ensemble.HistGradientBoostingClassifier` and `ensemble.HistGradientBoostingRegressor`. The depth now corresponds to the number of edges to go from the root to the deepest leaf. Stumps (trees with one split) are now allowed. #16182 by Santhosh B

- **[Fix]** Fixed a bug in `ensemble.BaggingClassifier`, `ensemble.BaggingRegressor` and `ensemble.IsolationForest` where the attribute `estimators_samples_` did not generate the proper indices used during fit. #16437 by Jin-Hwan CHO.

- **[Fix]** Fixed a bug in `ensemble.StackingClassifier` and `ensemble.StackingRegressor` where the `sample_weight` argument was not being passed to `cross_val_predict` when evaluating the base estimators on cross-validation folds to obtain the input to the meta estimator. #16539 by Bill DeRose.
• **[FEATURE]** Added additional option `loss="poisson"` to `ensemble.HistGradientBoostingRegressor`, which adds Poisson deviance with log-link useful for modeling count data. #16692 by Christian Lorentzen

• **[FIX]** Fixed a bug where `ensemble.HistGradientBoostingRegressor` and `ensemble.HistGradientBoostingClassifier` would fail with multiple calls to fit when `warm_start=True`, `early_stopping=True`, and there is no validation set. #16663 by Thomas Fan.

**sklearn.feature_extraction**

• **[EFFICIENCY]** `sklearn.feature_extraction.text.CountVectorizer` now sorts features after pruning them by document frequency. This improves performances for datasets with large vocabularies combined with `min_df` or `max_df`. #15834 by Santiago M. Mola.

**sklearn.feature_selection**

• **[ENHANCEMENT]** Added support for multioutput data in `feature_selection.RFE` and `feature_selection.RFECV`. #16103 by Divyapraba M.

• **[API CHANGE]** Adds `feature_selection.SelectorMixin` back to public API. #16132 by @trimeta.

**sklearn.gaussian_process**

• **[ENHANCEMENT]** `gaussian_process.kernels.Matern` returns the RBF kernel when `nu=np.inf`. #15503 by Sam Dixon.

• **[FIX]** Fixed bug in `gaussian_process.GaussianProcessRegressor` that caused predicted standard deviations to only be between 0 and 1 when WhiteKernel is not used. #15782 by @plgreenLIRU.

**sklearn.impute**

• **[ENHANCEMENT]** `impute.IterativeImputer` accepts both scalar and array-like inputs for `max_value` and `min_value`. Array-like inputs allow a different max and min to be specified for each feature. #16403 by Narendra Mukherjee.

• **[ENHANCEMENT]** `impute.SimpleImputer`, `impute.KNNImputer`, and `impute.IterativeImputer` accepts pandas’ nullable integer dtype with missing values. #16508 by Thomas Fan.

**sklearn.inspection**

• **[FEATURE]** `inspection.partial_dependence` and `inspection.plot_partial_dependence` now support the fast ‘recursion’ method for `ensemble.RandomForestRegressor` and `tree.DecisionTreeRegressor`. #15864 by Nicolas Hug.
**sklearn.linear_model**

- **[Major Feature]** Added generalized linear models (GLM) with non normal error distributions, including `linear_model.PoissonRegressor`, `linear_model.GammaRegressor` and `linear_model.TweedieRegressor` which use Poisson, Gamma and Tweedie distributions respectively. #14300 by Christian Lorentzen, Roman Yurchak, and Olivier Grisel.

- **[Efficiency]** `linear_model.RidgeCV` and `linear_model.RidgeClassifierCV` now does not allocate a potentially large array to store dual coefficients for all hyperparameters during its fit, nor an array to store all error or LOO predictions unless `store_cv_values` is True. #15652 by Jérôme Dockès.

- **[Enhancement]** `linear_model.LassoLars` and `linear_model.Lars` now support a jitter parameter that adds random noise to the target. This might help with stability in some edge cases. #15179 by @angelaambroz.

- **[Fix]** Fixed a bug where if a `sample_weight` parameter was passed to the fit method of `linear_model.RANSACRegressor`, it would not be passed to the wrapped `base_estimator` during the fitting of the final model. #15773 by Jeremy Alexandre.

- **[Fix]** Add `best_score_` attribute to `linear_model.RidgeCV` and `linear_model.RidgeClassifierCV`. #15655 by Jérôme Dockès.

- **[Fix]** Fixed a bug in `linear_model.RidgeClassifierCV` to pass a specific scoring strategy. Before the internal estimator outputs score instead of predictions. #14848 by Venkatachalam N.

- **[Fix]** `linear_model.LogisticRegression` will now avoid an unnecessary iteration when `solver='newton-cg'` by checking for inferior or equal instead of strictly inferior for maximum of `absgrad` and `tol` in `utils.optimize._newton_cg`. #16266 by Rushabh Vasani.

- **[Fix]** [Efficiency] `linear_model.ARDRegression` is more stable and much faster when `n_samples > n_features`. It can now scale to hundreds of thousands of samples. The stability fix might imply changes in the number of non-zero coefficients and in the predicted output. #16849 by Nicolas Hug.

sklearn.metrics

- [Enhancement] metrics.pairwise.pairwise_distances_chunked now allows its `reduce_func` to not have a return value, enabling in-place operations. #16397 by Joel Nothman.

- [Fix] Fixed a bug in metrics.mean_squared_error to not ignore argument `squared` when argument `multioutput='raw_values'`. #16323 by Rushabh Vasani

- [Fix] Fixed a bug in metrics.mutual_info_score where negative scores could be returned. #16362 by Thomas Fan.

- [Fix] Fixed a bug in metrics.confusion_matrix that would raise an error when `y_true` and `y_pred` were length zero and `labels` was not None. In addition, we raise an error when an empty list is given to the `labels` parameter. #16442 by Kyle Parsons.

- [API Change] Changed the formatting of values in metrics.ConfusionMatrixDisplay.plot and metrics.plot_confusion_matrix to pick the shorter format (either '2g' or 'd'). #16159 by Rick Mackenbach and Thomas Fan.

- [API Change] From version 0.25, metrics.pairwise.pairwise_distances will no longer automatically compute the `V` parameter for Mahalanobis distance and the `V` parameter for seuclidean distance if `Y` is passed. The user will be expected to compute this parameter on the training data of their choice and pass it to pairwise_distances. #16993 by Joel Nothman.

sklearn.model_selection

- [Enhancement] model_selection.GridSearchCV and model_selection.RandomizedSearchCV yields stack trace information in fit failed warning messages in addition to previously emitted type and details. #15622 by Gregory Morse.

- [Fix] model_selection.cross_val_predict supports method="predict_proba" when y=None. #15918 by Luca Kubin.

- [Fix] model_selection.fit_grid_point is deprecated in 0.23 and will be removed in 0.25. #16401 by Arie Pratama Sutiono

sklearn.multioutput

- [Feature] multioutput.MultiOutputRegressor.fit and multioutput.MultiOutputClassifier.fit now can accept fit_params to pass to the estimator.fit method of each step. #15953 #15959 by Ke Huang.

- [Enhancement] multioutput.RegressorChain now supports fit_params for base_estimator during fit. #16111 by Venkatachalam N.

sklearn.naive_bayes

- [Fix] A correctly formatted error message is shown in naive_bayes.CategoricalNB when the number of features in the input differs between predict and fit. #16090 by Madhura Jayaratne.
sklearn.neural_network

- [EFFICIENCY] neural_network.MLPClassifier and neural_network.MLPRegressor has reduced memory footprint when using stochastic solvers, 'sgd' or 'adam', and shuffle=True. #14075 by @meyer89.
- [Fix] Increases the numerical stability of the logistic loss function in neural_network.MLPClassifier by clipping the probabilities. #16117 by Thomas Fan.

sklearn.inspection

- [Enhancement] inspection.PartialDependenceDisplay now exposes the deciles lines as attributes so they can be hidden or customized. #15785 by Nicolas Hug

sklearn.preprocessing

- [Feature] argument drop of preprocessing.OneHotEncoder will now accept value 'if_binary' and will drop the first category of each feature with two categories. #16245 by Rushabh Vasani.
- [Enhancement] preprocessing.OneHotEncoder's drop_idx_ ndarray can now contain None, where drop_idx_[i] = None means that no category is dropped for index i. #16585 by Chiara Marmo.
- [Enhancement] preprocessing.OneHotEncoder is now faster at transforming. #15762 by Thomas Fan.
- [Fix] Fix a bug in preprocessing.StandardScaler which was incorrectly computing statistics when calling partial_fit on sparse inputs. #16466 by Guillaume Lemaître.
- [Fix] Fix a bug in preprocessing.Normalizer with norm='max', which was not taking the absolute value of the maximum values before normalizing the vectors. #16632 by Maura Pintor and Battista Biggio.

sklearn.semi_supervised

- [Fix] semi_supervised.LabelSpreading and semi_supervised.LabelPropagation avoids divide by zero warnings when normalizing label_distributions_. #15946 by @ngshya.

sklearn.svm

- [Fix] [Efficiency] Improved libsvm and liblinear random number generators used to randomly select coordinates in the coordinate descent algorithms. Platform-dependent C rand() was used, which is only able to generate numbers up to 32767 on windows platform (see this blog post) and also has poor randomization power as suggested by this presentation. It was replaced with C++11 mt19937, a Mersenne Twister that correctly generates 31bits/63bits random numbers on all platforms. In addition, the crude “modulo” postprocessor used to get a random number in a bounded interval was replaced by the tweaked Lemire method as suggested by this blog post. Any model using the svm.libsvm or the svm.liblinear solver, including svm.LinearSVC, svm.LinearSVR, svm.NuSVC, svm.NuSVR, svm.OneClassSVM, svm.SVC, svm.SVR, linear_model.LogisticRegression, is affected. In particular users can expect a better convergence when the number of samples (LibSVM) or the number of features (LibLinear) is large. #13511 by Sylvain Marié.
• [Fix] Fix use of custom kernel not taking float entries such as string kernels in `svm.SVC` and `svm.SVR`. Note that custom kernels are now expected to validate their input where they previously received valid numeric arrays. #11296 by Alexandre Gramfort and Georgi Peev.

• [API CHANGE] `svm.SVR` and `svm.OneClassSVM` attributes, `probA_` and `probB_`, are now deprecated as they were not useful. #15558 by Thomas Fan.

**sklearn.tree**

• [Fix] `tree.plot_tree` `rotate` parameter was unused and has been deprecated. #15806 by Chiara Marmo.

**sklearn.utils**

• [MAJOR FEATURE] Estimators can now be displayed with a rich html representation. This can be enabled in Jupyter notebooks by setting `display='diagram'` in `set_config`. The raw html can be returned by using `utils.estimator_html_repr`. #14180 by Thomas Fan.

• [Enhancement] improve error message in `utils.validation.column_or_1d`. #15926 by Loïc Estève.

• [Enhancement] add warning in `utils.check_array` for pandas sparse DataFrame. #16021 by Rushabh Vasani.

• [Enhancement] `utils.check_array` now constructs a sparse matrix from a pandas DataFrame that contains only `SparseArray` columns. #16728 by Thomas Fan.

• [Enhancement] `utils.validation.check_array` supports pandas’ nullable integer dtype with missing values when `force_all_finite` is set to `False` or `allow-nan` in which case the data is converted to floating point values where `pd.NA` values are replaced by `np.nan`. As a consequence, all `sklearn.preprocessing` transformers that accept numeric inputs with missing values represented as `np.nan` now also accepts being directly fed pandas dataframes with `pd.Int*` or `pd.UInt*` typed columns that use `pd.NA` as a missing value marker. #16508 by Thomas Fan.

• [API CHANGE] Passing classes to `utils.estimator_checks.check_estimator` and `utils.estimator_checks.parametrize_with_checks` is now deprecated, and support for classes will be removed in 0.24. Pass instances instead. #17032 by Nicolas Hug.

• [API CHANGE] The private utility `_safe_tags` in `utils.estimator_checks` was removed, hence all tags should be obtained through `estimator._get_tags()`. Note that Mixins like `RegressorMixin` must come before base classes in the MRO for `_get_tags()` to work properly. #16950 by Nicolas Hug.

• [Fix] `utils.all_estimators` now only returns public estimators. #15380 by Thomas Fan.
Miscellaneous

- **[Major Feature]** Adds a HTML representation of estimators to be shown in a jupyter notebook or lab. This visualization is activated by setting the `display` option in `sklearn.set_config`. #14180 by Thomas Fan.

- **[Enhancement]** `scikit-learn` now works with `mypy` without errors. #16726 by Roman Yurchak.

- **[API Change]** Most estimators now expose a `n_features_in_` attribute. This attribute is equal to the number of features passed to the `fit` method. See SLEP010 for details. #16112 by Nicolas Hug.

- **[API Change]** Estimators now have a `requires_y` tag which is False by default except for estimators that inherit from `~sklearn.base.RegressorMixin` or `~sklearn.base.ClassifierMixin`. This tag is used to ensure that a proper error message is raised when `y` was expected but `None` was passed. #16622 by Nicolas Hug.

- **[API Change]** The default setting `print_changed_only` has been changed from `False` to `True`. This means that the `repr` of estimators is now more concise and only shows the parameters whose default value has been changed when printing an estimator. You can restore the previous behaviour by using `sklearn.set_config(print_changed_only=False)`. Also, note that it is always possible to quickly inspect the parameters of any estimator using `est.get_params(deep=False)`. #17061 by Nicolas Hug.

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.22, including:

1.7. Release History
1.7.5 Version 0.22.2.post1

March 3 2020

The 0.22.2.post1 release includes a packaging fix for the source distribution but the content of the packages is otherwise identical to the content of the wheels with the 0.22.2 version (without the .post1 suffix). Both contain the following changes.

Changelog

sklearn.impute

• [EFFICIENCY] Reduce impute.KNNImputer asymptotic memory usage by chunking pairwise distance computation. #16397 by Joel Nothman.

sklearn.metrics

• [FIX] Fixed a bug in metrics.plot_roc_curve where the name of the estimator was passed in the metrics.RocCurveDisplay instead of the parameter name. It results in a different plot when calling metrics.RocCurveDisplay.plot for the subsequent times. #16500 by Guillaume Lemaitre.

• [FIX] Fixed a bug in metrics.plot_precision_recall_curve where the name of the estimator was passed in the metrics.PrecisionRecallDisplay instead of the parameter name. It results in a different plot when calling metrics.PrecisionRecallDisplay.plot for the subsequent times. #16505 by Guillaume Lemaitre.

sklearn.neighbors

• [FIX] Fix a bug which converted a list of arrays into a 2-D object array instead of a 1-D array containing NumPy arrays. This bug was affecting neighbors.NearestNeighbors.radius_neighbors. #16076 by Guillaume Lemaitre and Alex Shacked.

1.7.6 Version 0.22.1

January 2 2020

This is a bug-fix release to primarily resolve some packaging issues in version 0.22.0. It also includes minor documentation improvements and some bug fixes.

Changelog

sklearn.cluster

• [FIX] cluster.KMeans with algorithm="elkan" now uses the same stopping criterion as with the default algorithm="full". #15930 by @inder128.
sklearn.inspection

- [Fix] `inspection.permutation_importance` will return the same importances when a random_state is given for both n_jobs=1 or n_jobs>1 both with shared memory backends (thread-safety) and isolated memory, process-based backends. Also avoid casting the data as object dtype and avoid read-only error on large dataframes with n_jobs>1 as reported in #15810. Follow-up of #15898 by Shivam Gargsy. #15933 by Guillaume Lemaître and Olivier Grisel.

- [Fix] `inspection.plot_partial_dependence` and `inspection.PartialDependenceDisplay.plot` now consistently checks the number of axes passed in. #15760 by Thomas Fan.

sklearn.metrics

- [Fix] `metrics.plot_confusion_matrix` now raises error when normalize is invalid. Previously, it runs fine with no normalization. #15888 by Hanmin Qin.

- [Fix] `metrics.plot_confusion_matrix` now colors the label color correctly to maximize contrast with its background. #15936 by Thomas Fan and @DizietAsahi.

- [Fix] `metrics.classification_report` does no longer ignore the value of the zero_division keyword argument. #15879 by Bibhash Chandra Mitra.

- [Fix] Fixed a bug in `metrics.plot_confusion_matrix` to correctly pass the values_format parameter to the ConfusionMatrixDisplay plot() call. #15937 by Stephen Blystone.

sklearn.model_selection

- [Fix] `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` accept scalar values provided in fit_params. Change in 0.22 was breaking backward compatibility. #15863 by Adrin Jalali and Guillaume Lemaître.

sklearn.naive_bayes

- [Fix] Removed abstractmethod decorator for the method _check_X in naive_bayes.BaseNB that could break downstream projects inheriting from this deprecated public base class. #15996 by Brigitta Sipőcz.

sklearn.preprocessing

- [Fix] `preprocessing.QuantileTransformer` now guarantees the quantiles_ attribute to be completely sorted in non-decreasing manner. #15751 by Tirth Patel.
sklearn.semi_supervised

• [Fix] `semi_supervised.LabelPropagation` and `semi_supervised.LabelSpreading` now allow callable kernel function to return sparse weight matrix. #15868 by Niklas Smedmark-Margulies.

sklearn.utils

• [Fix] `utils.check_array` now correctly converts pandas DataFrame with boolean columns to floats. #15797 by Thomas Fan.
• [Fix] `utils.check_is_fitted` accepts back an explicit attributes argument to check for specific attributes as explicit markers of a fitted estimator. When no explicit attributes are provided, only the attributes that end with a underscore and do not start with double underscore are used as “fitted” markers. The all_or_any argument is also no longer deprecated. This change is made to restore some backward compatibility with the behavior of this utility in version 0.21. #15947 by Thomas Fan.

1.7.7 Version 0.22.0

December 3 2019

For a short description of the main highlights of the release, please refer to `Release Highlights for scikit-learn 0.22`.

Legend for changelogs

• [Major Feature]: something big that you couldn’t do before.
• [Feature]: something that you couldn’t do before.
• [Efficiency]: an existing feature now may not require as much computation or memory.
• [Enhancement]: a miscellaneous minor improvement.
• [Fix]: something that previously didn’t work as documented – or according to reasonable expectations – should now work.
• [API Change]: you will need to change your code to have the same effect in the future; or a feature will be removed in the future.

Website update

Our website was revamped and given a fresh new look. #14849 by Thomas Fan.

Clear definition of the public API

Scikit-learn has a public API, and a private API.

We do our best not to break the public API, and to only introduce backward-compatible changes that do not require any user action. However, in cases where that’s not possible, any change to the public API is subject to a deprecation cycle of two minor versions. The private API isn’t publicly documented and isn’t subject to any deprecation cycle, so users should not rely on its stability.
A function or object is public if it is documented in the API Reference and if it can be imported with an import path without leading underscores. For example sklearn.pipeline.make_pipeline is public, while sklearn.pipeline._name_estimators is private. sklearn.ensemble._gb.BaseEnsemble is private too because the whole _gb module is private.

Up to 0.22, some tools were de-facto public (no leading underscore), while they should have been private in the first place. In version 0.22, these tools have been made properly private, and the public API space has been cleaned. In addition, importing from most sub-modules is now deprecated: you should for example use from sklearn.cluster import Birch instead of from sklearn.cluster.birch import Birch (in practice, birch.py has been moved to _birch.py).

**Note:** All the tools in the public API should be documented in the API Reference. If you find a public tool (without leading underscore) that isn’t in the API reference, that means it should either be private or documented. Please let us know by opening an issue!

This work was tracked in issue 9250 and issue 12927.

**Deprecations: using FutureWarning from now on**

When deprecating a feature, previous versions of scikit-learn used to raise a DeprecationWarning. Since the DeprecationWarnings aren’t shown by default by Python, scikit-learn needed to resort to a custom warning filter to always show the warnings. That filter would sometimes interfere with users custom warning filters.

Starting from version 0.22, scikit-learn will show FutureWarnings for deprecations, as recommended by the Python documentation. FutureWarnings are always shown by default by Python, so the custom filter has been removed and scikit-learn no longer hinders with user filters. #15080 by Nicolas Hug.

**Changed models**

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- `cluster.KMeans` when `n_jobs=1`. [Fix]
- `decomposition.SparseCoder` with `algorithm='lasso_lars'` [Fix]
- `decomposition.SparsePCA` where `normalize_components` has no effect due to deprecation.
- `ensemble.HistGradientBoostingClassifier` and `ensemble.HistGradientBoostingRegressor` [Fix], [Feature], [Enhancement].
- `impute.IterativeImputer` when `X` has features with no missing values. [Feature]
- `linear_model.Ridge` when `X` is sparse. [Fix]
- `model_selection.StratifiedKFold` and any use of `cv=int` with a classifier. [Fix]
- `cross_decomposition.CCA` when using scipy >= 1.3 [Fix]

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)
Changelog

sklearn.base

• [API CHANGE] From version 0.24 base.BaseEstimator.get_params will raise an AttributeError rather than return None for parameters that are in the estimator’s constructor but not stored as attributes on the instance. #14464 by Joel Nothman.

sklearn.calibration

• [Fix] Fixed a bug that made calibration.CalibratedClassifierCV fail when given a sample_weight parameter of type list (in the case where sample_weights are not supported by the wrapped estimator). #13575 by William de Vazelhes.

sklearn.cluster

• [Feature] cluster.SpectralClustering now accepts precomputed sparse neighbors graph as input. #10482 by Tom Dupre la Tour and Kumar Ashutosh.
• [Enhancement] cluster.SpectralClustering now accepts a n_components parameter. This parameter extends SpectralClustering class functionality to match cluster.spectral_clustering. #13726 by Shuzhe Xiao.
• [Fix] Fixed a bug where cluster.KMeans produced inconsistent results between n_jobs=1 and n_jobs>1 due to the handling of the random state. #9288 by Bryan Yang.
• [Fix] Fixed a bug where elkan algorithm in cluster.KMeans was producing Segmentation Fault on large arrays due to integer index overflow. #15057 by Vladimir Korolev.
• [Fix] MeanShift now accepts a max_iter with a default value of 300 instead of always using the default 300. It also now exposes an n_iter_ indicating the maximum number of iterations performed on each seed. #15120 by Adrin Jalali.
• [Fix] cluster.AgglomerativeClustering and cluster.FeatureAgglomeration now raise an error if affinity='cosine' and X has samples that are all-zeros. #7943 by @mthorrell.

sklearn.compose

• [Feature] Adds compose.make_column_selector which is used with compose.ColumnTransformer to select DataFrame columns on the basis of name and dtype. #12303 by Thomas Fan.
• [Fix] Fixed a bug in compose.ColumnTransformer which failed to select the proper columns when using a boolean list, with NumPy older than 1.12. #14510 by Guillaume Lemaitre.
• [Fix] Fixed a bug in compose.TransformedTargetRegressor which did not pass **fit_params to the underlying regressor. #14890 by Miguel Cabrera.
• [Fix] The compose.ColumnTransformer now requires the number of features to be consistent between fit and transform. A FutureWarning is raised now, and this will raise an error in 0.24. If the number of features isn’t consistent and negative indexing is used, an error is raised. #14544 by Adrin Jalali.
sklearn.cross_decomposition

- [Feature] cross_decomposition.PLSCanonical and cross_decomposition.PLSRegression have a new function inverse_transform to transform data to the original space. #15304 by Jaime Ferrando Huertas.

- [Enhancement] decomposition.KernelPCA now properly checks the eigenvalues found by the solver for numerical or conditioning issues. This ensures consistency of results across solvers (different choices for eigen_solver), including approximate solvers such as 'randomized' and 'lobpcg' (see #12068). #12145 by Sylvain Marié

- [Fix] Fixed a bug where cross_decomposition.PLSCanonical and cross_decomposition.PLSRegression were raising an error when fitted with a target matrix $Y$ in which the first column was constant. #13609 by Camila Williamson.

- [Fix] cross_decomposition.CCA now produces the same results with scipy 1.3 and previous scipy versions. #15661 by Thomas Fan.

sklearn.datasets

- [Feature] datasets.fetch_openml now supports heterogeneous data using pandas by setting as_frame=True. #13902 by Thomas Fan.

- [Feature] datasets.fetch_openml now includes the target_names in the returned Bunch. #15160 by Thomas Fan.

- [Enhancement] The parameter return_X_y was added to datasets.fetch_20newsgroups and datasets.fetch_olivetti_faces. #14259 by Sourav Singh.

- [Enhancement] datasets.make_classification now accepts array-like weights parameter, i.e. list or numpy.array, instead of list only. #14764 by Cat Chenal.

- [Enhancement] The parameter normalize was added to datasets.fetch_20newsgroups_vectorized. #14740 by Stéphan Tulkens

- [Fix] Fixed a bug in datasets.fetch_openml, which failed to load an OpenML dataset that contains an ignored feature. #14623 by Sarra Habchi.

sklearn.decomposition

- [Efficiency] decomposition.NMF(solver='mu') fitted on sparse input matrices now uses batching to avoid briefly allocating an array with size (#non-zero elements, n_components). #15257 by Mart Willocx.

- [Enhancement] decomposition.dict_learning and decomposition.dict_learning_online now accept method_max_iter and pass it to decomposition.sparse_encode. #12650 by Adrin Jalali.

- [Enhancement] decomposition.IncrementalPCA now accepts sparse matrices as input, converting them to dense in batches thereby avoiding the need to store the entire dense matrix at once. #13960 by Scott Gigante.

- [Fix] decomposition.sparse_encode now passes the max_iter to the underlying linear_model.LassoLars when algorithm='lasso_lars'. #12650 by Adrin Jalali.
sklearn.dummy

- **[Fix]** `dummy.DummyClassifier` now handles checking the existence of the provided constant in multioutput cases. #14908 by Martina G. Vilas.

- **[API Change]** The default value of the `strategy` parameter in `dummy.DummyClassifier` will change from `'stratified'` in version 0.22 to `'prior'` in 0.24. A FutureWarning is raised when the default value is used. #15382 by Thomas Fan.

- **[API Change]** The `outputs_2d_` attribute is deprecated in `dummy.DummyClassifier` and `dummy.DummyRegressor`. It is equivalent to `n_outputs > 1`. #14933 by Nicolas Hug

sklearn.ensemble

- **[Major Feature]** Added `ensemble.StackingClassifier` and `ensemble.StackingRegressor` to stack predictors using a final classifier or regressor. #11047 by Guillaume Lemaître and Caio Oliveira and #15138 by Jon Cusick.

- **[Major Feature]** Many improvements were made to `ensemble.HistGradientBoostingClassifier` and `ensemble.HistGradientBoostingRegressor`:
  - **[Feature]** Estimators now natively support dense data with missing values both for training and predicting. They also support infinite values. #13911 and #14406 by Nicolas Hug, Adrin Jalali and Olivier Grisel.
  - **[Feature]** Estimators now have an additional `warm_start` parameter that enables warm starting. #14012 by Johann Faouzi.
  - **[Feature]** `inspection.partial_dependence` and `inspection.plot_partial_dependence` now support the fast ‘recursion’ method for both estimators. #13769 by Nicolas Hug.
  - **[Enhancement]** for `ensemble.HistGradientBoostingClassifier` the training loss or score is now monitored on a class-wise stratified subsample to preserve the class balance of the original training set. #14194 by Johann Faouzi.
  - **[Enhancement]** `ensemble.HistGradientBoostingRegressor` now supports the `least_absolute_deviation` loss. #13896 by Nicolas Hug.
  - **[Fix]** Estimators now bin the training and validation data separately to avoid any data leak. #13933 by Nicolas Hug.
  - **[Fix]** Fixed a bug where early stopping would break with string targets. #14710 by Guillaume Lemaître.
  - **[Fix]** `ensemble.HistGradientBoostingClassifier` now raises an error if `categorical_crossentropy` loss is given for a binary classification problem. #14869 by Adrin Jalali.

Note that pickles from 0.21 will not work in 0.22.

- **[Enhancement]** Addition of `max_samples` argument allows limiting size of bootstrap samples to be less than size of dataset. Added to `ensemble.RandomForestClassifier`, `ensemble.RandomForestRegressor`, `ensemble.ExtraTreesClassifier`, `ensemble.ExtraTreesRegressor`. #14682 by Matt Hancock and #5963 by Pablo Duboue.

- **[Fix]** `ensemble.VotingClassifier.predict_proba` will no longer be present when `voting='hard'`. #14287 by Thomas Fan.

- **[Fix]** The `named_estimators_` attribute in `ensemble.VotingClassifier` and `ensemble.VotingRegressor` now correctly maps to dropped estimators. Previously, the `named_estimators_` mapping was incorrect whenever one of the estimators was dropped. #15375 by Thomas Fan.
• [Fix] Run by default `utils.estimator_checks.check_estimator` on both `ensemble.VotingClassifier` and `ensemble.VotingRegressor`. It leads to solve issues regarding shape consistency during `predict` which was failing when the underlying estimators were not outputting consistent array dimensions. Note that it should be replaced by refactoring the common tests in the future. #14305 by Guillaume Lemaitre.

• [Fix] `ensemble.AdaBoostClassifier` computes probabilities based on the decision function as in the literature. Thus, `predict` and `predict_proba` give consistent results. #14114 by Guillaume Lemaitre.

• [Fix] Stacking and Voting estimators now ensure that their underlying estimators are either all classifiers or all regressors. `ensemble.StackingClassifier`, `ensemble.StackingRegressor`, and `ensemble.VotingClassifier` and `VotingRegressor` now raise consistent error messages. #15084 by Guillaume Lemaitre.

• [Fix] `ensemble.AdaBoostRegressor` where the loss should be normalized by the max of the samples with non-null weights only. #14294 by Guillaume Lemaitre.

• [API CHANGE] `presort` is now deprecated in `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor`, and the parameter has no effect. Users are recommended to use `ensemble.HistGradientBoostingClassifier` and `ensemble.HistGradientBoostingRegressor` instead. #14907 by Adrin Jalali.

sklearn.feature_extraction

• [Enhancement] A warning will now be raised if a parameter choice means that another parameter will be unused on calling the `fit()` method for `feature_extraction.text.HashingVectorizer`, `feature_extraction.text.CountVectorizer` and `feature_extraction.text.TfidfVectorizer`. #14602 by Gaurav Chawla.

• [Fix] Functions created by `build_preprocessor` and `build_analyzer` of `feature_extraction.text.VectorizerMixin` can now be pickled. #14430 by Dillon Niederhut.

• [Fix] `feature_extraction.text.strip_accents_unicode` now correctly removes accents from strings that are in NFKD normalized form. #15100 by Daniel Grady.

• [Fix] Fixed a bug that caused `feature_extraction.DictVectorizer` to raise an `OverflowError` during the `transform` operation when producing a `scipy.sparse` matrix on large input data. #15463 by Norvan Sahiner.

• [API CHANGE] Deprecated unused `copy` param for `feature_extraction.text.TfidfVectorizer.transform` it will be removed in v0.24. #14520 by Guillem G. Subies.

sklearn.feature_selection

• [Enhancement] Updated the following `feature_selection` estimators to allow NaN/Inf values in `transform` and `fit`: `feature_selection.RFE`, `feature_selection.RFE_CV`, `feature_selection.SelectFromModel`, and `feature_selection.VarianceThreshold`. Note that if the underlying estimator of the feature selector does not allow NaN/Inf then it will still error, but the feature selectors themselves no longer enforce this restriction unnecessarily. #11635 by Alec Peters.

• [Fix] Fixed a bug where `feature_selection.VarianceThreshold` with `threshold=0` did not remove constant features due to numerical instability, by using range rather than variance in this case. #13704 by Roddy MacSween.
sklearn.gaussian_process

- **[Feature]** Gaussian process models on structured data: `gaussian_process.GaussianProcessRegressor` and `gaussian_process.GaussianProcessClassifier` can now accept a list of generic objects (e.g. strings, trees, graphs, etc.) as the X argument to their training/prediction methods. A user-defined kernel should be provided for computing the kernel matrix among the generic objects, and should inherit from `gaussian_process.kernels.GenericKernelMixin` to notify the GPR/GPC model that it handles non-vectorial samples. #15557 by Yu-Hang Tang.

- **[Efficiency]** `gaussian_process.GaussianProcessClassifier.log_marginal_likelihood` and `gaussian_process.GaussianProcessRegressor.log_marginal_likelihood` now accept a `clone_kernel=True` keyword argument. When set to False, the kernel attribute is modified, but may result in a performance improvement. #14378 by Masashi Shibata.

- **[API Change]** From version 0.24 `gaussian_process.kernels.Kernel.get_params` will raise an AttributeError rather than return None for parameters that are in the estimator’s constructor but not stored as attributes on the instance. #14464 by Joel Nothman.

sklearn.impute

- **[Major Feature]** Added `impute.KNNImputer`, to impute missing values using k-Nearest Neighbors. #12852 by Ashim Bhattarai and Thomas Fan and #15010 by Guillaume Lemaitre.

- **[Feature]** `impute.IterativeImputer` has new `skip_compute` flag that is False by default, which, when True, will skip computation on features that have no missing values during the fit phase. #13773 by Sergey Feldman.

- **[Efficiency]** `impute.MissingIndicator.fit_transform` avoid repeated computation of the masked matrix. #14356 by Harsh Soni.

- **[Fix]** `impute.IterativeImputer` now works when there is only one feature. By Sergey Feldman.

- **[Fix]** Fixed a bug in `impute.IterativeImputer` where features where imputed in the reverse desired order with imputation_order either "ascending" or "descending". #15393 by Venkatachalam N.

sklearn.inspection

- **[Major Feature]** `inspection.permutation_importance` has been added to measure the importance of each feature in an arbitrary trained model with respect to a given scoring function. #13146 by Thomas Fan.

- **[Enhancement]** `inspection.plot_partial_dependence` has been extended to now support the new visualization API described in the User Guide. #14646 by Thomas Fan.

- **[Enhancement]** `inspection.partial_dependence` accepts pandas DataFrame and `pipeline.Pipeline` containing `compose.ColumnTransformer`. In addition `inspection.plot_partial_dependence` will use the column names by default when a dataframe is passed. #14028 and #15429 by Guillaume Lemaitre.
sklearn.kernel_approximation

• [Fix] Fixed a bug where `kernel_approximation.Nystroem` raised a `KeyError` when using `kernel="precomputed"`. #14706 by Venkatachalam N.

sklearn.linear_model

• [Efficiency] The `liblinear` logistic regression solver is now faster and requires less memory. #14108, #14170, #14296 by Alex Henrie.

• [Enhancement] `linear_model.BayesianRidge` now accepts hyperparameters `alpha_init` and `lambda_init` which can be used to set the initial value of the maximization procedure in `fit`. #13618 by Yoshihiro Uchida.

• [Fix] `linear_model.Ridge` now correctly fits an intercept when `X` is sparse, `solver="auto"` and `fit_intercept=True`, because the default solver in this configuration has changed to `sparse_cg`, which can fit an intercept with sparse data. #13995 by Jérôme Dockès.

• [Fix] `linear_model.Ridge` with `solver='sag'` now accepts F-ordered and non-contiguous arrays and makes a conversion instead of failing. #14458 by Guillaume Lemaitre.

• [Fix] `linear_model.LassoCV` no longer forces `precompute=False` when fitting the final model. #14591 by Andreas Müller.

• [Fix] `linear_model.RidgeCV` and `linear_model.RidgeClassifierCV` now correctly scores when `cv=None`. #14864 by Venkatachalam N.

• [Fix] Fixed a bug in `linear_model.LogisticRegressionCV` where the `scores_`, `n_iter_` and `coef_paths_` attribute would have a wrong ordering with `penalty="elastic-net"`. #15044 by Nicolas Hug

• [Fix] `linear_model.MultiTaskLassoCV` and `linear_model.MultiTaskElasticNetCV` with `X` of dtype int and `fit_intercept=True`. #15086 by Alex Gramfort.

• [Fix] The liblinear solver now supports `sample_weight`. #15038 by Guillaume Lemaitre.

sklearn.manifold

• [Feature] `manifold.Isomap`, `manifold.TSNE`, and `manifold.SpectralEmbedding` now accept precomputed sparse neighbors graph as input. #10482 by Tom Dupre la Tour and Kumar Ashutosh.

• [Feature] Exposed the `n_jobs` parameter in `manifold.TSNE` for multi-core calculation of the neighbors graph. This parameter has no impact when `metric="precomputed"` or (metric="euclidean" and method="exact"). #15082 by Roman Yurchak.

• [Efficiency] Improved efficiency of `manifold.TSNE` when `method="barnes-hut"` by computing the gradient in parallel. #13213 by Thomas Moreau

• [Fix] Fixed a bug where `manifold.spectral_embedding` (and therefore `manifold.SpectralEmbedding` and `cluster.SpectralClustering`) computed wrong eigenvalues with `eigen_solver='amg'` when `n_samples < 5 * n_components`. #14647 by Andreas Müller.

• [Fix] Fixed a bug in `manifold.spectral_embedding` used in `manifold.SpectralEmbedding` and `cluster.SpectralClustering` where `eigen_solver='amg'` would sometimes result in a `LinAlgError`. #13393 by Andrew Knyazev #13707 by Scott White

• [API Change] Deprecate `training_data_` unused attribute in `manifold.Isomap`. #10482 by Tom Dupre la Tour.
sklearn.metrics

- [Major Feature] `metrics.plot_roc_curve` has been added to plot roc curves. This function introduces the visualization API described in the User Guide. #14357 by Thomas Fan.

- [Feature] Added a new parameter `zero_division` to multiple classification metrics: `precision_score`, `recall_score`, `f1_score`, `fbeta_score`, `precision_recall_fscore_support`, `classification_report`. This allows to set returned value for ill-defined metrics. #14900 by Marc Torrellas Socastro.

- [Feature] Added the `metrics.pairwise.nan_euclidean_distances` metric, which calculates euclidean distances in the presence of missing values. #12852 by Ashim Bhattarai and Thomas Fan.

- [Feature] New ranking metrics `metrics.ndcg_score` and `metrics.dcg_score` have been added to compute Discounted Cumulative Gain and Normalized Discounted Cumulative Gain. #9951 by Jérôme Dockès.

- [Feature] `metrics.plot_precision_recall_curve` has been added to plot precision recall curves. #14936 by Thomas Fan.

- [Feature] `metrics.plot_confusion_matrix` has been added to plot confusion matrices. #15083 by Thomas Fan.

- [Feature] Added multiclass support to `metrics.roc_auc_score` with corresponding scorers 'roc_auc_ovr', 'roc_auc_ovo', 'roc_auc_ovo_weighted', and 'roc_auc_ovr_weighted'. #12789 and #15274 by Kathy Chen, Mohamed Maskani, and Thomas Fan.

- [Feature] Add `metrics.mean_tweedie_deviance` measuring the Tweedie deviance for a given power parameter. Also add mean Poisson deviance `metrics.mean_poisson_deviance` and mean Gamma deviance `metrics.mean_gamma_deviance` that are special cases of the Tweedie deviance for power=1 and power=2 respectively. #13938 by Christian Lorentzen and Roman Yurchak.

- [Enhancement] Improved performance of `metrics.pairwise.manhattan_distances` in the case of sparse matrices. #15049 by Paolo Toccaceli <ptocca>.

- [Enhancement] The parameter `beta` in `metrics.fbeta_score` is updated to accept the zero and float('+inf') value. #13231 by Dong-hee Na.

- [Enhancement] Added parameter squared in `metrics.mean_squared_error` to return root mean squared error. #13467 by Urvang Patel.

- [Enhancement] Allow computing averaged metrics in the case of no true positives. #14595 by Andreas Müller.

- [Enhancement] Multilabel metrics now supports list of lists as input. #14865 Srivatsan Ramesh, Herilalaina Rakotoarison, Léonard Binet.

- [Enhancement] `metrics.median_absolute_error` now supports multioutput parameter. #14732 by Agamemnon Krasoulis.

- [Enhancement] ‘roc_auc_ovo_weighted’ and ‘roc_auc_ovo_weighted’ can now be used as the scoring parameter of model-selection tools. #14417 by Thomas Fan.

- [Enhancement] `metrics.confusion_matrix` accepts a parameters normalize allowing to normalize the confusion matrix by column, rows, or overall. #15625 by Guillaume Lemaitre <glemaitre>.

- [Fix] Raise a ValueError in `metrics.silhouette_score` when a precomputed distance matrix contains non-zero diagonal entries. #12258 by Stephen Tierney.

- [API Change] `scoring="neg_brier_score"` should be used instead of `scoring="brier_score_loss"` which is now deprecated. #14898 by Stefan Matcovici.
**sklearn.model_selection**

- **[Enhancement]** `model_selection.learning_curve` now accepts parameter `return_times` which can be used to retrieve computation times in order to plot model scalability (see learning_curve example). #13938 by Hadrien Reboul.

- **[Enhancement]** `model_selection.RandomizedSearchCV` now accepts lists of parameter distributions. #14549 by Andreas Müller.

- **[Fix]** Reimplemented `model_selection.StratifiedKFold` to fix an issue where one test set could be `n_classes` larger than another. Test sets should now be near-equally sized. #14704 by Joel Nothman.

- **[Fix]** The `cv_results_` attribute of `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` now only contains unfitted estimators. This potentially saves a lot of memory since the state of the estimators isn’t stored. #15096 by Andreas Müller.

- **[API Change]** `model_selection.KFold` and `model_selection.StratifiedKFold` now raise a warning if `random_state` is set but `shuffle` is False. This will raise an error in 0.24.

**sklearn.multioutput**

- **[Fix]** `multioutput.MultiOutputClassifier` now has attribute `classes_`. #14629 by Agamemnon Krasoulis.

- **[Fix]** `multioutput.MultiOutputClassifier` now has `predict_proba` as property and can be checked with `hasattr`. #15488 #15490 by Rebekah Kim

**sklearn.neural_bayes**

- **[Major Feature]** Added `naive_bayes.CategoricalNB` that implements the Categorical Naive Bayes classifier. #12569 by Tim Bicker and Florian Wilhelm.

**sklearn.neighbors**

- **[Major Feature]** Added `neighbors.KNeighborsTransformer` and `neighbors.RadiusNeighborsTransformer`, which transform input dataset into a sparse neighbors graph. They give finer control on nearest neighbors computations and enable easy pipeline caching for multiple use. #10482 by Tom Dupre la Tour.

- **[Feature]** `neighbors.KNeighborsClassifier`, `neighbors.KNeighborsRegressor`, `neighbors.RadiusNeighborsClassifier`, `neighbors.RadiusNeighborsRegressor`, and `neighbors.LocalOutlierFactor` now accept precomputed sparse neighbors graph as input. #10482 by Tom Dupre la Tour and Kumar Ashutosh.

- **[Feature]** `neighbors.RadiusNeighborsClassifier` now supports predicting probabilities by using `predict_proba` and supports more `outlier_label` options: ‘most_frequent’, or different `outlier_labels` for multi-outputs. #9597 by Wenbo Zhao.

- **[Efficiency]** Efficiency improvements for `neighbors.RadiusNeighborsClassifier.predict`. #9597 by Wenbo Zhao.
• [Fix] `neighbors.KNeighborsRegressor` now throws error when `metric='precomputed'` and fit on non-square data. #14336 by Gregory Dexter.

**sklearn.neural_network**

• [Feature] Add `max_fun` parameter in `neural_network.BaseMultilayerPerceptron`, `neural_network.MLPRegressor`, and `neural_network.MLPClassifier` to give control over maximum number of function evaluation to not meet `tol` improvement. #9274 by Daniel Perry.

**sklearn.pipeline**

• [Enhancement] `pipeline.Pipeline` now supports `score_samples` if the final estimator does. #13806 by Anaël Beaugnon.
• [Fix] The `fit` in `FeatureUnion` now accepts `fit_params` to pass to the underlying transformers. #15119 by Adrin Jalali.
• [API Change] None as a transformer is now deprecated in `pipeline.FeatureUnion`. Please use 'drop' instead. #15053 by Thomas Fan.

**sklearn.preprocessing**

• [Efficiency] `preprocessing.PolynomialFeatures` is now faster when the input data is dense. #13290 by Xavier Dupré.
• [Fix] KernelCenterer now throws error when fit on non-square `preprocessing.KernelCenterer` #14336 by Gregory Dexter.

**sklearn.model_selection**

• [Fix] `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` now supports the `_pairwise` property, which prevents an error during cross-validation for estimators with pairwise inputs (such as `neighbors.KNeighborsClassifier` when `metric` is set to 'precomputed'). #13925 by Isaac S. Robson and #15524 by Xun Tang.

**sklearn.svm**

• [Enhancement] `svm.SVC` and `svm.NuSVC` now accept a `break_ties` parameter. This parameter results in `predict` breaking the ties according to the confidence values of `decision_function`, if `decision_function_shape='ovr'`, and the number of target classes > 2. #12557 by Adrin Jalali.
• [Enhancement] SVM estimators now throw a more specific error when `kernel='precomputed'` and fit on non-square data. #14336 by Gregory Dexter.
• [Fix] `svm.SVC`, `svm.SVR`, `svm.NuSVC` and `svm.OneClassSVM` when received values negative or zero for parameter `sample_weight` in method `fit()`, generated an invalid model. This behavior occurred only in some border scenarios. Now in these cases, `fit()` will fail with an Exception. #14286 by Alex Shacked.
• [Fix] The n_support_ attribute of svm.SVR and svm.OneClassSVM was previously non-initialized, and had size 2. It has now size 1 with the correct value. #15099 by Nicolas Hug.

• [Fix] fixed a bug in BaseLibSVM._sparse_fit where n_SV=0 raised a ZeroDivisionError. #14894 by Danna Naser.

• [Fix] The liblinear solver now supports sample_weight. #15038 by Guillaume Lemaitre.

sklearn.tree

• [API Change] presort is now deprecated in tree.DecisionTreeClassifier and tree.DecisionTreeRegressor, and the parameter has no effect. #14907 by Adrin Jalali.

• [API Change] The classes_ and n_classes_ attributes of tree.DecisionTreeRegressor are now deprecated. #15028 by Mei Guan, Nicolas Hug, and Adrin Jalali.

sklearn.utils

• [Feature] check_estimator can now generate checks by setting generate_only=True. Previously, running check_estimator will stop when the first check fails. With generate_only=True, all checks can run independently and report the ones that are failing. Read more in Rolling your own estimator. #14381 by Thomas Fan.

• [Feature] Added a pytest specific decorator, parametrize_with_checks, to parametrize estimator checks for a list of estimators. #14381 by Thomas Fan.

• [Feature] A new random variable, utils.fixes.loguniform implements a log-uniform random variable (e.g., for use in RandomizedSearchCV). For example, the outcomes 1, 10 and 100 are all equally likely for loguniform(1, 100). See #11232 by Scott Sievert and Nathaniel Saul, and SciPy PR 10815 <https://github.com/scipy/scipy/pull/10815>.

• [Enhancement] utils.safe_indexing (now deprecated) accepts an axis parameter to index array-like across rows and columns. The column indexing can be done on NumPy array, SciPy sparse matrix, and Pandas DataFrame. An additional refactoring was done. #14035 and #14475 by Guillaume Lemaître.

• [Enhancement] utilities.extmath.safe_sparse_dot works between 3D+ ndarray and sparse matrix. #14538 by Jérémie du Boisberranger.

• [Fix] utilities.check_array is now raising an error instead of casting NaN to integer. #14872 by Roman Yurchak.

• [Fix] utilities.check_array will now correctly detect numeric dtypes in pandas dataframes, fixing a bug where float32 was upcast to float64 unnecessarily. #15094 by Andreas Müller.

• [API Change] The following utils have been deprecated and are now private:
  - choose_check_classifiers_labels
  - enforce_estimator_tags_y
  - mocking.MockDataFrame

1.7. Release History
- mocking.CheckingClassifier
- optimize.newton_cg
- random.random_choice_csc
- utils.choose_check_classifiers_labels
- utils.enforce_estimator_tags_y
- utils.optimize.newton_cg
- utils.random.random_choice_csc
- utils.safe_indexing
- utils.mocking
- utils.fast_dict
- utils.seq_dataset
- utils.weight_vector
- utils.fixes.parallel_helper (removed)
- All of utils.testing except for all_estimators which is now in utils.

sklearn.isotonic

- [FIX] Fixed a bug where isotonic.IsotonicRegression.fit raised error when X.dtype == 'float32' and X.dtype != y.dtype. #14902 by Lucas.

Miscellaneous

- [FIX] Port lobpcg from SciPy which implement some bug fixes but only available in 1.3+. #13609 and #14971 by Guillaume Lemaitre.
- [API CHANGE] Scikit-learn now converts any input data structure implementing a duck array to a numpy array (using __array__) to ensure consistent behavior instead of relying on __array_function__ (see NEP 18). #14702 by Andreas Müller.
- [API CHANGE] Replace manual checks with check_is_fitted. Errors thrown when using a non-fitted estimators are now more uniform. #13013 by Agamemnon Krasoulis.

Changes to estimator checks

These changes mostly affect library developers.

- Estimators are now expected to raise a NotFittedError if predict or transform is called before fit; previously an AttributeError or ValueError was acceptable. #13013 by Agamemnon Krasoulis.
- Binary only classifiers are now supported in estimator checks. Such classifiers need to have the binary_only=True estimator tag. #13875 by Trevor Stephens.
- Estimators are expected to convert input data (X, y, sample_weights) to numpy.ndarray and never call __array_function__ on the original datatype that is passed (see NEP 18). #14702 by Andreas Müller.
- requires_positive_X estimator tag (for models that require X to be non-negative) is now used by utils.estimator_checks.check_estimator to make sure a proper error message is raised if X contains some negative entries. #14680 by Alex Gramfort.
• Added check that pairwise estimators raise error on non-square data #14336 by Gregory Dexter.

• Added two common multioutput estimator tests check_classifier_multioutput and check_regressor_multioutput. #13392 by Rok Mihevc.

• [Fix] Added check_transformer_data_not_an_array to checks where missing

• [Fix] The estimators tags resolution now follows the regular MRO. They used to be overrideable only once. #14884 by Andreas Müller.

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.21, including:

1.7.8 Version 0.21.3

Legend for changelogs

- [MAJOR FEATURE]: something big that you couldn’t do before.
- [FEATURE]: something that you couldn’t do before.
- [EFFICIENCY]: an existing feature now may not require as much computation or memory.
- [ENHANCEMENT]: a miscellaneous minor improvement.
- [FIX]: something that previously didn’t work as documented – or according to reasonable expectations – should now work.
- [API CHANGE]: you will need to change your code to have the same effect in the future; or a feature will be removed in the future.

July 30, 2019

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- The v0.20.0 release notes failed to mention a backwards incompatibility in `metrics.make_scorer` when `needs_proba=True` and `y_true` is binary. Now, the scorer function is supposed to accept a 1D `y_pred` (i.e., probability of the positive class, shape `(n_samples,)`), instead of a 2D `y_pred` (i.e., shape `(n_samples, 2)`).

Changelog

sklearn.cluster

- [FIX] Fixed a bug in `cluster.KMeans` where computation with `init='random'` was single threaded for `n_jobs > 1` or `n_jobs = -1`. #12955 by Prabakaran Kumaresshan.
- [FIX] Fixed a bug in `cluster.OPTICS` where users were unable to pass float `min_samples` and `min_cluster_size`. #14496 by Fabian Klopfer and Hanmin Qin.
- [FIX] Fixed a bug in `cluster.KMeans` where KMeans++ initialisation could rarely result in an IndexError. #11756 by Joel Nothman.

sklearn.compose

- [FIX] Fixed an issue in `compose.ColumnTransformer` where using DataFrames whose column order differs between `:func:fit` and `:func:transform` could lead to silently passing incorrect columns to the remainder transformer. #14237 by Andreas Schuderer <schuderer>.
sklearn.datasets

- [Fix] datasets.fetch_california_housing, datasets.fetch_covtype, datasets.fetch_kddcup99, datasets.fetch_olivetti_faces, datasets.fetch_rcv1, and datasets.fetch_species_distributions try to persist the previously cache using the new joblib if the cached data was persisted using the deprecated sklearn.externals.joblib. This behavior is set to be deprecated and removed in v0.23. #14197 by Adrin Jalali.

sklearn.ensemble

sklearn.impute

- [Fix] Fixed a bug in impute.SimpleImputer and impute.IterativeImputer so that no errors are thrown when there are missing values in training data. #13974 by Frank Hoang <fhoang7>.

sklearn.inspection

- [Fix] Fixed a bug in inspection.plot_partial_dependence where target parameter was not being taken into account for multiclass problems. #14393 by Guillem G. Subies.

sklearn.linear_model

- [Fix] Fixed a bug in linear_model.LogisticRegressionCV where refit=False would fail depending on the 'multiclass' and 'penalty' parameters (regression introduced in 0.21). #14087 by Nicolas Hug.
- [Fix] Compatibility fix for linear_model.ARDRegression and Scipy>=1.3.0. Adapts to upstream changes to the default pinvh cutoff threshold which otherwise results in poor accuracy in some cases. #14067 by Tim Staley.

sklearn.neighbors

- [Fix] Fixed a bug in neighbors.NeighborhoodComponentsAnalysis where the validation of initial parameters n_components, max_iter and tol required too strict types. #14092 by Jérémie du Boisberranger.
sklearn.tree

- [Fix] Fixed bug in `tree.export_text` when the tree has one feature and a single feature name is passed in. #14053 by Thomas Fan.
- [Fix] Fixed an issue with `plot_tree` where it displayed entropy calculations even for `gini` criterion in `DecisionTreeClassifiers`. #13947 by Frank Hoang.

1.7.9 Version 0.21.2
24 May 2019

Changelog

sklearn.decomposition

- [Fix] Fixed a bug in `cross_decomposition.CCA` improving numerical stability when \( Y \) is close to zero. #13903 by Thomas Fan.

sklearn.metrics

- [Fix] Fixed a bug in `metrics.pairwise.euclidean_distances` where a part of the distance matrix was left un-instanciated for sufficiently large float32 datasets (regression introduced in 0.21). #13910 by Jérémie du Boisberranger.

sklearn.preprocessing

- [Fix] Fixed a bug in `preprocessing.OneHotEncoder` where the new `drop` parameter was not reflected in `get_feature_names`. #13894 by James Myatt.

sklearn.utils.sparsefuncs

- [Fix] Fixed a bug where `min_max_axis` would fail on 32-bit systems for certain large inputs. This affects `preprocessing.MaxAbsScaler`, `preprocessing.normalize` and `preprocessing.LabelBinarizer`. #13741 by Roddy MacSween.

1.7.10 Version 0.21.1
17 May 2019

This is a bug-fix release to primarily resolve some packaging issues in version 0.21.0. It also includes minor documentation improvements and some bug fixes.
Changelog

sklearn.inspection

• [Fix] Fixed a bug in `inspection.partial_dependence` to only check classifier and not regressor for the multiclass-multioutput case. #14309 by Guillaume Lemaître.

sklearn.metrics

• [Fix] Fixed a bug in `metrics.pairwise_distances` where it would raise `AttributeError` for boolean metrics when X had a boolean dtype and Y == None. #13864 by Paresh Mathur.
• [Fix] Fixed two bugs in `metrics.pairwise_distances` when n_jobs > 1. First it used to return a distance matrix with same dtype as input, even for integer dtype. Then the diagonal was not zeros for euclidean metric when Y is X. #13877 by Jérémie du Boisberranger.

sklearn.neighbors

• [Fix] Fixed a bug in `neighbors.KernelDensity` which could not be restored from a pickle if `sample_weight` had been used. #13772 by Aditya Vyas.

1.7.11 Version 0.21.0

May 2019

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

• `discriminant_analysis.LinearDiscriminantAnalysis` for multiclass classification. [Fix]
• `discriminant_analysis.LinearDiscriminantAnalysis` with 'eigen' solver. [Fix]
• `linear_model.BayesianRidge` [Fix]
• Decision trees and derived ensembles when both max_depth and max_leaf_nodes are set. [Fix]
• `linear_model.LogisticRegression` and `linear_model.LogisticRegressionCV` with 'saga' solver. [Fix]
• `ensemble.GradientBoostingClassifier` [Fix]
• `sklearn.feature_extraction.text.HashingVectorizer`, `sklearn.feature_extraction.text.TfidfVectorizer`, and `sklearn.feature_extraction.text.CountVectorizer` [Fix]
• `neural_network.MLPClassifier` [Fix]
• `svm.SVC.decision_function` and `multiclass.OneVsOneClassifier.decision_function`. [Fix]
• `linear_model.SGDClassifier` and any derived classifiers. [Fix]
• Any model using the `linear_model._sag.sag_solver` function with a 0 seed, including `linear_model.LogisticRegression`, `linear_model.LogisticRegressionCV`, `linear_model.Ridge`, and `linear_model.RidgeCV` with ‘sag’ solver. [Fix]

• `linear_model.RidgeCV` when using leave-one-out cross-validation with sparse inputs. [Fix]

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

### Known Major Bugs

• The default `max_iter` for `linear_model.LogisticRegression` is too small for many solvers given the default `tol`. In particular, we accidentally changed the default `max_iter` for the liblinear solver from 1000 to 100 iterations in #3591 released in version 0.16. In a future release we hope to choose better default `max_iter` and `tol` heuristically depending on the solver (see #13317).

### Changelog

Support for Python 3.4 and below has been officially dropped.

#### sklearn.base

• [API CHANGE] The R2 score used when calling `score` on a regressor will use `multioutput='uniform_average'` from version 0.23 to keep consistent with `metrics.r2_score`. This will influence the `score` method of all the multioutput regressors (except for `multioutput.MultiOutputRegressor`). #13157 by Hanmin Qin.

#### sklearn.calibration

• [ENHANCEMENT] Added support to bin the data passed into `calibration.calibration_curve` by quantiles instead of uniformly between 0 and 1. #13086 by Scott Cole.

• [ENHANCEMENT] Allow n-dimensional arrays as input for `calibration.CalibratedClassifierCV`. #13485 by William de Vazelhes.

#### sklearn.cluster

• [MAJOR FEATURE] A new clustering algorithm: `cluster.OPTICS`: an algorithm related to `cluster.DBSCAN`, that has hyperparameters easier to set and that scales better, by Shane, Adrin Jalali, Erich Schubert, Hanmin Qin, and Assia Benbihi.

• [Fix] Fixed a bug where `cluster.Birch` could occasionally raise an AttributeError. #13651 by Joel Nothman.

• [Fix] Fixed a bug in `cluster.KMeans` where empty clusters weren’t correctly relocated when using sample weights. #13486 by Jérémie du Boisberranger.

• [API CHANGE] The `n_components` attribute in `cluster.AgglomerativeClustering` and `cluster.FeatureAgglomeration` has been renamed to `n_connected_components`. #13427 by Stephane Couvreur.
- [ENHANCEMENT] `cluster.AgglomerativeClustering` and `cluster.FeatureAgglomeration` now accept a `distance_threshold` parameter which can be used to find the clusters instead of `n_clusters`. #9069 by Vathsala Achar and Adrin Jalali.

**sklearn.compose**

- [API CHANGE] `compose.ColumnTransformer` is no longer an experimental feature. #13835 by Hanmin Qin.

**sklearn.datasets**

- [Fix] Added support for 64-bit group IDs and pointers in SVMLight files. #10727 by Bryan K Woods.
- [Fix] `datasets.load_sample_images` returns images with a deterministic order. #13250 by Thomas Fan.

**sklearn.decomposition**

- [Fix] Fixed a bug in `decomposition.KernelPCA`. `fit().transform()` now produces the correct output (the same as `fit_transform()`) in case of non-removed zero eigenvalues (`remove_zero_eig=False`). `fit_inverse_transform` was also accelerated by using the same trick as `fit_transform` to compute the transform of `X`. #12143 by Sylvain Marié.
- [Fix] Fixed a bug in `decomposition.NMF` where `init = 'nndsvd'`, `init = 'nndsvdA'`, and `init = 'nndsvdar'` are allowed when `n_components <= min(n_samples, n_features)`. #11650 by Hossein Pourbozorg and Zijie (ZJ) Poh.
- [API CHANGE] The default value of the `init` argument in `decomposition.NMF` will change from `random` to `None` in version 0.23 to make it consistent with `decomposition.NMF`. A FutureWarning is raised when the default value is used. #12988 by Zijie (ZJ) Poh.

**sklearn.discriminant_analysis**

- [ENHANCEMENT] `discriminant_analysis.LinearDiscriminantAnalysis` now preserves `float32` and `float64` dtypes. #8769 and #11000 by Thibault Sejourne.
- [Fix] A ChangedBehaviourWarning is now raised when `discriminant_analysis.LinearDiscriminantAnalysis` is given as parameter `n_components > min(n_features, n_classes - 1)`, and `n_components` is changed to `min(n_features, n_classes - 1)` if so. Previously the change was made, but silently. #11526 by William de Vazelhes.
- [Fix] Fixed a bug in `discriminant_analysis.LinearDiscriminantAnalysis` where the predicted probabilities would be incorrectly computed in the multiclass case. #6848, by Agamemnon Krasoulis and Guillaume Lemaitre <glemaitre>.
- [Fix] Fixed a bug in `discriminant_analysis.LinearDiscriminantAnalysis` where the predicted probabilities would be incorrectly computed with `eigen` solver. #11727, by Agamemnon Krasoulis.
sklearn.dummy

- [Fix] Fixed a bug in `dummy.DummyClassifier` where the `predict_proba` method was returning int32 array instead of float64 for the `stratified` strategy. #13266 by Christos Aridas.
- [Fix] Fixed a bug in `dummy.DummyClassifier` where it was throwing a dimension mismatch error in prediction time if a column vector y with shape=(n, 1) was given at `fit` time. #13545 by Nick Sorros and Adrin Jalali.

sklearn.ensemble

- [Major Feature] Add two new implementations of gradient boosting trees: `ensemble.HistGradientBoostingClassifier` and `ensemble.HistGradientBoostingRegressor`. The implementation of these estimators is inspired by LightGBM and can be orders of magnitude faster than `ensemble.GradientBoostingRegressor` and `ensemble.GradientBoostingClassifier` when the number of samples is larger than tens of thousands of samples. The API of these new estimators is slightly different, and some of the features from `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor` are not yet supported.

These new estimators are experimental, which means that their results or their API might change without any deprecation cycle. To use them, you need to explicitly import `enable_hist_gradient_boosting`:

```python
>>> # explicitly require this experimental feature
>>> from sklearn.experimental import enable_hist_gradient_boosting
# noqa
>>> # now you can import normally from sklearn.ensemble
>>> from sklearn.ensemble import HistGradientBoostingClassifier
#12807 by Nicolas Hug.
```

- [Efficiency] Make `ensemble.IsolationForest` prefer threads over processes when running with `n_jobs > 1` as the underlying decision tree fit calls do release the GIL. This changes reduces memory usage and communication overhead. #12543 by Isaac Storch and Olivier Grisel.

- [Efficiency] Make `ensemble.IsolationForest` more memory efficient by avoiding keeping in memory each tree prediction. #13260 by Nicolas Goix.

- [Efficiency] `ensemble.IsolationForest` now uses chunks of data at prediction step, thus capping the memory usage. #13283 by Nicolas Goix.

- [Efficiency] `sklearn.ensemble.GradientBoostingClassifier` and `sklearn.ensemble.GradientBoostingRegressor` now keep the input y as float64 to avoid it being copied internally by trees. #13524 by Adrin Jalali.

- [Enhancement] `ensemble.IsolationForest` now exposes `warm_start` parameter, allowing iterative addition of trees to an isolation forest. #13496 by Peter Marko.

  - sum up to 1
– all the single node trees in feature importance calculation are ignored
– in case all trees have only one single node (i.e. a root node), feature importances will be an array of all zeros.

#13636 and #13620 by Adrin Jalali.

• [Fix] Fixed a bug in `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor`, which didn’t support scikit-learn estimators as the initial estimator. Also added support of initial estimator which does not support sample weights. #12436 by Jérémie du Boisberranger and #12983 by Nicolas Hug.

• [Fix] Fixed the output of the average path length computed in `ensemble.IsolationForest` when the input is either 0, 1 or 2. #13251 by Albert Thomas and joshuakennethjones.

• [Fix] Fixed a bug in `ensemble.GradientBoostingClassifier` where the gradients would be incorrectly computed in multiclass classification problems. #12715 by Nicolas Hug.

• [Fix] Fixed a bug in `ensemble.GradientBoostingClassifier` where validation sets for early stopping were not sampled with stratification. #13164 by Nicolas Hug.

• [Fix] Fixed a bug in `ensemble.GradientBoostingClassifier` where the default initial prediction of a multiclass classifier would predict the classes priors instead of the log of the priors. #12983 by Nicolas Hug.

• [Fix] Fixed a bug in `ensemble.RandomForestClassifier` where the `predict` method would error for multiclass multioutput forests models if any targets were strings. #12834 by Elizabeth Sander.

• [Fix] Fixed a bug in `ensemble.gradient_boosting.LossFunction` and `ensemble.gradient_boosting.LeastSquaresError` where the default value of `learning_rate` in `update_terminal_regions` is not consistent with the document and the caller functions. Note however that directly using these loss functions is deprecated. #6463 by movelikeriver.

• [Fix] `ensemble.partial_dependence` (and consequently the new version `sklearn.inspection.partial_dependence`) now takes sample weights into account for the partial dependence computation when the gradient boosting model has been trained with sample weights. #13193 by Samuel O. Ronsin.

• [API CHANGE] `ensemble.partial_dependence` and `ensemble.plot_partial_dependence` are now deprecated in favor of `inspection.partial_dependence` and `inspection.plot_partial_dependence`. #12599 by Trevor Stephens and Nicolas Hug.

• [Fix] `ensemble.VotingClassifier` and `ensemble.VotingRegressor` were failing during `fit` in one of the estimators was set to `None` and `sample_weight` was not `None`. #13779 by Guillaume Lemaître.

• [API CHANGE] `ensemble.VotingClassifier` and `ensemble.VotingRegressor` accept 'drop' to disable an estimator in addition to None to be consistent with other estimators (i.e., `pipeline.FeatureUnion` and `compose.ColumnTransformer`). #13780 by Guillaume Lemaître.

---

**sklearn.externals**

• [API CHANGE] Deprecated `externals.six` since we have dropped support for Python 2.7. #12916 by Hanmin Qin.
**sklearn.feature_extraction**

- [Fix] If `input='file'` or `input='filename'`, and a callable is given as the `analyzer`, `sklearn.feature_extraction.text.HashingVectorizer`, `sklearn.feature_extraction.text.TfidfVectorizer`, and `sklearn.feature_extraction.text.CountVectorizer` now read the data from the file(s) and then pass it to the given `analyzer`, instead of passing the file name(s) or the file object(s) to the analyzer. #13641 by Adrin Jalali.

**sklearn.impute**

- [Major Feature] Added `impute.IterativeImputer`, which is a strategy for imputing missing values by modeling each feature with missing values as a function of other features in a round-robin fashion. #8478 and #12177 by Sergey Feldman and Ben Lawson.

  The API of IterativeImputer is experimental and subject to change without any deprecation cycle. To use them, you need to explicitly import `enable_iterative_imputer`:

  ```
  >>> from sklearn.experimental import enable_iterative_imputer  # noqa
  ... # now you can import normally from sklearn.impute
  >>> from sklearn.impute import IterativeImputer
  ```

- [Feature] The `impute.SimpleImputer` and `impute.IterativeImputer` have a new parameter 'add_indicator', which simply stacks a `impute.MissingIndicator` transform into the output of the imputer's transform. That allows a predictive estimator to account for missingness. #12583, #13601 by Danylo Baibak.

- [Fix] In `impute.MissingIndicator` avoid implicit densification by raising an exception if input is sparse and `missing_values` property is set to 0. #13240 by Bartosz Telenczuk.

- [Fix] Fixed two bugs in `impute.MissingIndicator`. First, when `X` is sparse, all the non-zero non missing values used to become explicit False in the transformed data. Then, when `features='missing-only'`, all features used to be kept if there were no missing values at all. #13562 by Jérémie du Boisberranger.

**sklearn.inspection**

(new subpackage)

- [Feature] Partial dependence plots (`inspection.plot_partial_dependence`) are now supported for any regressor or classifier (provided that they have a `predict_proba` method). #12599 by Trevor Stephens and Nicolas Hug.

**sklearn.isotonic**

- [Feature] Allow different dtypes (such as float32) in `isotonic.IsotonicRegression`. #8769 by Vlad Niculae
sklearn.linear_model

- **Enhancement** `linear_model.Ridge` now preserves float32 and float64 dtypes. #8769 and #11000 by Guillaume Lemaire and Joan Massich.

- **Feature** `linear_model.LogisticRegression` and `linear_model.LogisticRegressionCV` now support Elastic-Net penalty, with the ‘saga’ solver. #11646 by Nicolas Hug.

- **Feature** Added `linear_model.lars_path_gram`, which is `linear_model.lars_path` in the sufficient stats mode, allowing users to compute `linear_model.lars_path` without providing X and y. #11699 by Kuai Yu.

- **Enhancement** `linear_model.make_dataset` now preserves float32 and float64 dtypes, reducing memory consumption in stochastic gradient, SAG and SAGA solvers. #8769 and #11000 by Nelle Varoquaux, Arthur Imbert, Guillaume Lemaire, and Joan Massich.

- **Enhancement** `linear_model.LogisticRegression` now supports an unregularized objective when penalty='none' is passed. This is equivalent to setting C=np.inf with L2 regularization. Not supported by the liblinear solver. #12860 by Nicolas Hug.

- **Enhancement** sparse_cg solver in `linear_model.Ridge` now supports fitting the intercept (i.e. fit_intercept=True) when inputs are sparse. #13336 by Bartosz Telenczuk.

- **Enhancement** The coordinate descent solver used in Lasso, ElasticNet, etc. now issues a ConvergenceWarning when it completes without meeting the desired tolerance. #11754 and #13397 by Brent Fagan and Adrin Jalali.

- **Fix** Fixed a bug in `linear_model.LogisticRegression` and `linear_model.LogisticRegressionCV` with ‘saga’ solver, where the weights would not be correctly updated in some cases. #11646 by Tom Dupre la Tour.

- **Fix** Fixed the posterior mean, posterior covariance and returned regularization parameters in `linear_model.BayesianRidge`. The posterior mean and the posterior covariance were not the ones computed with the last update of the regularization parameters and the returned regularization parameters were not the final ones. Also fixed the formula of the log marginal likelihood used to compute the score when compute_score=True. #12174 by Albert Thomas.

- **Fix** Fixed a bug in `linear_model.LassoLarsIC`, where user input copy_X=False at instance creation would be overridden by default parameter value copy_X=True in fit. #12972 by Lucio Fernandez-Arjona.

- **Fix** Fixed a bug in `linear_model.LinearRegression` that was not returning the same coefficients and intercepts with fit_intercept=True in sparse and dense case. #13279 by Alexandre Gramfort.

- **Fix** Fixed a bug in `linear_model.HuberRegressor` that was broken when X was of dtype bool. #13328 by Alexandre Gramfort.

- **Fix** Fixed a performance issue of saga and sag solvers when called in a joblib.Parallel setting with n_jobs > 1 and backend="threading", causing them to perform worse than in the sequential case. #13389 by Pierre Glaser.

- **Fix** Fixed a bug in `linear_model.stochastic_gradient.BaseSGDClassifier` that was not deterministic when trained in a multi-class setting on several threads. #13422 by Clément Doumouro.

- **Fix** Fixed bug in `linear_model.ridge_regression` and `linear_model.RidgeClassifier` that caused unhandled exception for arguments return_intercept=True and solver=auto (default) or any other solver different from sag. #13363 by Bartosz Telenczuk.

- **Fix** `linear_model.ridge_regression` will now raise an exception if return_intercept=True and solver is different from sag. Previously, only warning was issued. #13363 by Bartosz Telenczuk.
• [Fix] `linear_model.ridge_regression` will choose `sparse_cg` solver for sparse inputs when `solver=auto` and `sample_weight` is provided (previously `cholesky` solver was selected). #13363 by Bartosz Telenczuk

• [API CHANGE] The use of `linear_model.lars_path` with `X=None` while passing `Gram` is deprecated in version 0.21 and will be removed in version 0.23. Use `linear_model.lars_path_gram` instead. #11699 by Kuai Yu.

• [API CHANGE] `linear_model.logistic_regression_path` is deprecated in version 0.21 and will be removed in version 0.23. #12821 by Nicolas Hug.

• [Fix] `linear_model.RidgeCV` with leave-one-out cross-validation now correctly fits an intercept when `fit_intercept=True` and the design matrix is sparse. #13350 by Jérôme Dockès

sklearn.manifold

• [Efficiency] Make `manifold.tsne.trustworthiness` use an inverted index instead of an `np.where` lookup to find the rank of neighbors in the input space. This improves efficiency in particular when computed with lots of neighbors and/or small datasets. #9907 by William de Vazelhes.

sklearn.metrics

• [Feature] Added the `metrics.max_error` metric and a corresponding 'max_error' scorer for single output regression. #12232 by Krishna Sangeeth.

• [Feature] Add `metrics.multilabel_confusion_matrix`, which calculates a confusion matrix with true positive, false positive, false negative and true negative counts for each class. This facilitates the calculation of set-wise metrics such as recall, specificity, fall out and miss rate. #11179 by Shangwu Yao and Joel Nothman.

• [Feature] `metrics.jaccard_score` has been added to calculate the Jaccard coefficient as an evaluation metric for binary, multilabel and multiclass tasks, with an interface analogous to `metrics.f1_score`. #13151 by Gaurav Dhingra and Joel Nothman.

• [Feature] Added `metrics.pairwise.haversine_distances` which can be accessed with metric='pairwise' through `metrics.pairwise_distances` and estimators. (Haversine distance was previously available for nearest neighbors calculation.) #12568 by Wei Xue, Emmanuel Arias and Joel Nothman.

• [Efficiency] Faster `metrics.pairwise_distances` with `n_jobs > 1` by using a thread-based backend, instead of process-based backends. #8216 by Pierre Glaser and Romuald Menuet

• [Efficiency] The pairwise manhattan distances with sparse input now uses the BLAS shipped with scipy instead of the bundled BLAS. #12732 by Jérémie du Boisberranger

• [Enhancement] Use label accuracy instead of micro-average on `metrics.classification_report` to avoid confusion. micro-average is only shown for multi-label or multi-class with a subset of classes because it is otherwise identical to accuracy. #12334 by Emmanuel Arias, Joel Nothman and Andreas Müller

• [Enhancement] Added `beta` parameter to `metrics.homogeneity_completeness_v_measure` and `metrics.v_measure_score` to configure the tradeoff between homogeneity and completeness. #13607 by Stephane Couvreur and and Ivan Sanchez.

• [Fix] The metric `metrics.r2_score` is degenerate with a single sample and now it returns NaN and raises exceptions. `UndefinedMetricWarning`. #12855 by Pawel Sendyk.

• [Fix] Fixed a bug where `metrics.brier_score_loss` will sometimes return incorrect result when there’s only one class in `y_true`. #13628 by Hanmin Qin.
• [Fix] Fixed a bug in metrics.label_ranking_average_precision_score where sample_weight wasn’t taken into account for samples with degenerate labels. #13447 by Dan Ellis.

• [API CHANGE] The parameter labels in metrics.hamming_loss is deprecated in version 0.21 and will be removed in version 0.23. #10580 by Reshama Shaikh and Sandra Mitrovic.

• [Fix] The function metrics.pairwise.euclidean_distances, and therefore several estimators with metric='euclidean', suffered from numerical precision issues with float32 features. Precision has been increased at the cost of a small drop of performance. #13554 by @Celelibi and Jérémie du Boisberranger.

• [API CHANGE] metrics.jaccard_similarity_score is deprecated in favour of the more consistent metrics.jaccard_score. The former behavior for binary and multiclass targets is broken. #13151 by Joel Nothman.

sklearn.mixture

• [Fix] Fixed a bug in mixture.BaseMixture and therefore on estimators based on it, i.e. mixture.GaussianMixture and mixture.BayesianGaussianMixture, where fit_predict and fit.predict were not equivalent. #13142 by Jérémie du Boisberranger.

sklearn.model_selection

• [Feature] Classes GridSearchCV and RandomizedSearchCV now allow for refit=callable to add flexibility in identifying the best estimator. See Balance model complexity and cross-validated score. #11354 by Wenhao Zhang, Joel Nothman and Adrin Jalali.

• [Enhancement] Classes GridSearchCV, RandomizedSearchCV, and methods cross_val_score, cross_val_predict, cross_validate, now print train scores when return_train_scores is True and verbose > 2. For learning_curve, and validation_curve only the latter is required. #12613 and #12669 by Marc Torrellas.

• [Enhancement] Some CV splitter classes and model_selection.train_test_split now raise ValueError when the resulting training set is empty. #12861 by Nicolas Hug.

• [Fix] Fixed a bug where model_selection.StratifiedKFold shuffles each class’s samples with the same random_state, making shuffle=True ineffective. #13124 by Hanmin Qin.

• [Fix] Added ability for model_selection.cross_val_predict to handle multi-label (and multoutput-multiclass) targets with predict_proba-type methods. #8773 by Stephen Hoover.

• [Fix] Fixed an issue in cross_val_predict where method="predict_proba" returned always 0.0 when one of the classes was excluded in a cross-validation fold. #13366 by Guillaume Fournier

sklearn.multiclass

• [Fix] Fixed an issue in multiclass.OneVsOneClassifier.decision_function where the decision_function value of a given sample was different depending on whether the decision_function was evaluated on the sample alone or on a batch containing this same sample due to the scaling used in decision_function. #10440 by Jonathan Ohayon.
sklearn.multioutput

• [Fix] Fixed a bug in multioutput.MultiOutputClassifier where the predict_proba method incorrectly checked for predict_proba attribute in the estimator object. #12222 by Rebekah Kim

sklearn.neighbors

• [Major Feature] Added neighbors.NeighborhoodComponentsAnalysis for metric learning, which implements the Neighborhood Components Analysis algorithm. #10058 by William de Vazelhes and John Chiotellis.

sklearn.neural_network

• [Fix] Fixed a bug in neural_network.MLPClassifier and neural_network.MLPRegressor where the option shuffle=False was being ignored. #12582 by Sam Waterbury.

• [Fix] Fixed a bug in neural_network.MLPClassifier where validation sets for early stopping were not sampled with stratification. In the multilabel case however, splits are still not stratified. #13164 by Nicolas Hug.

sklearn.pipeline

• [Feature] pipeline.Pipeline can now use indexing notation (e.g. my_pipeline[0:-1]) to extract a subsequence of steps as another Pipeline instance. A Pipeline can also be indexed directly to extract a particular step (e.g. my_pipeline['svc']), rather than accessing named_steps. #2568 by Joel Nothman.

• [Feature] Added optional parameter verbose in pipeline.Pipeline, compose.ColumnTransformer and pipeline.FeatureUnion and corresponding make_ helpers for showing progress and timing of each step. #11364 by Baze Petrushev, Karan Desai, Joel Nothman, and Thomas Fan.

• [Enhancement] pipeline.Pipeline now supports using 'passthrough' as a transformer, with the same effect as None. #11144 by Thomas Fan.

• [Enhancement] pipeline.Pipeline implements __len__ and therefore len(pipeline) returns the number of steps in the pipeline. #13439 by Lakshya KD.

sklearn.preprocessing

• [Feature] preprocessing.OneHotEncoder now supports dropping one feature per category with a new drop parameter. #12908 by Drew Johnston.

• [Efficiency] preprocessing.OneHotEncoder and preprocessing.OrdinalEncoder now handle pandas DataFrames more efficiently. #13253 by @maikia.

• [Efficiency] Make preprocessing.MultiLabelBinarizer cache class mappings instead of calculating it every time on the fly. #12116 by Ekaterina Krivich and Joel Nothman.

• [Efficiency] preprocessing.PolynomialFeatures now supports compressed sparse row (CSR) matrices as input for degrees 2 and 3. This is typically much faster than the dense case as it scales with matrix density and expansion degree (on the order of density^degree), and is much, much faster than the compressed sparse column (CSC) case. #12197 by Andrew Nystrom.
• [EFFICIENCY] Speed improvement in `preprocessing PolynomialFeatures`, in the dense case. Also added a new parameter `order` which controls output order for further speed performances. #12251 by Tom Dupre la Tour.

• [FIX] Fixed the calculation overflow when using a float16 dtype with `preprocessing StandardScaler`. #13007 by Raffaello Baluyot

• [FIX] Fixed a bug in `preprocessing QuantileTransformer` and `preprocessing QuantileTransformer` to force n_quantiles to be at most equal to n_samples. Values of n_quantiles larger than n_samples were either useless or resulting in a wrong approximation of the cumulative distribution function estimator. #13333 by Albert Thomas.

• [API CHANGE] The default value of `copy` in `preprocessing QuantileTransformer` will change from False to True in 0.23 in order to make it more consistent with the default copy values of other functions in `preprocessing` and prevent unexpected side effects by modifying the value of X inplace. #13459 by Hunter McGushion.

**sklearn.svm**

• [FIX] Fixed an issue in `svm SVC decision_function` when `decision_function_shape='ovr'`. The decision_function value of a given sample was different depending on whether the decision_function was evaluated on the sample alone or on a batch containing this same sample due to the scaling used in decision_function. #10440 by Jonathan Ohayon.

**sklearn.tree**

• [FEATURE] Decision Trees can now be plotted with matplotlib using `tree plot tree` without relying on the `dot` library, removing a hard-to-install dependency. #8508 by Andreas Müller.

• [FEATURE] Decision Trees can now be exported in a human readable textual format using `tree export text`. #6261 by Giuseppe Vettigli <JustGlowing>.

• [FEATURE] `get_n_leaves` and `get_depth` have been added to `tree BaseDecisionTree` and consequently all estimators based on it, including `tree DecisionTreeClassifier`, `tree DecisionTreeRegressor`, `tree ExtraTreeClassifier`, and `tree ExtraTreeRegressor`. #12300 by Adrin Jalali.

• [FIX] Trees and forests did not previously predict multi-output classification targets with string labels, despite accepting them in fit. #11458 by Mitar Milutinovic.

• [FIX] Fixed an issue with `tree BaseDecisionTree` and consequently all estimators based on it, including `tree DecisionTreeClassifier`, `tree DecisionTreeRegressor`, `tree ExtraTreeClassifier`, and `tree ExtraTreeRegressor`, where they used to exceed the given `max_depth` by 1 while expanding the tree if `max_leaf_nodes` and `max_depth` were both specified by the user. Please note that this also affects all ensemble methods using decision trees. #12344 by Adrin Jalali.
sklearn.utils

- [FEATURE] **utils.resample** now accepts a **stratify** parameter for sampling according to class distributions. #13549 by Nicolas Hug.

- [API CHANGE] Deprecated **warn_on_dtype** parameter from **utils.check_array** and **utils.check_X_y**. Added explicit warning for dtype conversion in **check_pairwise_arrays** if the metric being passed is a pairwise boolean metric. #13382 by Prathmesh Savale.

Multiple modules

- [MAJOR FEATURE] The **__repr__()** method of all estimators (used when calling **print(estimator)**) has been entirely re-written, building on Python's pretty printing standard library. All parameters are printed by default, but this can be altered with the **print_changed_only** option in **sklearn.set_config**. #11705 by Nicolas Hug.

- [MAJOR FEATURE] Add estimators tags: these are annotations of estimators that allow programmatic inspection of their capabilities, such as sparse matrix support, supported output types and supported methods. Estimator tags also determine the tests that are run on an estimator when **check_estimator** is called. Read more in the **User Guide**. #8022 by Andreas Müller.

- [EFFICIENCY] Memory copies are avoided when casting arrays to a different dtype in multiple estimators. #11973 by Roman Yurchak.

- [Fix] Fixed a bug in the implementation of the **our_rand_r** helper function that was not behaving consistently across platforms. #13422 by Madhura Parikh and Clément Doumouro.

Miscellaneous

- [ENHANCEMENT] Joblib is no longer vendored in scikit-learn, and becomes a dependency. Minimal supported version is joblib 0.11, however using version >= 0.13 is strongly recommended. #13531 by Roman Yurchak.

Changes to estimator checks

These changes mostly affect library developers.

- Add **check_fit_idempotent** to **check_estimator**, which checks that when **fit** is called twice with the same data, the output of **predict**, **predict_proba**, **transform**, and **decision_function** does not change. #12328 by Nicolas Hug

- Many checks can now be disabled or configured with **Estimator Tags**. #8022 by Andreas Müller.

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.20, including:

adanhawth, Aditya Vyas, Adrin Jalali, Agamemnon Krasoulis, Albert Thomas, Alberto Torres, Alexandre Gramfort, amourav, Andrea Navarrete, Andreas Mueller, Andrew Nystrom, assiaben, Aurélien Bellet, Bartosz Michalowski, Bartosz Telenczuk, bauks, BenjaStudio, bertrandhaut, Bharat Raghunathan, brentfagan, Bryan Woods, Cat Chenal, Cheuk Ting Ho, Chris Choe, Christos Aridas, Clément Doumouro, Cole Smith, Connessor, Corey Levinson, Dan Ellis, Dan Stine, Danylo Baibak, daten-kieker, Denis Kataev, Didi Bar-Zev, Dillon Gardner, Dmitry Mottl, Dmitry Vukolov, Dougal J. Sutherland, Dowon, drewmjohnston, Dror Atariah, Edward J Brown, Ekaterina Krivich, Elizabeth Sander, Emmanuel Arias, Eric Chang, Eric Larson, Erich Schubert, esvhd, Falak, Feda Curic, Federico Caselli,
1.7.12 Version 0.20.4

July 30, 2019

This is a bug-fix release with some bug fixes applied to version 0.20.3.

Changelog

The bundled version of joblib was upgraded from 0.13.0 to 0.13.2.

sklearn.cluster

- [Fix] Fixed a bug in cluster.KMeans where KMeans++ initialisation could rarely result in an IndexError. #11756 by Joel Nothman.

sklearn.compose

- [Fix] Fixed an issue in compose.ColumnTransformer where using DataFrames whose column order differs between :func:fit and :func:transform could lead to silently passing incorrect columns to the remainder transformer. #14237 by Andreas Schuderer <schuderer>.
sklearn.decomposition

- [Fix] Fixed a bug in cross_decomposition.CCA improving numerical stability when Y is close to zero. #13903 by Thomas Fan.

sklearn.model_selection

- [Fix] Fixed a bug where model_selection.StratifiedKFold shuffles each class’s samples with the same random_state, making shuffle=True ineffective. #13124 by Hanmin Qin.

sklearn.neighbors

- [Fix] Fixed a bug in neighbors.KernelDensity which could not be restored from a pickle if sample_weight had been used. #13772 by Aditya Vyas.

1.7.13 Version 0.20.3

March 1, 2019

This is a bug-fix release with some minor documentation improvements and enhancements to features released in 0.20.0.

Changelog

sklearn.cluster

- [Fix] Fixed a bug in cluster.KMeans where computation was single threaded when n_jobs > 1 or n_jobs = -1. #12949 by Prabakaran Kumaresshan.

sklearn.compose

- [Fix] Fixed a bug in compose.ColumnTransformer to handle negative indexes in the columns list of the transformers. #12946 by Pierre Tallotte.

sklearn.covariance

- [Fix] Fixed a regression in covariance.graphical_lasso so that the case n_features=2 is handled correctly. #13276 by Aurélien Bellet.
sklearn.decomposition

- [Fix] Fixed a bug in `decomposition.sparse_encode` where computation was single threaded when \( n_{\text{jobs}} > 1 \) or \( n_{\text{jobs}} = -1 \). #13005 by Prabakaran Kumaresshan.

sklearn.datasets

- [Efficiency] `sklearn.datasets.fetch_openml` now loads data by streaming, avoiding high memory usage. #13312 by Joris Van den Bossche.

sklearn.feature_extraction

- [Fix] Fixed a bug in `feature_extraction.text.CountVectorizer` which would result in the sparse feature matrix having conflicting `indptr` and `indices` precisions under very large vocabularies. #11295 by Gabriel Vacaliuc.

sklearn.impute

- [Fix] add support for non-numeric data in `sklearn.impute.MissingIndicator` which was not supported while `sklearn.impute.SimpleImputer` was supporting this for some imputation strategies. #13046 by Guillaume Lemaitre.

sklearn.linear_model

- [Fix] Fixed a bug in `linear_model.MultiTaskElasticNet` and `linear_model.MultiTaskLasso` which were breaking when `warm_start = True`. #12360 by Aakanksha Joshi.

sklearn.preprocessing

- [Fix] Fixed a bug in `preprocessing.KBinsDiscretizer` where `strategy='kmeans'` fails with an error during transformation due to unsorted bin edges. #13134 by Sandro Casagrande.
- [Fix] Fixed a bug in `preprocessing.OneHotEncoder` where the deprecation of `categorical_features` was handled incorrectly in combination with `handle_unknown='ignore'`. #12881 by Joris Van den Bossche.
- [Fix] Bins whose width are too small (i.e., <= 1e-8) are removed with a warning in `preprocessing.KBinsDiscretizer`. #13165 by Hanmin Qin.

sklearn.svm

- [Fix] Fixed a bug in `svm.SVC`, `svm.NuSVC`, `svm.SVR`, `svm.NuSVR` and `svm.OneClassSVM` where the `scale` option of parameter `gamma` is erroneously defined as \( 1 / (n_{\text{features}} \times X.\text{std}()) \). It's now defined as \( 1 / (n_{\text{features}} \times X.\text{var}()) \). #13221 by Hanmin Qin.
1.7.14 Version 0.20.2

December 20, 2018

This is a bug-fix release with some minor documentation improvements and enhancements to features released in 0.20.0.

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- `sklearn.neighbors` when `metric='jaccard'` (bug fix)
- Use of 'seuclidean' or 'mahalanobis' metrics in some cases (bug fix)

Changelog

sklearn.compose

- [FIX] Fixed an issue in `compose.make_column_transformer` which raises unexpected error when columns is pandas Index or pandas Series. #12704 by Hanmin Qin.

sklearn.metrics

- [FIX] Fixed a bug in `metrics.pairwise_distances` and `metrics.pairwise_distances_chunked` where parameters V of "seuclidean" and VI of "mahalanobis" metrics were computed after the data was split into chunks instead of being pre-computed on whole data. #12701 by Jeremie du Boisberranger.
**sklearn.neighbors**

- [Fix] Fixed `sklearn.neighbors.DistanceMetric.jaccard` distance function to return 0 when two all-zero vectors are compared. #12685 by Thomas Fan.

**sklearn.utils**

- [Fix] Calling `utils.check_array` on `pandas.Series` with categorical data, which raised an error in 0.20.0, now returns the expected output again. #12699 by Joris Van den Bossche.

**Code and Documentation Contributors**

With thanks to:

### 1.7.15 Version 0.20.1

**November 21, 2018**

This is a bug-fix release with some minor documentation improvements and enhancements to features released in 0.20.0. Note that we also include some API changes in this release, so you might get some extra warnings after updating from 0.20.0 to 0.20.1.

**Changed models**

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- `decomposition.IncrementalPCA` (bug fix)

**Changelog**

**sklearn.cluster**

- [Efficiency] make `cluster.MeanShift` no longer try to do nested parallelism as the overhead would hurt performance significantly when `n_jobs > 1`. #12159 by Olivier Grisel.
- [Fix] Fixed a bug in `cluster.DBSCAN` with precomputed sparse neighbors graph, which would add explicitly zeros on the diagonal even when already present. #12105 by Tom Dupre la Tour.
sklearn.compose

- [Fix] Fixed an issue in `compose.ColumnTransformer` when stacking columns with types not convertible to a numeric. #11912 by Adrin Jalali.
- [API CHANGE] `compose.ColumnTransformer` now applies the `sparse_threshold` even if all transformation results are sparse. #12304 by Andreas Müller.
- [API CHANGE] `compose.make_column_transformer` now expects `(transformer, columns)` instead of `(columns, transformer)` to keep consistent with `compose.ColumnTransformer`. #12339 by Adrin Jalali.

sklearn.datasets

- [Fix] `datasets.fetch_openml` to correctly use the local cache. #12246 by Jan N. van Rijn.
- [Fix] `datasets.fetch_openml` to correctly handle ignore attributes and row id attributes. #12330 by Jan N. van Rijn.
- [Fix] Fixed integer overflow in `datasets.make_classification` for values of `n_informative` parameter larger than 64. #10811 by Roman Feldbauer.
- [Fix] Fixed olivetti faces dataset `DESCR` attribute to point to the right location in `datasets.fetch_olivetti_faces`. #12441 by Jérémie du Boisberranger.
- [Fix] `datasets.fetch_openml` to retry downloading when reading from local cache fails. #12517 by Thomas Fan.

sklearn.decomposition

- [Fix] Fixed a regression in `decomposition.IncrementalPCA` where 0.20.0 raised an error if the number of samples in the final batch for fitting IncrementalPCA was smaller than `n_components`. #12234 by Ming Li.

sklearn.ensemble

- [Fix] Fixed a bug mostly affecting `ensemble.RandomForestClassifier` where `class_weight='balanced_subsample'` failed with more than 32 classes. #12165 by Joel Nothman.
- [Fix] Fixed a bug affecting `ensemble.BaggingClassifier, ensemble.BaggingRegressor` and `ensemble.IsolationForest`, where `max_features` was sometimes rounded down to zero. #12388 by Connor Tann.

sklearn.feature_extraction

- [Fix] Fixed a regression in v0.20.0 where `feature_extraction.text.CountVectorizer` and other text vectorizers could error during stop words validation with custom preprocessors or tokenizers. #12393 by Roman Yurchak.
sklearn.linear_model

- [Fix] `linear_model.SGDClassifier` and variants with early_stopping=True would not use a consistent validation split in the multiclass case and this would cause a crash when using those estimators as part of parallel parameter search or cross-validation. #12122 by Olivier Grisel.

- [Fix] Fixed a bug affecting SGDClassifier in the multiclass case. Each one-versus-all step is run in a `joblib.Parallel` call and mutating a common parameter, causing a segmentation fault if called within a backend using processes and not threads. We now use `require=sharedmem` at the `joblib.Parallel` instance creation. #12518 by Pierre Glaser and Olivier Grisel.

sklearn.metrics

- [Fix] Fixed a bug in `metrics.pairwise.pairwise_distances_argmin_min` which returned the square root of the distance when the metric parameter was set to “euclidean”. #12481 by Jérémie du Boisberranger.

- [Fix] Fixed a bug in `metrics.pairwise.pairwise_distances_chunked` which didn’t ensure the diagonal is zero for euclidean distances. #12612 by Andreas Müller.

- [API CHANGE] The `metrics.calinski_harabaz_score` has been renamed to `metrics.calinski_harabasz_score` and will be removed in version 0.23. #12211 by Lisa Thomas, Mark Hannel and Melissa Ferrari.

sklearn.mixture

- [Fix] Ensure that the fit_predict method of `mixture.GaussianMixture` and `mixture.BayesianGaussianMixture` always yield assignments consistent with fit followed by predict even if the convergence criterion is too loose or not met. #12451 by Olivier Grisel.

sklearn.neighbors

- [Fix] force the parallelism backend to threading for `neighbors.KDTree` and `neighbors.BallTree` in Python 2.7 to avoid pickling errors caused by the serialization of their methods. #12171 by Thomas Moreau.

sklearn.preprocessing

- [Fix] Fixed bug in `preprocessing.KBinsDiscretizer` where the transform method mutates the _encoder attribute. The transform method is now thread safe. #12514 by Hanmin Qin.

- [Fix] Fixed a bug in `preprocessing.PowerTransformer` where the Yeo-Johnson transform was incorrect for lambda parameters outside of [0, 2] #12522 by Nicolas Hug.

- [Fix] Fixed a bug in `preprocessing.OneHotEncoder` where transform failed when set to ignore unknown numpy strings of different lengths #12471 by Gabriel Marzinotto.

- [API CHANGE] The default value of the method argument in `preprocessing.power_transform` will be changed from `box-cox` to `yeo-johnson` to match `preprocessing.PowerTransformer` in version 0.23. A FutureWarning is raised when the default value is used. #12317 by Eric Chang.

1.7. Release History
sklearn.utils

• [Fix] Use float64 for mean accumulator to avoid floating point precision issues in preprocessing. StandardScaler and decomposition.IncrementalPCA when using float32 datasets. #12338 by bauks.

• [Fix] Calling utils.check_array on pandas.Series, which raised an error in 0.20.0, now returns the expected output again. #12625 by Andreas Müller

Miscellaneous

• [Fix] When using site joblib by setting the environment variable SKLEARN_SITE_JOBLIB, added compatibility with joblib 0.11 in addition to 0.12+. #12350 by Joel Nothman and Roman Yurchak.

• [Fix] Make sure to avoid raising FutureWarning when calling np.vstack with numpy 1.16 and later (use list comprehensions instead of generator expressions in many locations of the scikit-learn code base). #12467 by Olivier Grisel.

• [API CHANGE] Removed all mentions of sklearn.externals.joblib, and deprecated joblib methods exposed in sklearn.utils, except for utils.parallel_backend and utils.register_parallel_backend, which allow users to configure parallel computation in scikit-learn. Other functionalities are part of joblib package and should be used directly, by installing it. The goal of this change is to prepare for unvendoring joblib in future version of scikit-learn. #12345 by Thomas Moreau

1.7.16 Version 0.20.0

September 25, 2018

This release packs in a mountain of bug fixes, features and enhancements for the Scikit-learn library, and improvements to the documentation and examples. Thanks to our contributors!

This release is dedicated to the memory of Raghav Rajagopalan.

Warning: Version 0.20 is the last version of scikit-learn to support Python 2.7 and Python 3.4. Scikit-learn 0.21 will require Python 3.5 or higher.
Highlights

We have tried to improve our support for common data-science use-cases including missing values, categorical variables, heterogeneous data, and features/targets with unusual distributions. Missing values in features, represented by NaNs, are now accepted in column-wise preprocessing such as scalers. Each feature is fitted disregarding NaNs, and data containing NaNs can be transformed. The new impute module provides estimators for learning despite missing data.

ColumnTransformer handles the case where different features or columns of a pandas.DataFrame need different preprocessing. String or pandas Categorical columns can now be encoded with OneHotEncoder or OrdinalEncoder.

TransformedTargetRegressor helps when the regression target needs to be transformed to be modeled. PowerTransformer and KBinsDiscretizer join QuantileTransformer as non-linear transformations.

Beyond this, we have added sample_weight support to several estimators (including KMeans, BayesianRidge and KernelDensity) and improved stopping criteria in others (including MLPRegressor, GradientBoostingRegressor and SGDRegressor).

This release is also the first to be accompanied by a Glossary of Common Terms and API Elements developed by Joel Nothman. The glossary is a reference resource to help users and contributors become familiar with the terminology and conventions used in Scikit-learn.

Sorry if your contribution didn’t make it into the highlights. There’s a lot here…

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- cluster.MeanShift (bug fix)
- decomposition.IncrementalPCA (bug fix)
- decomposition.SparsePCA (bug fix)
- ensemble.GradientBoostingClassifier (bug fix affecting feature importances)
- isotonic.IsotonicRegression (bug fix)
- linear_model.ARDRegression (bug fix)
- linear_model.LogisticRegressionCV (bug fix)
- linear_model.OrthogonalMatchingPursuit (bug fix)
- linear_model.PassiveAggressiveClassifier (bug fix)
- linear_model.PassiveAggressiveRegressor (bug fix)
- linear_model.Perceptron (bug fix)
- linear_model.SGDClassifier (bug fix)
- linear_model.SGDRegressor (bug fix)
- metrics.roc_auc_score (bug fix)
- metrics.roc_curve (bug fix)
- neural_network.BaseMultilayerPerceptron (bug fix)
- neural_network.MLPClassifier (bug fix)
• `neural_network.MLPRegressor` (bug fix)

• The v0.19.0 release notes failed to mention a backwards incompatibility with `model_selection.StratifiedKFold` when `shuffle=True` due to #7823.

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

**Known Major Bugs**

• #11924: `linear_model.LogisticRegressionCV` with `solver='lbfgs'` and `multi_class='multinomial'` may be non-deterministic or otherwise broken on macOS. This appears to be the case on Travis CI servers, but has not been confirmed on personal MacBooks! This issue has been present in previous releases.

• #9354: `metrics.pairwise.euclidean_distances` (which is used several times throughout the library) gives results with poor precision, which particularly affects its use with 32-bit float inputs. This became more problematic in versions 0.18 and 0.19 when some algorithms were changed to avoid casting 32-bit data into 64-bit.

**Changelog**

Support for Python 3.3 has been officially dropped.

**sklearn.cluster**

• [**Major Feature**] `cluster.AgglomerativeClustering` now supports Single Linkage clustering via `linkage='single'`. #9372 by Leland McInnes and Steve Astels.

• [**Feature**] `cluster.KMeans` and `cluster.MiniBatchKMeans` now support sample weights via new parameter `sample_weight` in `fit` function. #10933 by Johannes Hansen.

• [**Efficiency**] `cluster.KMeans`, `cluster.MiniBatchKMeans` and `cluster.k_means` passed with `algorithm='full'` now enforces row-major ordering, improving runtime. #10471 by Gaurav Dhingra.

• [**Efficiency**] `cluster.DBSCAN` now is parallelized according to `n_jobs` regardless of `algorithm`. #8003 by Joël Billaud.

• [**Enhancement**] `cluster.KMeans` now gives a warning if the number of distinct clusters found is smaller than `n_clusters`. This may occur when the number of distinct points in the data set is actually smaller than the number of cluster one is looking for. #10059 by Christian Braune.

• [**Fix**] Fixed a bug where the `fit` method of `cluster.AffinityPropagation` stored cluster centers as 3d array instead of 2d array in case of non-convergence. For the same class, fixed undefined and arbitrary behavior in case of training data where all samples had equal similarity. #9612. By Jonatan Samooha.

• [**Fix**] Fixed a bug in `cluster.spectral_clustering` where the normalization of the spectrum was using a division instead of a multiplication. #8129 by Jan Margota, Guillaume Lemaître, and Devansh D..

• [**Fix**] Fixed a bug in `cluster.k_means_elkan` where the returned `iteration` was 1 less than the correct value. Also added the missing `n_iter_` attribute in the docstring of `cluster.KMeans`. #11353 by Jeremie du Boisberranger.

• [**Fix**] Fixed a bug in `cluster.mean_shift` where the assigned labels were not deterministic if there were multiple clusters with the same intensities. #11901 by Adrin Jalali.
scikit-learn user guide, Release 0.24.dev0

• [API CHANGE] Deprecate pooling_func unused parameter in cluster.
  AgglomerativeClustering. #9875 by Kumar Ashutosh.

sklearn.compose

• New module.
  - [MAJOR FEATURE] Added compose.ColumnTransformer, which allows to apply different transformers to different columns of arrays or pandas DataFrames. #9012 by Andreas Müller and Joris Van den Bossche, and #11315 by Thomas Fan.
  - [MAJOR FEATURE] Added the compose.TransformedTargetRegressor which transforms the target y before fitting a regression model. The predictions are mapped back to the original space via an inverse transform. #9041 by Andreas Müller and Guillaume Lemaitre.

sklearn.covariance

• [EFFICIENCY] Runtime improvements to covariance.GraphicalLasso. #9858 by Steven Brown.
• [API CHANGE] The covariance.graph_lasso, covariance.GraphLasso and covariance.GraphLassoCV have been renamed to covariance.graphical_lasso, covariance.GraphicalLasso and covariance.GraphicalLassoCV respectively and will be removed in version 0.22. #9993 by Artiem Krinitsyn

sklearn.datasets

• [MAJOR FEATURE] Added datasets.fetch_openml to fetch datasets from OpenML. OpenML is a free, open data sharing platform and will be used instead of mldata as it provides better service availability. #9908 by Andreas Müller and Jan N. van Rijn.
• [FEATURE] In datasets.make_blobs, one can now pass a list to the n_samples parameter to indicate the number of samples to generate per cluster. #8617 by Maskani Filali Mohamed and Konstantinos Katrioplas.
• [FEATURE] Add filename attribute to datasets that have a CSV file. #9101 by alex-33 and Maskani Filali Mohamed.
• [FEATURE] return_X_y parameter has been added to several dataset loaders. #10774 by Chris Catalfo.
• [FIX] Fixed a bug in datasets.load_boston which had a wrong data point. #10795 by Takeshi Yoshizawa.
• [FIX] Fixed a bug in datasets.load_iris which had two wrong data points. #11082 by Sadhana Srinivasan and Hanmin Qin.
• [FIX] Fixed a bug in datasets.fetch_kddcup99, where data were not properly shuffled. #9731 by Nicolas Goix.
• [FIX] Fixed a bug in datasets.make_circles, where no odd number of data points could be generated. #10045 by Christian Braune.
• [API CHANGE] Deprecated sklearn.datasets.fetch_mldata to be removed in version 0.22. ml-data.org is no longer operational. Until removal it will remain possible to load cached datasets. #11466 by Joel Nothman.
sklearn.decomposition

- [FEATURE] `decomposition.dict_learning` functions and models now support positivity constraints. This applies to the dictionary and sparse code. #6374 by John Kirkham.

- [FEATURE] [Fix] `decomposition.SparsePCA` now exposes `normalize_components`. When set to True, the train and test data are centered with the train mean respectively during the fit phase and the transform phase. This fixes the behavior of SparsePCA. When set to False, which is the default, the previous abnormal behaviour still holds. The False value is for backward compatibility and should not be used. #11585 by Ivan Panico.

- [EFFICIENCY] Efficiency improvements in `decomposition.dict_learning`. #11420 and others by John Kirkham.

- [Fix] Fix for uninformative error in `decomposition.IncrementalPCA`: now an error is raised if the number of components is larger than the chosen batch size. The `n_components=None` case was adapted accordingly. #6452. By Wally Gauze.

- [Fix] Fixed a bug where the `partial_fit` method of `decomposition.IncrementalPCA` used integer division instead of float division on Python 2. #9492 by James Bourbeau.

- [Fix] In `decomposition.PCA` selecting a `n_components` parameter greater than the number of samples now raises an error. Similarly, the `n_components=None` case now selects the minimum of `n_samples` and `n_features`. #8484 by Wally Gauze.

- [Fix] Fixed a bug in `decomposition.PCA` where users will get unexpected error with large datasets when `n_components='mle'` on Python 3 versions. #9886 by Hanmin Qin.

- [Fix] Fixed an underflow in calculating KL-divergence for `decomposition.NMF` #10142 by Tom Dupre la Tour.

- [Fix] Fixed a bug in `decomposition.SparseCoder` when running OMP sparse coding in parallel using read-only memory mapped datastructures. #5956 by Vighnesh Birodkar and Olivier Grisel.

sklearn.discriminant_analysis

- [EFFICIENCY] Memory usage improvement for `_class_means` and `_class_cov` in `discriminant_analysis`. #10898 by Nanxin Chen.

sklearn.dummy

- [FEATURE] `dummy.DummyRegressor` now has a `return_std` option in its `predict` method. The returned standard deviations will be zeros.

- [FEATURE] `dummy.DummyClassifier` and `dummy.DummyRegressor` now only require `X` to be an object with finite length or shape. #9832 by Vrishank Bhardwaj.

- [FEATURE] `dummy.DummyClassifier` and `dummy.DummyRegressor` can now be scored without supplying test samples. #11951 by Rüdiger Busche.
sklearn.ensemble

- [Feature] `ensemble.BaggingRegressor` and `ensemble.BaggingClassifier` can now be fit with missing/non-finite values in X and/or multi-output Y to support wrapping pipelines that perform their own imputation. #9707 by Jimmy Wan.

- [Feature] `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor` now support early stopping via `n_iter_no_change`, `validation_fraction` and `tol`. #7071 by Raghav RV.

- [Feature] Added `named_estimators_` parameter in `ensemble.VotingClassifier` to access fitted estimators. #9157 by Herilalaina Rakotoarison.

- [Fix] Fixed a bug when fitting `ensemble.GradientBoostingClassifier` or `ensemble.GradientBoostingRegressor` with `warm_start=True` which previously raised a segmentation fault due to a non-conversion of CSC matrix into CSR format expected by `decision_function`. Similarly, Fortran-ordered arrays are converted to C-ordered arrays in the dense case. #9991 by Guillaume Lemaitre.

- [Fix] Fixed a bug in `ensemble.GradientBoostingRegressor` and `ensemble.GradientBoostingClassifier` to have feature importances summed and then normalized, rather than normalizing on a per-tree basis. The previous behavior over-weighted the Gini importance of features that appear in later stages. This issue only affected feature importances. #11176 by Gil Forsyth.

- [API Change] The default value of the `n_estimators` parameter of `ensemble.RandomForestClassifier`, `ensemble.RandomForestRegressor`, `ensemble.ExtraTreesClassifier`, `ensemble.ExtraTreesRegressor`, and `ensemble.RandomTreesEmbedding` will change from 10 in version 0.20 to 100 in 0.22. A `FutureWarning` is raised when the default value is used. #11542 by Anna Ayzenshtat.

- [API Change] Classes derived from `ensemble.BaseBagging`. The attribute `estimators_samples_` will return a list of arrays containing the indices selected for each bootstrap instead of a list of arrays containing the mask of the samples selected for each bootstrap. Indices allows to repeat samples while mask does not allow this functionality. #9524 by Guillaume Lemaitre.

- [Fix] `ensemble.BaseBagging` where one could not deterministically reproduce fit result using the object attributes when `random_state` is set. #9723 by Guillaume Lemaitre.

sklearn.feature_extraction

- [Feature] Enable the call to `get_feature_names` in unfitted `feature_extraction.text.CountVectorizer` initialized with a vocabulary. #10908 by Mohamed Maskani.

- [Enhancement] `idf_` can now be set on a `feature_extraction.text.TfidfTransformer`. #10899 by Sergey Melderis.

- [Fix] Fixed a bug in `feature_extraction.image.extract_patches_2d` which would throw an exception if `max_patches` was greater than or equal to the number of all possible patches rather than simply returning the number of possible patches. #10101 by Varun Agrawal.

- [Fix] Fixed a bug in `feature_extraction.text.CountVectorizer`, `feature_extraction.text.TfidfVectorizer`, `feature_extraction.text.HashingVectorizer` to support 64 bit sparse array indexing necessary to process large datasets with more than $2 \times 10^9$ tokens (words or n-grams). #9147 by Claes-Fredrik Mannby and Roman Yurchak.

- [Fix] Fixed bug in `feature_extraction.text.TfidfVectorizer` which was ignoring the parameter `dtype`. In addition, `feature_extraction.text.TfidfTransformer` will preserve `dtype` for floating and raise a warning if `dtype` requested is integer. #10441 by Mayur Kulkarni and Guillaume Lemaitre.
sklearn.feature_selection

- [FEATURE] Added select K best features functionality to `feature_selection.SelectFromModel`. #6689 by Nihar Sheth and Quazi Rahman.
- [FEATURE] Added `min_features_to_select` parameter to `feature_selection.RFECV` to bound evaluated features counts. #11293 by Brent Yi.
- [FEATURE] `feature_selection.RFECV`'s fit method now supports `groups`. #9656 by Adam Greenhall.
- [FIX] Fixed computation of `n_features_to_compute` for edge case with tied CV scores in `feature_selection.RFECV`. #9222 by Nick Hoh.

sklearn.gaussian_process

- [EFFICIENCY] In `gaussian_process.GaussianProcessRegressor`, method `predict` is faster when using `return_std=True` in particular more when called several times in a row. #9234 by andrewwww and Minghui Liu.

sklearn.impute

- New module, adopting `preprocessing.Imputer` as `impute.SimpleImputer` with minor changes (see under preprocessing below).
- [MAJOR FEATURE] Added `impute.MissingIndicator` which generates a binary indicator for missing values. #8075 by Maniteja Nandana and Guillaume Lemaître.
- [FEATURE] The `impute.SimpleImputer` has a new strategy, 'constant', to complete missing values with a fixed one, given by the `fill_value` parameter. This strategy supports numeric and non-numeric data, and so does the 'most_frequent' strategy now. #11211 by Jeremie du Boisberranger.

sklearn.isotonic

- [FIX] Fixed a bug in `isotonic.IsotonicRegression` which incorrectly combined weights when fitting a model to data involving points with identical X values. #9484 by Dallas Card

sklearn.linear_model

- [FEATURE] `linear_model.SGDClassifier`, `linear_model.SGDRegressor`, `linear_model.PassiveAggressiveClassifier`, `linear_model.PassiveAggressiveRegressor` and `linear_model.Perceptron` now expose `early_stopping`, `validation_fraction` and `n_iter_no_change` parameters, to stop optimization monitoring the score on a validation set. A new learning rate "adaptive" strategy divides the learning rate by 5 each time `n_iter_no_change` consecutive epochs fail to improve the model. #9043 by Tom Dupre la Tour.
- [FIX] Fixed a bug in `logistic.logistic_regression_path` to ensure that the returned coefficients are correct when `multi_class='multinomial'`. Previously, some of the coefficients would override each other, leading to incorrect results in `linear_model.LogisticRegressionCV`. #11724 by Nicolas Hug.
• [Fix] Fixed a bug in `linear_model.LogisticRegression` where when using the parameter `multi_class='multinomial'`, the `predict_proba` method was returning incorrect probabilities in the case of binary outcomes. #9939 by Roger Westover.

• [Fix] Fixed a bug in `linear_model.LogisticRegressionCV` where the `score` method always computes accuracy, not the metric given by the `scoring` parameter. #10998 by Thomas Fan.

• [Fix] Fixed a bug in `linear_model.LogisticRegressionCV` where the 'ovr' strategy was always used to compute cross-validation scores in the multiclass setting, even if 'multinomial' was set. #8720 by William de Vazelhes.

• [Fix] Fixed a bug in `linear_model.OrthogonalMatchingPursuit` that was broken when setting `normalize=False`. #10071 by Alexandre Gramfort.

• [Fix] Fixed a bug in `linear_model.ARDRegression` which caused incorrectly updated estimates for the standard deviation and the coefficients. #10153 by Jörg Döpfert.

• [Fix] Fixed a bug in `linear_model.ARDRegression` and `linear_model.BayesianRidge` which caused NaN predictions when fitted with a constant target. #10095 by Jörg Döpfert.

• [API CHANGE] The default values of the `solver` and `multi_class` parameters of `linear_model.LogisticRegression` will change respectively from 'liblinear' and 'ovr' in version 0.20 to 'lbfgs' and 'auto' in version 0.22. A FutureWarning is raised when the default values are used. #11905 by Tom Dupre la Tour.

• [API CHANGE] Deprecate `positive=True` option in `linear_model.Lars` as the underlying implementation is broken. Use `linear_model.Lasso` instead. #9837 by Alexandre Gramfort.

• [API CHANGE] `n_iter_` may vary from previous releases in `linear_model.LogisticRegression` with `solver='lbfgs'` and `linear_model.HuberRegressor`. For Scipy <= 1.0.0, the optimizer could perform more than the requested maximum number of iterations. Now both estimators will report at most `max_iter` iterations even if more were performed. #10723 by Joel Nothman.
sklearn.manifold

- **[Efficiency]** Speed improvements for both ‘exact’ and ‘barnes_hut’ methods in manifold.TSNE. #10593 and #10610 by Tom Dupre la Tour.
- **[Feature]** Support sparse input in manifold.Isomap.fit. #8554 by Leland McInnes.
- **[Feature]** manifold.t_sne.trustworthiness accepts metrics other than Euclidean. #9775 by William de Vazelhes.
- **[Fix]** Fixed a bug in manifold.spectral_embedding where the normalization of the spectrum was using a division instead of a multiplication. #8129 by Jan Margeta, Guillaume Lemaître, and Devansh D.
- **[API Change] [Feature]** Deprecate precomputed parameter in function manifold.t_sne.trustworthiness. Instead, the new parameter metric should be used with any compatible metric including ‘precomputed’, in which case the input matrix X should be a matrix of pairwise distances or squared distances. #9775 by William de Vazelhes.

sklearn.metrics

- **[Major Feature]** Added the metrics.davies_bouldin_score metric for evaluation of clustering models without a ground truth. #10827 by Luis Osa.
- **[Major Feature]** Added the metrics.balanced_accuracy_score metric and a corresponding 'balanced_accuracy' scorer for binary and multiclass classification. #8066 by @xyguo and Aman Dalmia, and #10587 by Joel Nothman.
- **[Feature]** Partial AUC is available via max_fpr parameter in metrics.roc_auc_score. #3840 by Alexander Niederbühl.
- **[Feature]** A scorer based on metrics.brier_score_loss is also available. #9521 by Hanmin Qin.
- **[Feature]** Added control over the normalization in metrics.normalized_mutual_info_score and metrics.adjusted_mutual_info_score via the average_method parameter. In version 0.22, the default normalizer for each will become the arithmetic mean of the entropies of each clustering. #11124 by Arya McCarthy.
- **[Feature]** Added output_dict parameter in metrics.classification_report to return classification statistics as dictionary. #11160 by Dan Barkhorn.
- **[Feature]** metrics.classification_report now reports all applicable averages on the given data, including micro, macro and weighted average as well as samples average for multilabel data. #11679 by Alexander Pacha.
- **[Feature]** metrics.average_precision_score now supports binary y_true other than {0, 1} or {-1, 1} through pos_label parameter. #9980 by Hanmin Qin.
- **[Feature]** metrics.label_ranking_average_precision_score now supports sample_weight. #10845 by Jose Perez-Parras Toledano.
- **[Feature]** Add dense_output parameter to metrics.pairwise.linear_kernel. When False and both inputs are sparse, will return a sparse matrix. #10999 by Taylor G Smith.
- **[Efficiency]** metrics.silhouette_score and metrics.silhouette_samples are more memory efficient and run faster. This avoids some reported freezes and MemoryErrors. #11135 by Joel Nothman.
• [Fix] Fixed a bug in `metrics.precision_recall_fscore_support` when truncated `range(n_labels)` is passed as value for `labels`. #10377 by Gaurav Dhingra.

• [Fix] Fixed a bug due to floating point error in `metrics.roc_auc_score` with non-integer sample weights. #9786 by Hanmin Qin.

• [Fix] Fixed a bug where `metrics.roc_curve` sometimes starts on y-axis instead of (0, 0), which is inconsistent with the document and other implementations. Note that this will not influence the result from `metrics.roc_auc_score` #10093 by alexyndin and Hanmin Qin.

• [Fix] Fixed a bug to avoid integer overflow. Casted product to 64 bits integer in `metrics.mutual_info_score`. #9772 by Kumar Ashutosh.

• [Fix] Fixed a bug where `metrics.average_precision_score` will sometimes return nan when `sample_weight` contains 0. #9980 by Hanmin Qin.

• [Fix] Fixed a bug in `metrics.fowlkes_mallows_score` to avoid integer overflow. Casted return value of `contingency_matrix` to int64 and computed product of square roots rather than square root of product. #9515 by Alan Liddell and Manh Dao.

• [API Change] Deprecate `reorder` parameter in `metrics.auc` as it’s no longer required for `metrics.roc_auc_score`. Moreover using `reorder=True` can hide bugs due to floating point error in the input. #9851 by Hanmin Qin.

• [API Change] In `metrics.normalized_mutual_info_score` and `metrics.adjusted_mutual_info_score`, warn that `average_method` will have a new default value. In version 0.22, the default normalizer for each will become the `arithmetic` mean of the entropies of each clustering. Currently, `metrics.normalized_mutual_info_score` uses the default of `average_method='geometric'`, and `metrics.adjusted_mutual_info_score` uses the default of `average_method='max'` to match their behaviors in version 0.19. #11124 by Arya McCarthy.

• [API Change] The `batch_size` parameter to `metrics.pairwise_distances_argmin_min` and `metrics.pairwise_distances_argmin` is deprecated to be removed in v0.22. It no longer has any effect, as batch size is determined by global `working_memory` config. See Limiting Working Memory. #10280 by Joel Nothman and Aman Dalmia.

**sklearn.mixture**

• [Feature] Added function `fit_predict` to `mixture.GaussianMixture` and `mixture.GaussianMixture`, which is essentially equivalent to calling `fit` and `predict`. #10336 by Shu Haoran and Andrew Peng.

• [Fix] Fixed a bug in `mixture.BaseMixture` where the reported `n_iter_` was missing an iteration. It affected `mixture.GaussianMixture` and `mixture.BayesianGaussianMixture`. #10740 by Erich Schubert and Guillaume Lemaître.

• [Fix] Fixed a bug in `mixture.BaseMixture` and its subclasses `mixture.GaussianMixture` and `mixture.BayesianGaussianMixture` where the `lower_bound_` was not the max lower bound across all initializations (when `n_init > 1`), but just the lower bound of the last initialization. #10869 by Aurélien Géron.
**sklearn.model_selection**

- **[Feature]** Add `return_estimator` parameter in `model_selection.cross_validate` to return estimators fitted on each split. #9686 by Aurélien Bellet.

- **[Feature]** New `refit_time_` attribute will be stored in `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` if `refit` is set to True. This will allow measuring the complete time it takes to perform hyperparameter optimization and refitting the best model on the whole dataset. #11310 by Matthias Feurer.

- **[Feature]** Expose `error_score` parameter in `model_selection.cross_validate`, `model_selection.cross_val_score`, `model_selection.learning_curve` and `model_selection.validation_curve` to control the behavior triggered when an error occurs in `model_selection._fit_and_score`. #11576 by Samuel O. Ronsin.

- **[Feature]** `BaseSearchCV` now has an experimental, private interface to support customized parameter search strategies, through its `__run_search` method. See the implementations in `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` and please provide feedback if you use this. Note that we do not assure the stability of this API beyond version 0.20. #9599 by Joel Nothman

- **[Enhancement]** Add improved error message in `model_selection.cross_val_score` when multiple metrics are passed in `scoring` keyword. #11006 by Ming Li.

- **[API Change]** The default number of cross-validation folds `cv` and the default number of splits `n_splits` in `model_selection.KFold`-like splitters will change from 3 to 5 in 0.22 as 3-fold has a lot of variance. #11557 by Alexandre Boucaud.

- **[API Change]** The default of `iid` parameter of `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` will change from True to False in version 0.22 to correspond to the standard definition of cross-validation, and the parameter will be removed in version 0.24 altogether. This parameter is of greatest practical significance where the sizes of different test sets in cross-validation were very unequal, i.e. in group-based CV strategies. #9085 by Laurent Diler and Andreas Müller.

- **[API Change]** The default value of the `error_score` parameter in `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` will change to `np.NaN` in version 0.22. #10677 by Kirill Zhdanovich.

- **[API Change]** Changed `ValueError` exception raised in `model_selection.ParameterSampler` to a `UserWarning` for case where the class is instantiated with a greater value of `n_iter` than the total space of parameters in the parameter grid. `n_iter` now acts as an upper bound on iterations. #10982 by Juliet Lawton

- **[API Change]** Invalid input for `model_selection.ParameterGrid` now raises `TypeError`. #10928 by Solitus Immensus

**sklearn.multioutput**

- **[Major Feature]** Added `multioutput.RegressorChain` for multi-target regression. #9257 by Kumar Ashutosh.
scikit-learn user guide, Release 0.24.dev0

sklearn.naive_bayes

- **[Major feature]** Added `naive_bayes.ComplementNB`, which implements the Complement Naive Bayes classifier described in Rennie et al. (2003). #8190 by Michael A. Alcorn.
- **[Feature]** Added `var_smoothing` parameter in `naive_bayes.GaussianNB` to give a precise control over variances calculation. #9681 by Dmitry Mottl.
- **[Fix]** Fixed a bug in `naive_bayes.GaussianNB` which incorrectly raised error for prior list which summed to 1. #10005 by Gaurav Dhingra.
- **[Fix]** Fixed a bug in `naive_bayes.MultinomialNB` which did not accept vector valued pseudocounts (alpha). #10346 by Tobias Madsen.

sklearn.neighbors

- **[Efficiency]** `neighbors.RadiusNeighborsRegressor` and `neighbors.RadiusNeighborsClassifier` are now parallelized according to `n_jobs` regardless of algorithm. #10887 by Joël Billaud.
- **[Efficiency]** Nearest neighbors query methods are now more memory efficient when `algorithm='brute'`. #11136 by Joel Nothman and Aman Dalmia.
- **[Feature]** Add `sample_weight` parameter to the `fit` method of `neighbors.KernelDensity` to enable weighting in kernel density estimation. #4394 by Samuel O. Ronsin.
- **[Feature]** Novelty detection with `neighbors.LocalOutlierFactor`: Add a novelty parameter to `neighbors.LocalOutlierFactor`. When novelty is set to True, `neighbors.LocalOutlierFactor` can then be used for novelty detection, i.e. predict on new unseen data. Available prediction methods are `predict`, `decision_function` and `score_samples`. By default, novelty is set to False, and only the `fit_predict` method is available. By Albert Thomas.
- **[Fix]** Fixed a bug in `neighbors.NearestNeighbors` where fitting a NearestNeighbors model fails when a) the distance metric used is a callable and b) the input to the NearestNeighbors model is sparse. #9579 by Thomas Kober.
- **[Fix]** Fixed a bug so `predict` in `neighbors.RadiusNeighborsRegressor` can handle empty neighbor set when using non uniform weights. Also raises a new warning when no neighbors are found for samples. #9655 by Andreas Bjerre-Nielsen.
- **[Fix][Efficiency]** Fixed a bug in `KDTree` construction that results in faster construction and querying times. #11556 by Jake VanderPlas.
- **[Fix]** Fixed a bug in `neighbors.KDTree` and `neighbors.BallTree` where pickled tree objects would change their type to the super class `BinaryTree`. #11774 by Nicolas Hug.

sklearn.neural_network

- **[Feature]** Add `n_iter_no_change` parameter in `neural_network.BaseMultilayerPerceptron`, `neural_network.MLPRegressor`, and `neural_network.MLPClassifier` to give control over maximum number of epochs to not meet `tol` improvement. #9456 by Nicholas Nadeau.
- **[Fix]** Fixed a bug in `neural_network.BaseMultilayerPerceptron`, `neural_network.MLPRegressor` and `neural_network.MLPClassifier` with new `n_iter_no_change` parameter now at 10 from previously hardcoded 2. #9456 by Nicholas Nadeau.
- [Fix] Fixed a bug in `neural_network.MLPRegressor` where fitting quit unexpectedly early due to local minima or fluctuations. #9456 by Nicholas Nadeau

### sklearn.pipeline

- [Feature] The `predict` method of `pipeline.Pipeline` now passes keyword arguments on to the pipeline’s last estimator, enabling the use of parameters such as `return_std` in a pipeline with caution. #9304 by Breno Freitas.

- [API Change] `pipeline.FeatureUnion` now supports `'drop'` as a transformer to drop features. #11144 by Thomas Fan.

### sklearn.preprocessing

- [Major Feature] Expanded `preprocessing.OneHotEncoder` to allow to encode categorical string features as a numeric array using a one-hot (or dummy) encoding scheme, and added `preprocessing.OrdinalEncoder` to convert to ordinal integers. Those two classes now handle encoding of all feature types (also handles string-valued features) and derives the categories based on the unique values in the features instead of the maximum value in the features. #9151 and #10521 by Vighnesh Birodkar and Joris Van den Bossche.

- [Major Feature] Added `preprocessing.KBinsDiscretizer` for turning continuous features into categorical or one-hot encoded features. #7668, #9647, #10195, #10192, #11272, #11467 and #11505. by Henry Lin, Hanmin Qin, Tom Dupre la Tour and Giovanni Giuseppe Costa.

- [Major Feature] Added `preprocessing.PowerTransformer`, which implements the Yeo-Johnson and Box-Cox power transformations. Power transformations try to find a set of feature-wise parametric transformations to approximately map data to a Gaussian distribution centered at zero and with unit variance. This is useful as a variance-stabilizing transformation in situations where normality and homoscedasticity are desirable. #10210 by Eric Chang and Maniteja Nandana, and #11520 by Nicolas Hug.

- [Major Feature] NaN values are ignored and handled in the following preprocessing methods: `preprocessing.MaxAbsScaler`, `preprocessing.MinMaxScaler`, `preprocessing.RobustScaler`, `preprocessing.StandardScaler`, `preprocessing.PowerTransformer`, `preprocessing.QuantileTransformer` classes and `preprocessing.maxabs_scale`, `preprocessing.minmax_scale`, `preprocessing.robust_scale`, `preprocessing.scale`, `preprocessing.power_transform`, `preprocessing.quantile_transform` functions respectively addressed in issues #11011, #11005, #11308, #11206, #11306, and #10437. By Lucija Gregov and Guillaume Lemaître.

- [Feature] `preprocessing.PolynomialFeatures` now supports sparse input. #10452 by Aman Dalmia and Joel Nothman.

- [Feature] `preprocessing.RobustScaler` and `preprocessing.robust_scale` can be fitted using sparse matrices. #11308 by Guillaume Lemaître.

- [Feature] `preprocessing.OneHotEncoder` now supports the `get_feature_names` method to obtain the transformed feature names. #10181 by Nirvan Anjirbag and Joris Van den Bossche.

- [Feature] A parameter `check_inverse` was added to `preprocessing.FunctionTransformer` to ensure that `func` and `inverse_func` are the inverse of each other. #9399 by Guillaume Lemaître.

- [Feature] The transform method of `sklearn.preprocessing.MultiLabelBinarizer` now ignores any unknown classes. A warning is raised stating the unknown classes classes found which are ignored. #10913 by Rodrigo Agundez.

- [Fix] Fixed bugs in `preprocessing.LabelEncoder` which would sometimes throw errors when `transform` or `inverse_transform` was called with empty arrays. #10458 by Mayur Kulkarni.
• [Fix] Fix ValueError in `preprocessing.LabelEncoder` when using `inverse_transform` on unseen labels. #9816 by Charlie Newey.

• [Fix] Fix bug in `preprocessing.OneHotEncoder` which discarded the `dtype` when returning a sparse matrix output. #11042 by Daniel Morales.

• [Fix] Fix `fit` and `partial_fit` in `preprocessing.StandardScaler` in the rare case when `with_mean=False` and `with_std=False` which was crashing by calling `fit` more than once and giving inconsistent results for `mean_` whether the input was a sparse or a dense matrix. `mean_` will be set to `None` with both sparse and dense inputs. `n_samples_seen_` will be also reported for both input types. #11235 by Guillaume Lemaitre.

• [API CHANGE] Deprecate `n_values` and `categorical_features` parameters and `active_features_`, `feature_indices_` and `n_values_` attributes of `preprocessing.OneHotEncoder`. The `n_values` parameter can be replaced with the new `categories_` parameter, and the attributes with the new `categories_` attribute. Selecting the categorical features with the `categorical_features` parameter is now better supported using the `compose.ColumnTransformer`. #10521 by Joris Van den Bossche.

• [API CHANGE] Deprecate `preprocessing.Imputer` and move the corresponding module to `impute.SimpleImputer`. #9726 by Kumar Ashutosh.

• [API CHANGE] The `axis` parameter that was in `preprocessing.Imputer` is no longer present in `impute.SimpleImputer`. The behavior is equivalent to `axis=0` (impute along columns). Row-wise imputation can be performed with `FunctionTransformer` (e.g., `FunctionTransformer(lambda X: SimpleImputer().fit_transform(X.T).T)`). #10829 by Guillaume Lemaitre and Gilberto Olimpio.

• [API CHANGE] The NaN marker for the missing values has been changed between the `preprocessing.Imputer` and the `impute.SimpleImputer`. `missing_values='NaN'` should now be `missing_values=np.nan`. #11211 by Jeremie du Boisberranger.

• [API CHANGE] In `preprocessing.FunctionTransformer`, the default of `validate` will be from `True` to `False` in 0.22. #10655 by Guillaume Lemaitre.

**sklearn.svm**

• [Fix] Fixed a bug in `svm.SVC` where when the argument `kernel` is unicode in Python2, the `predict_probas` method was raising an unexpected TypeError given dense inputs. #10412 by Jiongyan Zhang.

• [API CHANGE] Deprecate `random_state` parameter in `svm.OneClassSVM` as the underlying implementation is not random. #9497 by Albert Thomas.

• [API CHANGE] The default value of `gamma` parameter of `svm.SVC`, `NuSVC`, `SVR`, `NuSVR`, `OneClassSVM` will change from 'auto' to 'scale' in version 0.22 to account better for unscaled features. #8361 by Gaurav Dhingra and Ting Neo.
sklearn.tree

- [**Enhancement**] Although private (and hence not assured API stability), `tree._criterion.ClassificationCriterion` and `tree._criterion.RegressionCriterion` may now be cimported and extended. #10325 by Camil Staps.

- [**Fix**] Fixed a bug in `tree.BaseDecisionTree` with `splitter="best"` where split threshold could become infinite when values in X were near infinite. #10536 by Jonathan Ohayon.

- [**Fix**] Fixed a bug in `tree.MAE` to ensure sample weights are being used during the calculation of tree MAE impurity. Previous behaviour could cause suboptimal splits to be chosen since the impurity calculation considered all samples to be of equal weight importance. #11464 by John Stott.

sklearn.utils

- [**Feature**] `utils.check_array` and `utils.check_X_y` now have `accept_large_sparse` to control whether scipy.sparse matrices with 64-bit indices should be rejected. #11327 by Karan Dhingra and Joel Nothman.

- [**Efficiency**] [**Fix**] Avoid copying the data in `utils.check_array` when the input data is a memmap (and `copy=False`). #10663 by Arthur Mensch and Loïc Estève.

- [**API Change**] `utils.check_array` yield a `FutureWarning` indicating that arrays of bytes/strings will be interpreted as decimal numbers beginning in version 0.22. #10229 by Ryan Lee

Multiple modules

- [**Feature**] [**API Change**] More consistent outlier detection API: Add a `score_samples` method in `svm.OneClassSVM`, `ensemble.IsolationForest`, `neighbors.LocalOutlierFactor`, `covariance.EllipticEnvelope`. It allows to access raw score functions from original papers. A new `offset_` parameter allows to link `score_samples` and `decision_function` methods. The contamination parameter of `ensemble.IsolationForest` and `neighbors.LocalOutlierFactor` `decision_function` methods is used to define this `offset_` such that outliers (resp. inliers) have negative (resp. positive) `decision_function` values. By default, contamination is kept unchanged to 0.1 for a deprecation period. In 0.22, it will be set to “auto”, thus using method-specific score offsets. In `covariance.EllipticEnvelope` `decision_function` method, the `raw_values` parameter is deprecated as the shifted Mahalanobis distance will be always returned in 0.22. #9015 by Nicolas Goix.

- [**Feature**] [**API Change**] A `behaviour` parameter has been introduced in `ensemble.IsolationForest` to ensure backward compatibility. In the old behaviour, the `decision_function` is independent of the contamination parameter. A threshold attribute depending on the contamination parameter is thus used. In the new behaviour the `decision_function` is dependent on the contamination parameter, in such a way that 0 becomes its natural threshold to detect outliers. Setting `behaviour` to “old” is deprecated and will not be possible in version 0.22. Beside, the behaviour parameter will be removed in 0.24. #11553 by Nicolas Goix.

- [**API Change**] Added convergence warning to `svm.LinearSVC` and `linear_model.LogisticRegression` when `verbose` is set to 0. #10881 by Alexandre Sevin.

decomposition.fastica, cross_decomposition.PLSCanonical, cluster.
AffinityPropagation, and cluster.Birch. #10306 by Jonathan Siebert.

Miscellaneous

- [Major Feature] A new configuration parameter, working_memory was added to control memory consumption limits in chunked operations, such as the new metrics.pairwise_distances_chunked. See Limiting Working Memory. #10280 by Joel Nothman and Aman Dalmia.
- [Feature] The version of joblib bundled with Scikit-learn is now 0.12. This uses a new default multiprocessing implementation, named loky. While this may incur some memory and communication overhead, it should provide greater cross-platform stability than relying on Python standard library multiprocessing. #11741 by the Joblib developers, especially Thomas Moreau and Olivier Grisel.
- [Feature] An environment variable to use the site joblib instead of the vendored one was added (Environment variables). The main API of joblib is now exposed in sklearn.utils. #11166 by Gael Varoquaux.
- [Feature] Add almost complete PyPy 3 support. Known unsupported functionalities are datasets.load_svmlight_file, feature_extraction.FeatureHasher and feature_extraction.text.HashingVectorizer. For running on PyPy, PyPy3-v5.10+, Numpy 1.14.0+, and scipy 1.1.0+ are required. #11010 by Ronan Lamy and Roman Yurchak.
- [Feature] A utility method sklearn.show_versions was added to print out information relevant for debugging. It includes the user system, the Python executable, the version of the main libraries and BLAS binding information. #11596 by Alexandre Boucaud
- [Fix] Fixed a bug when setting parameters on meta-estimator, involving both a wrapped estimator and its parameter. #9999 by Marcus Voss and Joel Nothman.
- [Fix] Fixed a bug where calling sklearn.base.clone was not thread safe and could result in a “pop from empty list” error. #9569 by Andreas Müller.
- [API Change] The default value of n_jobs is changed from 1 to None in all related functions and classes. n_jobs=None means unset. It will generally be interpreted as n_jobs=1, unless the current joblib. Parallel backend context specifies otherwise (See Glossary for additional information). Note that this change happens immediately (i.e., without a deprecation cycle). #11741 by Olivier Grisel.
- [Fix] Fixed a bug in validation helpers where passing a Dask DataFrame results in an error. #12462 by Zachariah Miller

Changes to estimator checks

These changes mostly affect library developers.

- Checks for transformers now apply if the estimator implements transform, regardless of whether it inherits from sklearn.base.TransformerMixin. #10474 by Joel Nothman.
- Classifiers are now checked for consistency between decision_function and categorical predictions. #10500 by Narine Kokhlikyan.
- Allow tests in utils.estimator_checks.check_estimator to test functions that accept pairwise data. #9701 by Kyle Johnson
- Allow utils.estimator_checks.check_estimator to check that there is no private settings apart from parameters during estimator initialization. #9378 by Herilalaina Rakotoarison
- The set of checks in utils.estimator_checks.check_estimator now includes a check_set_params test which checks that set_params is equivalent to passing parameters in __init__ and warns if it encounters parameter validation. #7738 by Alvin Chiang
• Add invariance tests for clustering metrics. #8102 by Ankita Sinha and Guillaume Lemaître.

• Add `check_methods_subset_invariance` to `check_estimator`, which checks that estimator methods are invariant if applied to a data subset. #10428 by Jonathan Ohayon

• Add tests in `utils.estimator_checks.check_estimator` to check that an estimator can handle read-only memmap input data. #10663 by Arthur Mensch and Loïc Estève.

• `check_sample_weights_pandas_series` now uses 8 rather than 6 samples to accommodate for the default number of clusters in `cluster.KMeans`. #10933 by Johannes Hansen.

• Estimators are now checked for whether `sample_weight=None` equates to `sample_weight=np.ones(...)`. #11558 by Sergul Aydore.

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.19, including:

1.7.17 Version 0.19.2

July, 2018

This release is exclusively in order to support Python 3.7.

Related changes

- **n_iter_** may vary from previous releases in `linear_model.LogisticRegression` with `solver='lbfgs'` and `linear_model.HuberRegressor`. For Scipy <= 1.0.0, the optimizer could perform more than the requested maximum number of iterations. Now both estimators will report at most `max_iter` iterations even if more were performed. #10723 by Joel Nothman.

1.7.18 Version 0.19.1

October 23, 2017

This is a bug-fix release with some minor documentation improvements and enhancements to features released in 0.19.0.

Note there may be minor differences in TSNE output in this release (due to #9623), in the case where multiple samples have equal distance to some sample.

Changelog

API changes

- Reverted the addition of `metrics.ndcg_score` and `metrics.dcg_score` which had been merged into version 0.19.0 by error. The implementations were broken and undocumented.

- `return_train_score` which was added to `model_selection.GridSearchCV`, `model_selection.RandomizedSearchCV` and `model_selection.cross_validate` in version 0.19.0 will be changing its default value from True to False in version 0.21. We found that calculating training score could have a great effect on cross validation runtime in some cases. Users should explicitly set `return_train_score` to False if prediction or scoring functions are slow, resulting in a deleterious effect on CV runtime, or to True if they wish to use the calculated scores. #9677 by Kumar Ashutosh and Joel Nothman.

- `correlation_models` and `regression_models` from the legacy gaussian processes implementation have been belatedly deprecated. #9717 by Kumar Ashutosh.
Bug fixes

- Avoid integer overflows in `metrics.matthews_corrcoef`. #9693 by Sam Steingold.
- Fixed a bug in the objective function for `manifold.TSNE` (both exact and with the Barnes-Hut approximation) when `n_components >= 3`. #9711 by @goncalo-rodrigues.
- Fix regression in `model_selection.cross_val_predict` where it raised an error with method='predict_proba' for some probabilistic classifiers. #9641 by James Bourbeau.
- Fixed a bug where `datasets.make_classification` modified its input weights. #9865 by Sachin Kelkar.
- `model_selection.StratifiedShuffleSplit` now works with multioutput multiclass or multilabel data with more than 1000 columns. #9922 by Charlie Brummitt.
- Fixed a bug where `datasets.make_classification` modified its input weights. #9865 by Sachin Kelkar.

Regressions in 0.19.0 fixed in 0.19.1:

- Fixed a bug where parallelised prediction in random forests was not thread-safe and could (rarely) result in arbitrary errors. #9830 by Joel Nothman.
- Fix regression in `model_selection.cross_val_predict` where it no longer accepted X as a list. #9600 by Rasul Kerimov.
- Fixed handling of `cross_val_predict` for binary classification with method='decision_function'. #9593 by Reiichiro Nakano and core devs.
- Fix regression in `pipeline.Pipeline` where it no longer accepted steps as a tuple. #9604 by Joris Van den Bossche.
- Fix bug where `n_iter` was not properly deprecated, leaving `n_iter` unavailable for interim use in `linear_model.SGDClassifier`, `linear_model.SGDRegressor`, `linear_model.PassiveAgressiveClassifier`, `linear_model.PassiveAgressiveRegressor` and `linear_model.Perceptron`. #9558 by Andreas Müller.
- Dataset fetchers make sure temporary files are closed before removing them, which caused errors on Windows. #9847 by Joan Massich.
- Fixed a regression in `manifold.TSNE` where it no longer supported metrics other than ‘euclidean’ and ‘pre-computed’. #9623 by Oli Blum.

Enhancements

- Our test suite and `utils.estimator_checks.check_estimators` can now be run without Nose installed. #9697 by Joan Massich.
- To improve usability of version 0.19’s `pipeline.Pipeline` caching, memory now allows `joblib` Memory instances. This make use of the new `utils.validation.check_memory` helper. issue:9584 by Kumar Ashutosh
- Some fixes to examples: #9750, #9788, #9815
- Made a FutureWarning in SGD-based estimators less verbose. #9802 by Vrishank Bhardwaj.
Code and Documentation Contributors

With thanks to:

1.7.19 Version 0.19

August 12, 2017

Highlights

We are excited to release a number of great new features including `neighbors.LocalOutlierFactor` for anomaly detection, `preprocessing.QuantileTransformer` for robust feature transformation, and the `multioutput.ClassifierChain` meta-estimator to simply account for dependencies between classes in multilabel problems. We have some new algorithms in existing estimators, such as multiplicative update in `decomposition.NMF` and multinomial `linear_model.LogisticRegression` with L1 loss (use `solver='saga'`).

Cross validation is now able to return the results from multiple metric evaluations. The new `model_selection.cross_validate` can return many scores on the test data as well as training set performance and timings, and we have extended the `scoring` and `refit` parameters for grid/randomized search to handle multiple metrics.

You can also learn faster. For instance, the new option to cache transformations in `pipeline.Pipeline` makes grid search over pipelines including slow transformations much more efficient. And you can predict faster: if you’re sure you know what you’re doing, you can turn off validating that the input is finite using `config_context`.

We’ve made some important fixes too. We’ve fixed a longstanding implementation error in `metrics.average_precision_score`, so please be cautious with prior results reported from that function. A number of errors in the `manifold.TSNE` implementation have been fixed, particularly in the default Barnes-Hut approximation. `semi_supervised.LabelSpreading` and `semi_supervised.LabelPropagation` have had substantial fixes. LabelPropagation was previously broken. LabelSpreading should now correctly respect its alpha parameter.

Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- `cluster.KMeans` with sparse X and initial centroids given (bug fix)
- `cross_decomposition.PLSRegression` with `scale=True` (bug fix)
- `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor` where `min_impurity_split` is used (bug fix)
- gradient boosting `loss='quantile'` (bug fix)
- `ensemble.IsolationForest` (bug fix)
- `feature_selection.SelectFdr` (bug fix)
- `linear_model.RANSACRegressor` (bug fix)
• **linear_model.LassoLars** (bug fix)
• **linear_model.LassoLarsIC** (bug fix)
• **manifold.TSNE** (bug fix)
• **neighbors.NearestCentroid** (bug fix)
• **semi_supervised.LabelSpreading** (bug fix)
• **semi_supervised.LabelPropagation** (bug fix)
• tree based models where **min_weight_fraction_leaf** is used (enhancement)
• **model_selection.StratifiedKFold** with shuffle=True (this change, due to #7823 was not mentioned in the release notes at the time)

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

**Changelog**

**New features**

Classifiers and regressors

• Added **multioutput.ClassifierChain** for multi-label classification. By Adam Kleczewski.

• Added solver 'saga' that implements the improved version of Stochastic Average Gradient, in **linear_model.LogisticRegression** and **linear_model.Ridge**. It allows the use of L1 penalty with multinomial logistic loss, and behaves marginally better than 'sag' during the first epochs of ridge and logistic regression. #8446 by Arthur Mensch.

Other estimators

• Added the **neighbors.LocalOutlierFactor** class for anomaly detection based on nearest neighbors. #5279 by Nicolas Goix and Alexandre Gramfort.

• Added **preprocessing.QuantileTransformer** class and **preprocessing.quantile_transform** function for features normalization based on quantiles. #8363 by Denis Engemann, Guillaume Lemaître, Olivier Grisel, Raghav RV, Thierry Guillemot, and Gael Varoquaux.

• The new solver 'mu' implements a Multiplicate Update in **decomposition.NMF**, allowing the optimization of all beta-divergences, including the Frobenius norm, the generalized Kullback-Leibler divergence and the Itakura-Saito divergence. #5295 by Tom Dupre la Tour.

Model selection and evaluation

• **model_selection.GridSearchCV** and **model_selection.RandomizedSearchCV** now support simultaneous evaluation of multiple metrics. Refer to the **Specifying multiple metrics for evaluation** section of the user guide for more information. #7388 by Raghav RV

• Added the **model_selection.cross_validate** which allows evaluation of multiple metrics. This function returns a dict with more useful information from cross-validation such as the train scores, fit times and score times. Refer to **The cross_validate function and multiple metric evaluation** section of the userguide for more information. #7388 by Raghav RV

• Added **metrics.mean_squared_log_error**, which computes the mean square error of the logarithmic transformation of targets, particularly useful for targets with an exponential trend. #7655 by Karan Desai.

• Added **metrics.dcg_score** and **metrics.ndcg_score**, which compute Discounted cumulative gain (DCG) and Normalized discounted cumulative gain (NDCG). #7739 by David Gasquez.
• Added the `model_selection.RepeatedKFold` and `model_selection.RepeatedStratifiedKFold`. #8120 by Neeraj Gangwar.

Miscellaneous
• Validation that input data contains no NaN or inf can now be suppressed using `config_context`, at your own risk. This will save on runtime, and may be particularly useful for prediction time. #7548 by Joel Nothman.
• Added a test to ensure parameter listing in docstrings match the function/class signature. #9206 by Alexandre Gramfort and Raghav RV.

Enhancements

Trees and ensembles
• The `min_weight_fraction_leaf` constraint in tree construction is now more efficient, taking a fast path to declare a node a leaf if its weight is less than 2 * the minimum. Note that the constructed tree will be different from previous versions where `min_weight_fraction_leaf` is used. #7441 by Nelson Liu.
• `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor` now support sparse input for prediction. #6101 by Ibraim Ganiev.
• `ensemble.VotingClassifier` now allows changing estimators by using `ensemble.VotingClassifier.set_params`. An estimator can also be removed by setting it to None. #7674 by Yichuan Liu.
• `tree.export_graphviz` now shows configurable number of decimal places. #8698 by Guillaume Lemaître.
• Added `flatten_transform` parameter to `ensemble.VotingClassifier` to change output shape of `transform` method to 2 dimensional. #7794 by Ibraim Ganiev and Herilalaina Rakotoarison.

Linear, kernelized and related models
• `linear_model.SGDClassifier`, `linear_model.SGDRegressor`, `linear_model.PassiveAggressiveClassifier`, `linear_model.PassiveAggressiveRegressor` and `linear_model.Perceptron` now expose `max_iter` and `tol` parameters, to handle convergence more precisely. `n_iter` parameter is deprecated, and the fitted estimator exposes a `n_iter_` attribute, with actual number of iterations before convergence. #5036 by Tom Dupre la Tour.
• Added `average` parameter to perform weight averaging in `linear_model.PassiveAggressiveClassifier`. #4939 by Andrea Esuli.
• `linear_model.RANSACRegressor` no longer throws an error when calling `fit` if no inliers are found in its first iteration. Furthermore, causes of skipped iterations are tracked in newly added attributes, `n_skips_*`. #7914 by Michael Horrell.
• In `gaussian_process.GaussianProcessRegressor`, method `predict` is a lot faster with `return_std=True`. #8591 by Hadrien Bertrand.
• Added `return_std` to `predict` method of `linear_model.ARDRegression` and `linear_model.BayesianRidge`. #7838 by Sergey Feldman.
• Memory usage enhancements: Prevent cast from float32 to float64 in: `linear_model.MultiTaskElasticNet`, `linear_model.LogisticRegression` when using newton-cg solver; and `linear_model.Ridge` when using svd, sparse_cg, cholesky or lsqr solvers. #8835, #8061 by Joan Massich and Nicolas Cordier and Thierry Guillemot.

Other predictors
• Custom metrics for the neighbors binary trees now have fewer constraints: they must take two 1d-arrays and return a float. #6288 by Jake Vanderplas.

• algorithm='auto in neighbors estimators now chooses the most appropriate algorithm for all input types and metrics. #9145 by Herilalaina Rakotoarison and Reddy Chinthala.

Decomposition, manifold learning and clustering

• cluster.MiniBatchKMeans and cluster.KMeans now use significantly less memory when assigning data points to their nearest cluster center. #7721 by Jon Crall.

• decomposition.PCA, decomposition.IncrementalPCA and decomposition.TruncatedSVD now expose the singular values from the underlying SVD. They are stored in the attribute singular_values_, like in decomposition.IncrementalPCA. #7685 by Tommy Löfstedt.

• decomposition.NMF now faster when beta_loss=0. #9277 by @hongkahjun.

• Memory improvements for method barnes_hut in manifold.TSNE #7089 by Thomas Moreau and Olivier Grisel.

• Optimization schedule improvements for Barnes-Hut manifold.TSNE so the results are closer to the one from the reference implementation lvdmaaten/bhtsne by Thomas Moreau and Olivier Grisel.

• Memory usage enhancements: Prevent cast from float32 to float64 in decomposition.PCA and decomposition.randomized_svd_low_rank. #9067 by Raghav RV.

Preprocessing and feature selection

• Added norm_order parameter to feature_selection.SelectFromModel to enable selection of the norm order when coef_ is more than 1D. #6181 by Antoine Wendlinger.

• Added ability to use sparse matrices in feature_selection.f_regression with center=True. #8065 by Daniel LeJeune.

• Small performance improvement to n-gram creation in feature_extraction.text by binding methods for loops and special-casing unigrams. #7567 by Jaye Doepke.

• Relax assumption on the data for the kernel_approximation.SkewedChi2Sampler. Since the Skewed-Chi2 kernel is defined on the open interval \((-\text{skewedness}; +\infty)\), the transform function should not check whether \(X < 0\) but whether \(X < -\text{self.skewedness}\). #7573 by Romain Brault.

• Made default kernel parameters kernel-dependent in kernel_approximation.Nystroem. #5229 by Saurabh Bansod and Andreas Müller.

Model evaluation and meta-estimators

• pipeline.Pipeline is now able to cache transformers within a pipeline by using the memory constructor parameter. #7990 by Guillaume Lemaitre.

• pipeline.Pipeline steps can now be accessed as attributes of its named_steps attribute. #8586 by Herilalaina Rakotoarison.

• Added sample_weight parameter to pipeline.Pipeline.score. #7723 by Mikhail Korobov.

• Added ability to set n_jobs parameter to pipeline.make_union. A TypeError will be raised for any other kwargs. #8028 by Alexander Booth.

• model_selection.GridSearchCV, model_selection.RandomizedSearchCV and model_selection.cross_val_score now allow estimators with callable kernels which were previously prohibited. #8005 by Andreas Müller.

• model_selection.cross_val_predict now returns output of the correct shape for all values of the argument method. #7863 by Aman Dalmia.
- Added `shuffle` and `random_state` parameters to shuffle training data before taking prefixes of it based on training sizes in `model_selection.learning_curve`. #7506 by Narine Kokhlikyan.

- `model_selection.StratifiedShuffleSplit` now works with multioutput multiclass (or multilabel) data. #9044 by Vlad Niculae.

- Speed improvements to `model_selection.StratifiedShuffleSplit`. #5991 by Arthur Mensch and Joel Nothman.

- Add `shuffle` parameter to `model_selection.train_test_split`. #8845 by themrmax

- Add `max_train_size` parameter to `model_selection.TimeSeriesSplit` #8282 by Aman Dalmia.

- More clustering metrics are now available through `metrics.get_scorer` and `scoring` parameters. #8117 by Raghav RV.

- A scorer based on `metrics.explained_variance_score` is also available. #9259 by Hanmin Qin.

Metrics

- `metrics.matthews_corrcoef` now support multiclass classification. #8094 by Jon Crall.

- Add `sample_weight` parameter to `metrics.cohen_kappa_score`. #8335 by Victor Poughon.

Miscellaneous

- `utils.check_estimator` now attempts to ensure that methods transform, predict, etc. do not set attributes on the estimator. #7533 by Ekaterina Krivich.

- Added type checking to the `accept_sparse` parameter in `utils.validation` methods. This parameter now accepts only boolean, string, or list/tuple of strings. `accept_sparse=None` is deprecated and should be replaced by `accept_sparse=False`. #7880 by Josh Karnofsky.

- Make it possible to load a chunk of an svmlight formatted file by passing a range of bytes to `datasets.load_svmlight_file`. #935 by Olivier Grisel.

- `dummy.DummyClassifier` and `dummy.DummyRegressor` now accept non-finite features. #8931 by @Attractadore.

Bug fixes

Trees and ensembles

- Fixed a memory leak in trees when using trees with `criterion='mae'`. #8002 by Raghav RV.

- Fixed a bug where `ensemble.IsolationForest` uses an an incorrect formula for the average path length #8549 by Peter Wang.

- Fixed a bug where `ensemble.AdaBoostClassifier` throws `ZeroDivisionError` while fitting data with single class labels. #7501 by Dominik Krzeminski.

- Fixed a bug in `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor` where a float being compared to 0.0 using `==` caused a divide by zero error. #7970 by He Chen.

- Fix a bug where `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor` ignored the `min_impurity_split` parameter. #8006 by Sebastian Pölsterl.

- Fixed `oob_score` in `ensemble.BaggingClassifier`. #8936 by Michael Lewis
• Fixed excessive memory usage in prediction for random forests estimators. #8672 by Mike Benfield.
• Fixed a bug where `sample_weight` as a list broke random forests in Python 2 #8068 by @xor.
• Fixed a bug where `ensemble.IsolationForest` fails when `max_features` is less than 1. #5732 by Ishank Gulati.
• Fix a bug where gradient boosting with loss='quantile' computed negative errors for negative values of \( y_{\text{true}} - y_{\text{pred}} \) leading to wrong values when calling `__call__`. #8087 by Alexis Mignon
• Fix a bug where `ensemble.VotingClassifier` raises an error when a numpy array is passed in for weights. #7983 by Vincent Pham.
• Fixed a bug where `tree.export_graphviz` raised an error when the length of `features_names` does not match `n_features` in the decision tree. #8512 by Li Li.

Linear, kernelized and related models

• Fixed a bug where `linear_model.RANSACRegressor.fit` may run until `max_iter` if it finds a large inlier group early. #8251 by @aivision2020.
• Fixed a bug where `naive_bayes.MultinomialNB` and `naive_bayes.BernoulliNB` failed when `alpha=0`. #5814 by Yichuan Liu and Herilalaina Rakotoarison.
• Fixed a bug where `linear_model.LassoLars` does not give the same result as the LassoLars implementation available in R (lars library). #7849 by Jair Montoya Martinez.
• Fixed a bug in `linear_model.RandomizedLasso`, `linear_model.Lars`, `linear_model.LassoLars`, `linear_model.LarsCV` and `linear_model.LassoLarsCV`, where the parameter `precompute` was not used consistently across classes, and some values proposed in the docstring could raise errors. #5359 by Tom Dupre la Tour.
• Fix inconsistent results between `linear_model.RidgeCV` and `linear_model.Ridge` when using `normalize=True`. #9302 by Alexandre Gramfort.
• Fix a bug where `linear_model.LassoLars.fit` sometimes left `coef_` as a list, rather than an ndarray. #8160 by CJ Carey.
• Fix `linear_model.BayesianRidge.fit` to return ridge parameter `alpha_` and `lambda_` consistent with calculated coefficients `coef_` and `intercept_`. #8224 by Peter Gedeck.
• Fixed a bug in `svm.OneClassSVM` where it returned floats instead of integer classes. #8676 by Vathsala Achar.
• Fix AIC/BIC criterion computation in `linear_model.LassoLarsIC`. #9022 by Alexandre Gramfort and Mehmet Basbug.
• Fixed a memory leak in our LibLinear implementation. #9024 by Sergei Lebedev
• Fix bug where stratified CV splitters did not work with `linear_model.LassoCV`. #8973 by Paulo Haddad.
• Fixed a bug in `gaussian_process.GaussianProcessRegressor` when the standard deviation and covariance predicted without fit would fail with a meaningless error by default. #6573 by Quazi Marufur Rahman and Manoj Kumar.

Other predictors

• Fix `semi_supervised.BaseLabelPropagation` to correctly implement `LabelPropagation` and `LabelSpreading` as done in the referenced papers. #9239 by Andre Ambrosio Boechat, Utkarsh Upadhyay, and Joel Nothman.

Decomposition, manifold learning and clustering

• Fixed the implementation of `manifold.TSNE`
• early_exageration parameter had no effect and is now used for the first 250 optimization iterations.

• Fixed the AssertionError: Tree consistency failed exception reported in #8992.

• Improve the learning schedule to match the one from the reference implementation lvdmaaten/bhtsne. by Thomas Moreau and Olivier Grisel.

• Fix a bug in decomposition.LatentDirichletAllocation where the perplexity method was returning incorrect results because the transform method returns normalized document topic distributions as of version 0.18. #7954 by Gary Foreman.

• Fix output shape and bugs with n_jobs > 1 in decomposition.SparseCoder transform and decomposition.sparse_encode for one-dimensional data and one component. This also impacts the output shape of decomposition.DictionaryLearning. #8086 by Andreas Müller.

• Fixed the implementation of explained_variance_ in decomposition.PCA, decomposition.RandomizedPCA and decomposition.IncrementalPCA. #9105 by Hanmin Qin.

• Fixed the implementation of noise_variance_ in decomposition.PCA. #9108 by Hanmin Qin.

• Fixed a bug where cluster.DBSCAN gives incorrect result when input is a precomputed sparse matrix with initial rows all zero. #8306 by Akshay Gupta

• Fix a bug regarding fitting cluster.KMeans with a sparse array X and initial centroids, where X’s means were unnecessarily being subtracted from the centroids. #7872 by Josh Karnofsky.

• Fixes to the input validation in covariance.EllipticEnvelope. #8086 by Andreas Müller.

• Fixed a bug in covariance.MinCovDet where inputting data that produced a singular covariance matrix would cause the helper method _c_step to throw an exception. #3367 by Jeremy Steward

• Fixed a bug in manifold.TSNE affecting convergence of the gradient descent. #8768 by David DeTomaso.

• Fixed a bug in manifold.TSNE where it stored the incorrect kl_divergence_. #6507 by Sebastian Saeger.

• Fixed improper scaling in cross_decomposition.PLSRegression with scale=True. #7819 by jayzed82.

• cluster.bicluster.SpectralCoclustering and cluster.bicluster.SpectralBiclustering fit method conforms with API by accepting y and returning the object. #6126, #7814 by Laurent Direr and Maniteja Nandana.

• Fix bug where mixture sample methods did not return as many samples as requested. #7702 by Levi John Wolf.

• Fixed the shrinkage implementation in neighbors.NearestCentroid. #9219 by Hanmin Qin.

Preprocessing and feature selection

• For sparse matrices, preprocessing.normalize with return_norm=True will now raise a NotImplementedError with ‘l1’ or ‘l2’ norm and with norm ‘max’ the norms returned will be the same as for dense matrices. #7771 by Ang Lu.

• Fix a bug where feature_selection.SelectFdr did not exactly implement Benjamini-Hochberg procedure. It formerly may have selected fewer features than it should. #7490 by Peng Meng.

• Fixed a bug where linear_model.RandomizedLasso and linear_model.RandomizedLogisticRegression breaks for sparse input. #8259 by Aman Dalmia.

• Fix a bug where feature_extraction.FeatureHasher mandatorily applied a sparse random projection to the hashed features, preventing the use of feature_extraction.text.HashingVectorizer in a pipeline with feature_extraction.text.TfidfTransformer. #7565 by Roman Yurchak.
• Fix a bug where `feature_selection.mutual_info_regression` did not correctly use `n_neighbors`. #8181 by Guillaume Lemaitre.

Model evaluation and meta-estimators

• Fixed a bug where `model_selection.validation_curve` reused the same estimator for each parameter value. #7365 by Aleksandr Sandrovskii.

• `model_selection.permutation_test_score` now works with Pandas types. #5697 by Stijn Tonk.

• Several fixes to input validation in `multiclass.OutputCodeClassifier` #8086 by Andreas Müller.

• `multiclass.OneVsOneClassifier`'s `partial_fit` now ensures all classes are provided up-front. #6250 by Asish Panda.

• Fix `multiclass.MultioutputClassifier.predict_proba` to return a list of 2d arrays, rather than a 3d array. In the case where different target columns had different numbers of classes, a `ValueError` would be raised on trying to stack matrices with different dimensions. #8093 by Peter Bull.

• Cross validation now works with Pandas datatypes that that have a read-only index. #9507 by Loic Esteve.

Metrics

• `metrics.average_precision_score` no longer linearly interpolates between operating points, and instead weighs precisions by the change in recall since the last operating point, as per the Wikipedia entry. (#7356). By Nick Dingwall and Gael Varoquaux.

• Fix a bug in `metrics.classification._check_targets` which would return 'binary' if `y_true` and `y_pred` were both 'binary' but the union of `y_true` and `y_pred` was 'multiclass'. #8377 by Loic Esteve.

• Fixed an integer overflow bug in `metrics.confusion_matrix` and hence `metrics.cohen_kappa_score`. #8354, #7929 by Joel Nothman and Jon Crall.

• Fixed passing of gamma parameter to the chi2 kernel in `metrics.pairwise.pairwise_kernels` #5211 by Nick Rhinehart, Saurabh Bansod and Andreas Müller.

Miscellaneous

• Fixed a bug when `datasets.make_classification` fails when generating more than 30 features. #8159 by Herilalaina Rakotoarison.

• Fixed a bug where `datasets.make_moons` gives an incorrect result when `n_samples` is odd. #8198 by Josh Levy.

• Some `fetch__` functions in `datasets` were ignoring the `download_if_missing` keyword. #7944 by Ralf Gommers.

• Fix estimators to accept a `sample_weight` parameter of type `pandas.Series` in their `fit` function. #7825 by Kathleen Chen.

• Fix a bug in cases where `numpy.cumsum` may be numerically unstable, raising an exception if instability is identified. #7376 and #7331 by Joel Nothman and @yangarbiter.
• Fix a bug where base.BaseEstimator.__getstate__ obstructed pickling customizations of child-
classes, when used in a multiple inheritance context. #8316 by Holger Peters.
• Update Sphinx-Gallery from 0.1.4 to 0.1.7 for resolving links in documentation build with Sphinx>1.5 #8010,
  #7986 by Oscar Najera
• Add data_home parameter to sklearn.datasets.fetch_kddcup99. #9289 by Loic Estève.
• Fix dataset loaders using Python 3 version of makedirs to also work in Python 2. #9284 by Sébastien Santy.
• Several minor issues were fixed with thanks to the alerts of lgtm.com. #9278 by Jean Helie, among others.

API changes summary

Trees and ensembles

• Gradient boosting base models are no longer estimators. By Andreas Müller.
• All tree based estimators now accept a min_impurity_decrease parameter in lieu of the
  min_impurity_split, which is now deprecated. The min_impurity_decrease helps stop
  splitting the nodes in which the weighted impurity decrease from splitting is no longer at least
  min_impurity_decrease. #8449 by Raghav RV.

Linear, kernelized and related models

• n_iter parameter is deprecated in linear_model.SGDClassifier, linear_model.
  SGDRegressor, linear_model.PassiveAggressiveClassifier, linear_model.

Other predictors

• neighbors.LSHForest has been deprecated and will be removed in 0.21 due to poor performance. #9078
  by Laurent Dierer.
• neighbors.NearestCentroid no longer purports to support metric='precomputed' which now
  raises an error. #8515 by Sergül Aydore.
• The alpha parameter of semi_supervised.LabelPropagation now has no effect and is deprecated
  to be removed in 0.21. #9239 by Andre Ambrosio Boechat, Utkarsh Upadhyay, and Joel Nothman.

Decomposition, manifold learning and clustering

• Deprecate the doc_topic_distr argument of the perplexity method in decomposition.
  LatentDirichletAllocation because the user no longer has access to the unnormalized document topic
  distribution needed for the perplexity calculation. #7954 by Gary Foreman.
• The n_topics parameter of decomposition.LatentDirichletAllocation has been renamed to
  n_components and will be removed in version 0.21. #8922 by @Attractadore.
• decomposition.SparsePCA.transform's ridge_alpha parameter is deprecated in preference for
  class parameter. #8137 by Naoya Kanai.
• cluster.DBSCAN now has a metric_params parameter. #8139 by Naoya Kanai.

Preprocessing and feature selection

• feature_selection.SelectFromModel now has a partial_fit method only if the underlying es-
timator does. By Andreas Müller.
• feature_selection.SelectFromModel now validates the threshold parameter and sets the
  threshold_ attribute during the call to fit, and no longer during the call to transform. By
  Andreas Müller.
• The non_negative parameter in feature_extraction.FeatureHasher has been deprecated, and replaced with a more principled alternative, alternate_sign. #7565 by Roman Yurchak.

• linear_model.RandomizedLogisticRegression, and linear_model.RandomizedLasso have been deprecated and will be removed in version 0.21. #8995 by Ramana.S.

Model evaluation and meta-estimators

• Deprecate the fit_params constructor input to the model_selection.GridSearchCV and model_selection.RandomizedSearchCV in favor of passing keyword parameters to the fit methods of those classes. Data-dependent parameters needed for model training should be passed as keyword arguments to fit, and conforming to this convention will allow the hyperparameter selection classes to be used with tools such as model_selection.cross_val_predict. #2879 by Stephen Hoover.

• In version 0.21, the default behavior of splitters that use the test_size and train_size parameter will change, such that specifying train_size alone will cause test_size to be the remainder. #7459 by Nelson Liu.

• multiclass.OneVsRestClassifier now has partial_fit, decision_function and predict_proba methods only when the underlying estimator does. #7812 by Andreas Müller and Mikhail Korobov.

• multiclass.OneVsRestClassifier now has a partial_fit method only if the underlying estimator does. By Andreas Müller.

• The decision_function output shape for binary classification in multiclass.OneVsRestClassifier and multiclass.OneVsOneClassifier is now (n_samples,) to conform to scikit-learn conventions. #9100 by Andreas Müller.

• The multioutput.MultiOutputClassifier.predict_proba function used to return a 3d array (n_samples, n_classes, n_outputs). In the case where different target columns had different numbers of classes, a ValueError would be raised on trying to stack matrices with different dimensions. This function now returns a list of arrays where the length of the list is n_outputs, and each array is (n_samples, n_classes) for that particular output. #8093 by Peter Bull.

• Replace attribute named_steps dict to utils.Bunch in pipeline.Pipeline to enable tab completion in interactive environment. In the case conflict value on named_steps and dict attribute, dict behavior will be prioritized. #8481 by Herilalaina Rakotoarison.

Miscellaneous

• Deprecate the y parameter in transform and inverse_transform. The method should not accept y parameter, as it’s used at the prediction time. #8174 by Tahar Zanouda, Alexandre Gramfort and Raghav RV.

• SciPy >= 0.13.3 and NumPy >= 1.8.2 are now the minimum supported versions for scikit-learn. The following backported functions in utils have been removed or deprecated accordingly. #8854 and #8874 by Naoya Kanai.

• The store_covariances and covariances_ parameters of discriminant_analysis.QuadricDiscriminantAnalysis has been renamed to store_covariance and covariance_ to be consistent with the corresponding parameter names of the discriminant_analysis.LinearDiscriminantAnalysis. They will be removed in version 0.21. #7998 by Jiacheng.

Removed in 0.19:
- utils.fixes.argpartition
- utils.fixes.array_equal
- utils.fixes.astype
- utils.fixes.bincount
• Estimators with both methods decision_function and predict_proba are now required to have a monotonic relation between them. The method check_decision_proba_consistency has been added in utils.estimator_checks to check their consistency. #7578 by Shubham Bhardwaj

• All checks in utils.estimator_checks, in particular utils.estimator_checks.check_estimator now accept estimator instances. Most other checks do not accept estimator classes any more. #9019 by Andreas Müller.

• Ensure that estimators’ attributes ending with _ are not set in the constructor but only in the fit method. Most notably, ensemble estimators (deriving from ensemble.BaseEnsemble) now only have self.estimators_ available after fit. #7464 by Lars Buitinck and Loic Esteve.

Code and Documentation Contributors

Thanks to everyone who has contributed to the maintenance and improvement of the project since version 0.18, including:

1.7. Release History 119
1.7.20 Version 0.18.2

June 20, 2017

Last release with Python 2.6 support

Scikit-learn 0.18 is the last major release of scikit-learn to support Python 2.6. Later versions of scikit-learn will require Python 2.7 or above.

Changelog

- Fixes for compatibility with NumPy 1.13.0: #7946 #8355 by Loic Esteve.
- Minor compatibility changes in the examples #9010 #8040 #9149.
Code Contributors

Aman Dalmia, Loic Esteve, Nate Guerin, Sergei Lebedev

1.7.21 Version 0.18.1

November 11, 2016

Changelog

Enhancements

- Improved `sample_without_replacement` speed by utilizing numpy.random.permutation for most cases. As a result, samples may differ in this release for a fixed random state. Affected estimators:
  - `ensemble.BaggingClassifier`
  - `ensemble.BaggingRegressor`
  - `linear_model.RANSACRegressor`
  - `model_selection.RandomizedSearchCV`
  - `random_projection.SparseRandomProjection`

This also affects the `datasets.make_classification` method.

Bug fixes

- Fix issue where `min_grad_norm` and `n_iter_without_progress` parameters were not being utilised by `manifold.TSNE`. #6497 by Sebastian Säger
- Fix bug for svm's decision values when `decision_function_shape` is ovr in `svm.SVC`. svm.SVC's decision_function was incorrect from versions 0.17.0 through 0.18.0. #7724 by Bing Tian Dai
- Attribute `explained_variance_ratio` of `discriminant_analysis.LinearDiscriminantAnalysis` calculated with SVD and Eigen solver are now of the same length. #7632 by JPFrancoia
- Fixes issue in `Univariate feature selection` where score functions were not accepting multi-label targets. #7676 by Mohammed Affan
- Fixed setting parameters when calling `fit` multiple times on `feature_selection.SelectFromModel`. #7756 by Andreas Müller
- Fixes issue in `partial_fit` method of `multiclass.OneVsRestClassifier` when number of classes used in `partial_fit` was less than the total number of classes in the data. #7786 by Srivatsan Ramesh
- Fixes issue in `calibration.CalibratedClassifierCV` where the sum of probabilities of each class for a data was not 1, and CalibratedClassifierCV now handles the case where the training set has less number of classes than the total data. #7799 by Srivatsan Ramesh
- Fix a bug where `sklearn.feature_selection.SelectFdr` did not exactly implement Benjamini-Hochberg procedure. It formerly may have selected fewer features than it should. #7490 by Peng Meng.
- `sklearn.manifold.LocallyLinearEmbedding` now correctly handles integer inputs. #6282 by Jake Vanderplas.
The `min_weight_fraction_leaf` parameter of tree-based classifiers and regressors now assumes uniform sample weights by default if the `sample_weight` argument is not passed to the `fit` function. Previously, the parameter was silently ignored. #7301 by Nelson Liu.

Numerical issue with `linear_model.RidgeCV` on centered data when `n_features > n_samples`. #6178 by Bertrand Thirion

Tree splitting criterion classes’ cloning/pickling is now memory safe #7680 by Ibraim Ganiev.

Fixed a bug where `decomposition.NMF` sets its `n_iters_` attribute in `transform()`. #7553 by Ekaterina Krivich.

`sklearn.linear_model.LogisticRegressionCV` now correctly handles string labels. #5874 by Raghu RV.

Fixed a bug where `sklearn.model_selection.train_test_split` raised an error when `stratify` is a list of string labels. #7594 by Raghu RV.

Fixed a bug where `sklearn.model_selection.GridSearchCV` and `sklearn.model_selection.RandomizedSearchCV` were not pickleable because of a pickling bug in np.ma.MaskedArray. #7594 by Raghu RV.

All cross-validation utilities in `sklearn.model_selection` now permit one time cross-validation splitters for the `cv` parameter. Also non-deterministic cross-validation splitters (where multiple calls to `split` produce dissimilar splits) can be used as `cv` parameter. The `sklearn.model_selection.GridSearchCV` will cross-validate each parameter setting on the split produced by the first `split` call to the cross-validation splitter. #7660 by Raghu RV.

Fix bug where `preprocessing.MultiLabelBinarizer.fit_transform` returned an invalid CSR matrix. #7750 by CJ Carey.

Fixed a bug where `metrics.pairwise.cosine_distances` could return a small negative distance. #7732 by Artsion.

**API changes summary**

Trees and forests

The `min_weight_fraction_leaf` parameter of tree-based classifiers and regressors now assumes uniform sample weights by default if the `sample_weight` argument is not passed to the `fit` function. Previously, the parameter was silently ignored. #7301 by Nelson Liu.

Tree splitting criterion classes’ cloning/pickling is now memory safe. #7680 by Ibraim Ganiev.

Linear, kernelized and related models

Length of `explained_variance_ratio` of `discriminant_analysis.LinearDiscriminantAnalysis` changed for both Eigen and SVD solvers. The attribute has now a length of `min(n_components, n_classes - 1)`. #7632 by JP Franco.

Numerical issue with `linear_model.RidgeCV` on centered data when `n_features > n_samples`. #6178 by Bertrand Thirion.
1.7.22 Version 0.18

September 28, 2016

Last release with Python 2.6 support

Scikit-learn 0.18 will be the last version of scikit-learn to support Python 2.6. Later versions of scikit-learn will require Python 2.7 or above.

Model Selection Enhancements and API Changes

• The model_selection module

The new module sklearn.model_selection, which groups together the functionalities of formerly sklearn.cross_validation, sklearn.grid_search and sklearn.learning_curve, introduces new possibilities such as nested cross-validation and better manipulation of parameter searches with Pandas.

Many things will stay the same but there are some key differences. Read below to know more about the changes.

• Data-independent CV splitters enabling nested cross-validation

The new cross-validation splitters, defined in the sklearn.model_selection, are no longer initialized with any data-dependent parameters such as y. Instead they expose a split method that takes in the data and yields a generator for the different splits.

This change makes it possible to use the cross-validation splitters to perform nested cross-validation, facilitated by model_selection.GridSearchCV and model_selection.RandomizedSearchCV utilities.

• The enhanced cv_results_ attribute

The new cv_results_ attribute (of model_selection.GridSearchCV and model_selection. RandomizedSearchCV) introduced in lieu of the grid_scores_ attribute is a dict of 1D arrays with elements in each array corresponding to the parameter settings (i.e. search candidates).

The cv_results_ dict can be easily imported into pandas as a DataFrame for exploring the search results.

The cv_results_ arrays include scores for each cross-validation split (with keys such as 'split0_test_score'), as well as their mean ('mean_test_score') and standard deviation ('std_test_score').

The ranks for the search candidates (based on their mean cross-validation score) is available at cv_results_['rank_test_score'].

The parameter values for each parameter is stored separately as numpy masked object arrays. The value, for that search candidate, is masked if the corresponding parameter is not applicable. Additionally a list of all the parameter dicts are stored at cv_results_['params'].

• Parameters n_folds and n_iter renamed to n_splits

Some parameter names have changed: The n_folds parameter in new model_selection.KFold, model_selection.GroupKFold (see below for the name change), and model_selection. StratifiedKFold is now renamed to n_splits. The n_iter parameter in model_selection. ShuffleSplit, the new class model_selection.GroupShuffleSplit and model_selection. StratifiedShuffleSplit is now renamed to n_splits.

• Rename of splitter classes which accepts group labels along with data

1.7. Release History

Note the change from singular to plural form in model_selection.LeavePGroupsOut.

- **Fit parameter labels renamed to groups**
  The labels parameter in the split method of the newly renamed splitters model_selection.GroupKFold, model_selection.LeaveOneGroupOut, model_selection.LeavePGroupsOut, model_selection.GroupShuffleSplit is renamed to groups following the new nomenclature of their class names.

- **Parameter n_labels renamed to n_groups**
  The parameter n_labels in the newly renamed model_selection.LeavePGroupsOut is changed to n_groups.

- **Training scores and Timing information**
  cv_results_ also includes the training scores for each cross-validation split (with keys such as 'split0_train_score'), as well as their mean ('mean_train_score') and standard deviation ('std_train_score'). To avoid the cost of evaluating training score, set return_train_score=False.

  Additionally the mean and standard deviation of the times taken to split, train and score the model across all the cross-validation splits is available at the key 'mean_time' and 'std_time' respectively.

### Changelog

#### New features

**Classifiers and Regressors**

- The Gaussian Process module has been reimplemented and now offers classification and regression estimators through gaussian_process.GaussianProcessClassifier and gaussian_process.GaussianProcessRegressor. Among other things, the new implementation supports kernel engineering, gradient-based hyperparameter optimization or sampling of functions from GP prior and GP posterior. Extensive documentation and examples are provided. **By Jan Hendrik Metzen.**

- Added new supervised learning algorithm: **Multi-layer Perceptron** #3204 by Issam H. Laradji

- **Added linear_model.HuberRegressor**, a linear model robust to outliers. #5291 by Manoj Kumar.

- **Added the multioutput.MultiOutputRegressor** meta-estimator. It converts single output regressors to multi-output regressors by fitting one regressor per output. **By Tim Head.**

**Other estimators**

- **New mixture.GaussianMixture and mixture.BayesianGaussianMixture** replace former mixture models, employing faster inference for sounder results. **#7295 by Wei Xue and Thierry Guillemot.**

- Class decomposition.RandomizedPCA is now factored into decomposition.PCA and it is available calling with parameter svd_solver='randomized'. The default number of n_iter for 'randomized' has changed to 4. The old behavior of PCA is recovered by svd_solver='full'. An additional solver calls arpack and performs truncated (non-randomized) SVD. By default, the best solver is selected depending on the size of the input and the number of components requested. **#5299 by Giorgio Patrini.**

- **Added two functions for mutual information estimation:** feature_selection.mutual_info_classif and feature_selection.mutual_info_regression. **These**
functions can be used in feature_selection.SelectKBest and feature_selection.SelectPercentile as score functions. By Andrea Bravi and Nikolay Mayorov.

- Added the ensemble.IsolationForest class for anomaly detection based on random forests. By Nicolas Goix.

Model selection and evaluation

- Added metrics.cluster.fowlkes_mallows_score, the Fowlkes Mallows Index which measures the similarity of two clusterings of a set of points By Arnaud Fouchet and Thierry Guillemot.
- Added metrics.calinski_harabaz_score, which computes the Calinski and Harabaz score to evaluate the resulting clustering of a set of points. By Arnaud Fouchet and Thierry Guillemot.
- Added new cross-validation splitter model_selection.TimeSeriesSplit to handle time series data. #6586 by YenChen Lin

  - The cross-validation iterators are replaced by cross-validation splitters available from sklearn.model_selection, allowing for nested cross-validation. See Model Selection Enhancements and API Changes for more information. #4294 by Raghav RV.

Enhancements

Trees and ensembles

- Added a new splitting criterion for tree.DecisionTreeRegressor, the mean absolute error. This criterion can also be used in ensemble.ExtraTreesRegressor, ensemble.RandomForestRegressor, and the gradient boosting estimators. #6667 by Nelson Liu.
- Added weighted impurity-based early stopping criterion for decision tree growth. #6954 by Nelson Liu
- The random forest, extra tree and decision tree estimators now has a method decision_path which returns the decision path of samples in the tree. By Arnaud Joly.
- A new example has been added unveiling the decision tree structure. By Arnaud Joly.
- Random forest, extra trees, decision trees and gradient boosting estimator accept the parameter min_samples_split and min_samples_leaf provided as a percentage of the training samples. By yelite and Arnaud Joly.
- Gradient boosting estimators accept the parameter criterion to specify to splitting criterion used in built decision trees. #6667 by Nelson Liu.
- The memory footprint is reduced (sometimes greatly) for ensemble.bagging.BaseBagging and classes that inherit from it, i.e., ensemble.BaggingClassifier, ensemble.BaggingRegressor, and ensemble.IsolationForest, by dynamically generating attribute estimators_samples_ only when it is needed. By David Staub.
- Added n_jobs and sample_weight parameters for ensemble.VotingClassifier to fit underlying estimators in parallel. #5805 by Ibraim Ganiev.

Linear, kernelized and related models

- In linear_model.LogisticRegression, the SAG solver is now available in the multinomial case. #5251 by Tom Dupre la Tour.
- linear_model.RANSACRegressor, svm.LinearSVC and svm.LinearSVR now support sample_weight. By Imaculate.
- Add parameter `loss` to `linear_model.RANSACRegressor` to measure the error on the samples for every trial. By Manoj Kumar.

- Prediction of out-of-sample events with Isotonic Regression (`isotonic.IsotonicRegression`) is now much faster (over 1000x in tests with synthetic data). By Jonathan Arfa.

- Isotonic regression (`isotonic.IsotonicRegression`) now uses a better algorithm to avoid \(O(n^2)\) behavior in pathological cases, and is also generally faster (#6691). By Antony Lee.

- `naive_bayes.GaussianNB` now accepts data-independent class-priors through the parameter `priors`. By Guillaume Lemaître.

- `linear_model.ElasticNet` and `linear_model.Lasso` now works with `np.float32` input data without converting it into `np.float64`. This allows to reduce the memory consumption. #6913 by YenChen Lin.

- `semi_supervised.LabelPropagation` and `semi_supervised.LabelSpreading` now accept arbitrary kernel functions in addition to strings `knn` and `rbf`. #5762 by Utkarsh Upadhyay.

Decomposition, manifold learning and clustering

- Added `inverse_transform` function to `decomposition.NMF` to compute data matrix of original shape. By Anish Shah.

- `cluster.KMeans` and `cluster.MiniBatchKMeans` now works with `np.float32` and `np.float64` input data without converting it. This allows to reduce the memory consumption by using `np.float32`. #6846 by Sebastian Säger and YenChen Lin.

Preprocessing and feature selection

- `preprocessing.RobustScaler` now accepts `quantile_range` parameter. #5929 by Konstantin Podshumok.

- `feature_extraction.FeatureHasher` now accepts string values. #6173 by Ryad Zenine and Devashish Deshpande.

- Keyword arguments can now be supplied to `func` in `preprocessing.FunctionTransformer` by means of the `kw_args` parameter. By Brian McFee.

- `feature_selection.SelectKBest` and `feature_selection.SelectPercentile` now accept score functions that take `X`, `y` as input and return only the scores. By Nikolay Mayorov.

Model evaluation and meta-estimators

- `multiclass.OneVsOneClassifier` and `multiclass.OneVsRestClassifier` now support `partial_fit`. By Asish Panda and Philipp Dowling.

- Added support for substituting or disabling `pipeline.Pipeline` and `pipeline.FeatureUnion` components using the `set_params` interface that powers `sklearn.grid_search`. See `Selecting dimensionality reduction with Pipeline and GridSearchCV` By Joel Nothman and Robert McGibbon.

- The new `cv_results_` attribute of `model_selection.GridSearchCV` (and `model_selection.RandomizedSearchCV`) can be easily imported into pandas as a DataFrame. Ref `Model Selection Enhancements and API Changes` for more information. #6697 by Raghav RV.

- Generalization of `model_selection.cross_val_predict`. One can pass method names such as `predict_proba` to be used in the cross validation framework instead of the default `predict`. By Ori Ziv and Sears Merritt.

- The training scores and time taken for training followed by scoring for each search candidate are now available at the `cv_results_` dict. See `Model Selection Enhancements and API Changes` for more information. #7325 by Eugene Chen and Raghav RV.

Metrics
• Added labels flag to `metrics.log_loss` to explicitly provide the labels when the number of classes in `y_true` and `y_pred` differ. #7239 by Hong Guangguo with help from Mads Jensen and Nelson Liu.

• Support sparse contingency matrices in cluster evaluation (`metrics.cluster.supervised`) to scale to a large number of clusters. #7419 by Gregory Stupp and Joel Nothman.

• Add `sample_weight` parameter to `metrics.matthews_corrcoef`. By Jatin Shah and Raghav RV.

• Speed up `metrics.silhouette_score` by using vectorized operations. By Manoj Kumar.

• Add `sample_weight` parameter to `metrics.confusion_matrix`. By Bernardo Stein.

Miscellaneous

• Added `n_jobs` parameter to `feature_selection.RFECV` to compute the score on the test folds in parallel. By Manoj Kumar

• Codebase does not contain C/C++ cython generated files: they are generated during build. Distribution packages will still contain generated C/C++ files. By Arthur Mensch.

• Reduce the memory usage for 32-bit float input arrays of `utils.sparse_func.mean_variance_axis` and `utils.sparse_func.incr_mean_variance_axis` by supporting cython fused types. By YenChen Lin.

• The `ignore_warnings` now accept a category argument to ignore only the warnings of a specified type. By Thierry Guillemot.

• Added parameter `return_X_y` and return type `(data, target) : tuple` option to `load_iris` dataset #7049, `load_breast_cancer` dataset #7152, `load_digits` dataset, `load_diabetes` dataset, `load_linnerud` dataset, `load_boston` dataset #7154 by Manvendra Singh.

• Simplification of the `clone` function, deprecate support for estimators that modify parameters in `__init__`. #5540 by Andreas Müller.

• When unpickling a scikit-learn estimator in a different version than the one the estimator was trained with, a `UserWarning` is raised, see the documentation on model persistence for more details. (#7248) By Andreas Müller.

Bug fixes

Trees and ensembles

• Random forest, extra trees, decision trees and gradient boosting won’t accept anymore `min_samples_split=1` as at least 2 samples are required to split a decision tree node. By Arnaud Joly

• `ensemble.VotingClassifier` now raises `NotFittedError` if `predict`, `transform` or `predict_proba` are called on the non-fitted estimator. by Sebastian Raschka.

• Fix bug where `ensemble.AdaBoostClassifier` and `ensemble.AdaBoostRegressor` would perform poorly if the `random_state` was fixed (#7411). By Joel Nothman.

• Fix bug in ensembles with randomization where the ensemble would not set `random_state` on base estimators in a pipeline or similar nesting. (#7411). Note, results for `ensemble.BaggingClassifier`, `ensemble.BaggingRegressor`, `ensemble.AdaBoostClassifier` and `ensemble.AdaBoostRegressor` will now differ from previous versions. By Joel Nothman.

Linear, kernelized and related models

• Fixed incorrect gradient computation for `loss='squared_epsilon_insensitive'` in `linear_model.SGDClassifier` and `linear_model.SGDRegressor` (#6764). By Wenhua Yang.
• Fix bug in `linear_model.LogisticRegressionCV` where solver='liblinear' did not accept class_weights='balanced'. (#6817). By Tom Dupre la Tour.

• Fix bug in `neighbors.RadiusNeighborsClassifier` where an error occurred when there were outliers being labelled and a weight function specified (#6902). By LeonieBorne.

• Fix `linear_model.ElasticNet` sparse decision function to match output with dense in the multioutput case.

Decomposition, manifold learning and clustering

• `decomposition.RandomizedPCA` default number of iterated_power is 4 instead of 3. #5141 by Giorgio Patrini.

• `utils.extmath.randomized_svd` performs 4 power iterations by default, instead or 0. In practice this is enough for obtaining a good approximation of the true eigenvalues/vectors in the presence of noise. When n_components is small (< .1 * min(X.shape)) n_iter is set to 7, unless the user specifies a higher number. This improves precision with few components. #5299 by Giorgio Patrini.

• Whiten/non-whiten inconsistency between components of `decomposition.PCA` and `decomposition.RandomizedPCA` (now factored into PCA, see the New features) is fixed. components_ are stored with no whitening. #5299 by Giorgio Patrini.

• Fixed bug in `manifold.spectral_embedding` where diagonal of unnormalized Laplacian matrix was incorrectly set to 1. #4995 by Peter Fischer.

• Attribute `explained_variance_ratio_` calculated with the SVD solver of `discriminant_analysis.LinearDiscriminantAnalysis` now returns correct results. By JPPfrancaio

Preprocessing and feature selection

• `preprocessing.data._transform_selected` now always passes a copy of X to transform function when copy=True (#7194). By Caio Oliveira.

Model evaluation and meta-estimators

• `model_selection.StratifiedKFold` now raises error if all n_labels for individual classes is less than n_folds. #6182 by Devashish Deshpande.

• Fixed bug in `model_selection.StratifiedShuffleSplit` where train and test sample could overlap in some edge cases, see #6121 for more details. By Loic Esteve.

• Fix in sklearn.model_selection.StratifiedShuffleSplit to return splits of size train_size and test_size in all cases (#6472). By Andreas Müller.

• Cross-validation of `OneVsOneClassifier` and `OneVsRestClassifier` now works with precomputed kernels. #7350 by Russell Smith.

• Fix incomplete predict_proba method delegation from `model_selection.GridSearchCV` to `linear_model.SGDClassifier` (#7159) by Yichuan Liu.

Metrics

• Fix bug in `metrics.silhouette_score` in which clusters of size 1 were incorrectly scored. They should get a score of 0. By Joel Nothman.

• Fix bug in `metrics.silhouette_samples` so that it now works with arbitrary labels, not just those ranging from 0 to n_clusters - 1.
Fix bug where expected and adjusted mutual information were incorrect if cluster contingency cells exceeded 2**16. By Joel Nothman.

metrics.pairwise.pairwise_distances now converts arrays to boolean arrays when required in scipy.spatial.distance. #5460 by Tom Dupre la Tour.

Fix sparse input support in metrics.silhouette_score as well as example examples/text/document_clustering.py. By YenChen Lin.

metrics.roc_curve and metrics.precision_recall_curve no longer round y_score values when creating ROC curves; this was causing problems for users with very small differences in scores (#7353).

Miscellaneous

model_selection.tests._search._check_param_grid now works correctly with all types that extends/implements Sequence (except string), including range (Python 3.x) and xrange (Python 2.x). #7323 by Viacheslav Kovalevskyi.

tools.extmath.randomized_range_finder is more numerically stable when many power iterations are requested, since it applies LU normalization by default. If n_iter<2 numerical issues are unlikely, thus no normalization is applied. Other normalization options are available: 'none', 'LU' and 'QR'. #5141 by Giorgio Patrini.

Fix a bug where some formats of scipy.sparse matrix, and estimators with them as parameters, could not be passed to base.clone. By Loic Esteve.

datasets.load_svmlight_file now is able to read long int QID values. #7101 by Ibraim Ganiev.

API changes summary

Linear, kernelized and related models

residual_metric has been deprecated in linear_model.RANSACRegressor. Use loss instead. By Manoj Kumar.

Access to public attributes .X_ and .y_ has been deprecated in isotonic.IsotonicRegression. By Jonathan Arfa.

Decomposition, manifold learning and clustering

The old mixture.DPGMM is deprecated in favor of the new mixture.BayesianGaussianMixture (with the parameter weight_concentration_prior_type='dirichlet_process'). The new class solves the computational problems of the old class and computes the Gaussian mixture with a Dirichlet process prior faster than before. #7295 by Wei Xue and Thierry Guillemot.

The old mixture.VBGMM is deprecated in favor of the new mixture.BayesianGaussianMixture (with the parameter weight_concentration_prior_type='dirichlet_distribution'). The new class solves the computational problems of the old class and computes the Variational Bayesian Gaussian mixture faster than before. #6651 by Wei Xue and Thierry Guillemot.

The old mixture.GMM is deprecated in favor of the new mixture.GaussianMixture. The new class computes the Gaussian mixture faster than before and some of computational problems have been solved. #6666 by Wei Xue and Thierry Guillemot.

Model evaluation and meta-estimators

The sklearn.cross_validation, sklearn.grid_search and sklearn.learning_curve have been deprecated and the classes and functions have been reorganized into the sklearn. model_selection module. Ref Model Selection Enhancements and API Changes for more information. #4294 by Raghav RV.
• The `grid_scores_` attribute of `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` is deprecated in favor of the attribute `cv_results_`. Ref `Model Selection Enhancements and API Changes` for more information. #6697 by Raghav RV.

• The parameters `n_iter` or `n_folds` in old CV splitters are replaced by the new parameter `n_splits` since it can provide a consistent and unambiguous interface to represent the number of train-test splits. #7187 by YenChen Lin.

• `classes` parameter was renamed to `labels` in `metrics.hamming_loss`. #7260 by Sebastián Vanrell.

• The splitter classes `LabelKFold`, `LabelShuffleSplit`, `LeaveOneLabelOut` and `LeavePLabelsOut` are renamed to `model_selection.GroupKFold`, `model_selection.GroupShuffleSplit`, `model_selection.LeaveOneGroupOut` and `model_selection.LeavePGroupsOut` respectively. Also the parameter `labels` in the `split` method of the newly renamed splitters `model_selection.LeaveOneGroupOut` and `model_selection.LeavePGroupsOut` is renamed to `groups`. Additionally in `model_selection.LeavePGroupsOut`, the parameter `n_labels` is renamed to `n_groups`. #6660 by Raghav RV.

• Error and loss names for `scoring` parameters are now prefixed by `'neg_'`, such as `neg_mean_squared_error`. The unprefixed versions are deprecated and will be removed in version 0.20. #7261 by Tim Head.

1.7.23 Version 0.17.1

February 18, 2016

Changelog

Bug fixes

• Upgrade vendored joblib to version 0.9.4 that fixes an important bug in joblib.Parallel that can silently yield to wrong results when working on datasets larger than 1MB: https://github.com/joblib/joblib/blob/0.9.4/CHANGES.rst

• Fixed reading of Bunch pickles generated with scikit-learn version <= 0.16. This can affect users who have already downloaded a dataset with scikit-learn 0.16 and are loading it with scikit-learn 0.17. See #6196 for how this affected datasets.fetch_20newsgroups. By Loic Esteve.

• Fixed a bug that prevented using ROC AUC score to perform grid search on several CPU / cores on large arrays. See #6147 By Olivier Grisel.

• Fixed a bug that prevented to properly set the presort parameter in ensemble.GradientBoostingRegressor. See #5857 By Andrew McCulloh.

• Fixed a joblib error when evaluating the perplexity of a decomposition.LatentDirichletAllocation model. See #6258 By Chyi-Kwei Yau.

1.7.24 Version 0.17

November 5, 2015

Changelog

New features

• All the Scaler classes but preprocessing.RobustScaler can be fitted online by calling partial_fit. By Giorgio Patrini.

• The new class ensemble.VotingClassifier implements a “majority rule” / “soft voting” ensemble classifier to combine estimators for classification. By Sebastian Raschka.

• The new class preprocessing.RobustScaler provides an alternative to preprocessing.StandardScaler for feature-wise centering and range normalization that is robust to outliers. By Thomas Unterthiner.

• The new class preprocessing.MaxAbsScaler provides an alternative to preprocessing.MinMaxScaler for feature-wise range normalization when the data is already centered or sparse. By Thomas Unterthiner.
• The new class `preprocessing.FunctionTransformer` turns a Python function into a Pipeline-compatible transformer object. By Joe Jevnik.

• The new classes `cross_validation.LabelKFold` and `cross_validation.LabelShuffleSplit` generate train-test folds, respectively similar to `cross_validation.KFold` and `cross_validation.ShuffleSplit`, except that the folds are conditioned on a label array. By Brian McFee, Jean Kossaifi and Gilles Louppe.

• `decomposition.LatentDirichletAllocation` implements the Latent Dirichlet Allocation topic model with online variational inference. By Chyi-Kwei Yau, with code based on an implementation by Matt Hoffman. (#3659)

• The new solver `sag` implements a Stochastic Average Gradient descent and is available in both `linear_model.LogisticRegression` and `linear_model.Ridge`. This solver is very efficient for large datasets. By Danny Sullivan and Tom Dupre la Tour. (#4738)

• The new solver `cd` implements a Coordinate Descent in `decomposition.NMF`. Previous solver based on Projected Gradient is still available setting new parameter `solver` to `pg`, but is deprecated and will be removed in 0.19, along with `decomposition.ProjectedGradientNMF` and parameters `sparseness`, `beta` and `nls_max_iter`. New parameters `alpha` and `l1_ratio` control L1 and L2 regularization, and `shuffle` adds a shuffling step in the `cd` solver. By Tom Dupre la Tour and Mathieu Blondel.

Enhancements

• `manifold.TSNE` now supports approximate optimization via the Barnes-Hut method, leading to much faster fitting. By Christopher Erick Moody. (#4025)

• `cluster.mean_shift_.MeanShift` now supports parallel execution, as implemented in the `mean_shift` function. By Martino Sorbaro.

• `naive_bayes.GaussianNB` now supports fitting with `sample_weight`. By Jan Hendrik Metzen.

• `dummy.DummyClassifier` now supports a prior fitting strategy. By Arnaud Joly.

• Added a `fit_predict` method for `mixture.GMM` and subclasses. By Cory Lorenz.

• Added the `metrics.label_ranking_loss` metric. By Arnaud Joly.

• Added the `metrics.cohen_kappa_score` metric.

• Added a `warm_start` constructor parameter to the bagging ensemble models to increase the size of the ensemble. By Tim Head.

• Added option to use multi-output regression metrics without averaging. By Konstantin Shmelkov and Michael Eickenberg.

• Added `stratify` option to `cross_validation.train_test_split` for stratified splitting. By Miroslav Batchkarov.

• The `tree.export_graphviz` function now supports aesthetic improvements for `tree.DecisionTreeClassifier` and `tree.DecisionTreeRegressor`, including options for coloring nodes by their majority class or impurity, showing variable names, and using node proportions instead of raw sample counts. By Trevor Stephens.

• Improved speed of `newton-cg` solver in `linear_model.LogisticRegression`, by avoiding loss computation. By Mathieu Blondel and Tom Dupre la Tour.

• The `class_weight="auto"` heuristic in classifiers supporting `class_weight` was deprecated and replaced by the `class_weight="balanced"` option, which has a simpler formula and interpretation. By Hanna Wallach and Andreas Müller.
• Add `class_weight` parameter to automatically weight samples by class frequency for `linear_model.PassiveAggressiveClassifier`. By Trevor Stephens.

• Added backlinks from the API reference pages to the user guide. By Andreas Müller.

• The `labels` parameter to `sklearn.metrics.f1_score`, `sklearn.metrics.fbeta_score`, `sklearn.metrics.recall_score` and `sklearn.metrics.precision_score` has been extended. It is now possible to ignore one or more labels, such as where a multiclass problem has a majority class to ignore. By Joel Nothman.

• Add `sample_weight` support to `linear_model.RidgeClassifier`. By Trevor Stephens.

• Provide an option for sparse output from `sklearn.metrics.pairwise.cosine_similarity`. By Jaidev Deshpande.

• Add `minmax_scale` to provide a function interface for `MinMaxScaler`. By Thomas Unterthiner.

• `dump_svmlight_file` now handles multi-label datasets. By Chih-Wei Chang.

• RCV1 dataset loader (sklearn.datasets.fetch_rcv1). By Tom Dupre la Tour.

• The “Wisconsin Breast Cancer” classical two-class classification dataset is now included in scikit-learn, available with `sklearn.dataset.load_breast_cancer`.

• Upgraded to joblib 0.9.3 to benefit from the new automatic batching of short tasks. This makes it possible for scikit-learn to benefit from parallelism when many very short tasks are executed in parallel, for instance by the `grid_search.GridSearchCV` meta-estimator with `n_jobs > 1` used with a large grid of parameters on a small dataset. By Vlad Niculae, Olivier Grisel and Loic Esteve.

• For more details about changes in joblib 0.9.3 see the release notes: https://github.com/joblib/joblib/blob/master/CHANGES.rst#release-093

• Improved speed (3 times per iteration) of `decomposition.DictLearning` with coordinate descent method from `linear_model.Lasso`. By Arthur Mensch.

• Parallel processing (threaded) for queries of nearest neighbors (using the ball-tree) by Nikolay Mayorov.

• Allow `datasets.make_multilabel_classification` to output a sparse matrix. By Kashif Rasul.

• `cluster.DBSCAN` now accepts a sparse matrix of precomputed distances, allowing memory-efficient distance precomputation. By Joel Nothman.

• `tree.DecisionTreeClassifier` now exposes an `apply` method for retrieving the leaf indices samples are predicted as. By Daniel Galvez and Gilles Louppe.

• Speed up decision tree regressors, random forest regressors, extra trees regressors and gradient boosting estimators by computing a proxy of the impurity improvement during the tree growth. The proxy quantity is such that the split that maximizes this value also maximizes the impurity improvement. By Arnaud Joly, Jacob Schreiber and Gilles Louppe.

• Speed up tree based methods by reducing the number of computations needed when computing the impurity measure taking into account linear relationship of the computed statistics. The effect is particularly visible with extra trees and on datasets with categorical or sparse features. By Arnaud Joly.

• `ensemble.GradientBoostingRegressor` and `ensemble.GradientBoostingClassifier` now expose an `apply` method for retrieving the leaf indices each sample ends up in under each try. By Jacob Schreiber.

• Add `sample_weight` support to `linear_model.LinearRegression`. By Sonny Hu. (#4881)

• Add `n_iter_without_progress` to `manifold.TSNE` to control the stopping criterion. By Santi Villalba. (#5186)
• Added optional parameter `random_state` in `linear_model.Ridge` to set the seed of the pseudo random generator used in `sag` solver. By Tom Dupre la Tour.

• Added optional parameter `warm_start` in `linear_model.LogisticRegression`. If set to True, the solvers `lbfgs`, `newton-cg` and `sag` will be initialized with the coefficients computed in the previous fit. By Tom Dupre la Tour.

• Added `sample_weight` support to `linear_model.LogisticRegression` for the `lbfgs`, `newton-cg`, and `sag` solvers. By Valentin Stolbunov. Support added to the `liblinear` solver. By Manoj Kumar.

• Added optional parameter `presort` to `ensemble.GradientBoostingRegressor` and `ensemble.GradientBoostingClassifier`, keeping default behavior the same. This allows gradient boosters to turn off presorting when building deep trees or using sparse data. By Jacob Schreiber.

• Altered `metrics.roc_curve` to drop unnecessary thresholds by default. By Graham Clenaghan.

• Added `feature_selection.SelectFromModel` meta-transformer which can be used along with estimators that have `coef_` or `feature_importances_` attribute to select important features of the input data. By Maheshakya Wijewardena, Joel Nothman and Manoj Kumar.

• Added `metrics.pairwise.laplacian_kernel`. By Clyde Fare.

• `covariance.GraphLasso` allows separate control of the convergence criterion for the Elastic-Net subproblem via the `enet_tol` parameter.

• Improved verbosity in `decomposition.DictionaryLearning`.

• `ensemble.RandomForestClassifier` and `ensemble.RandomForestRegressor` no longer explicitly store the samples used in bagging, resulting in a much reduced memory footprint for storing random forest models.

• Added positive option to `linear_model.Lars` and `linear_model.lars_path` to force coefficients to be positive. (#5131)

• Added the `X_norm_squared` parameter to `metrics.pairwise.euclidean_distances` to provide precomputed squared norms for `X`.

• Added the `fit_predict` method to `pipeline.Pipeline`.

• Added the `preprocessing.min_max_scale` function.

Bug fixes

• Fixed non-determinism in `dummy.DummyClassifier` with sparse multi-label output. By Andreas Müller.

• Fixed the output shape of `linear_model.RANSACRegressor` to `(n_samples,)`. By Andreas Müller.

• Fixed bug in `decomposition.DictLearning` when `n_jobs < 0`. By Andreas Müller.

• Fixed bug where `grid_search.RandomizedSearchCV` could consume a lot of memory for large discrete grids. By Joel Nothman.

• Fixed bug in `linear_model.LogisticRegressionCV` where penalty was ignored in the final fit. By Manoj Kumar.

• Fixed bug in `ensemble.forest.ForestClassifier` while computing oob_score and `X` is a sparse `csc_matrix`. By Ankur Ankan.

• All regressors now consistently handle and warn when given `y` that is of shape `(n_samples, 1)`. By Andreas Müller and Henry Lin. (#5431)

• Fix in `cluster.KMeans` cluster reassignment for sparse input by Lars Buitinck.
• Fixed a bug in `lda.LDA` that could cause asymmetric covariance matrices when using shrinkage. By Martin Billinger.

• Fixed `cross_validation.cross_val_predict` for estimators with sparse predictions. By Buddha Prakash.

• Fixed the predict_proba method of `linear_model.LogisticRegression` to use soft-max instead of one-vs-rest normalization. By Manoj Kumar. (#5182)

• Fixed the partial_fit method of `linear_model.SGDClassifier` when called with average=True. By Andrew Lamb. (#5282)

• Fixed the predict_proba method of `linear_model.LogisticRegression` to use soft-max instead of one-vs-rest normalization. By Manoj Kumar. (#5182)

• Fixed the partial_fit method of `linear_model.SGDClassifier` when called with average=True. By Andrew Lamb. (#5282)

• Dataset fetchers use different filenames under Python 2 and Python 3 to avoid pickling compatibility issues. By Olivier Grisel. (#5355)

• Fixed a bug in `naive_bayes.GaussianNB` which caused classification results to depend on scale. By Jake Vanderplas.

• Fixed temporarily `linear_model.Ridge`, which was incorrect when fitting the intercept in the case of sparse data. The fix automatically changes the solver to ‘sag’ in this case. #5360 by Tom Dupre la Tour.

• Fixed a performance bug in `decomposition.RandomizedPCA` on data with a large number of features and fewer samples. (#4478) By Andreas Müller, Loic Esteve and Giorgio Patrini.

• Fixed bug in `cross_decomposition.PLS` that yielded unstable and platform dependent output, and failed on fit_transform. By Arthur Mensch.

• Fixes to the Bunch class used to store datasets.

• Fixed `ensemble.plot_partial_dependence` ignoring the percentiles parameter.

• Providing a set as vocabulary in `CountVectorizer` no longer leads to inconsistent results when pickling.

• Fixed the conditions on when a precomputed Gram matrix needs to be recomputed in `linear_model.LinearRegression`, `linear_model.OrthogonalMatchingPursuit`, `linear_model.Lasso` and `linear_model.ElasticNet`.

• Fixed inconsistent memory layout in the coordinate descent solver that affected `linear_model.DictionaryLearning` and `covariance.GraphLasso`. (#5337) By Olivier Grisel.

• `manifold.LocallyLinearEmbedding` no longer ignores the `reg` parameter.

• Nearest Neighbor estimators with custom distance metrics can now be pickled. (#4362)

• Fixed a bug in `pipeline.FeatureUnion` where transformer_weights were not properly handled when performing grid-searches.

• Fixed a bug in `linear_model.LogisticRegression` and `linear_model.LogisticRegressionCV` when using class_weight='balanced' or class_weight='auto'. By Tom Dupre la Tour.

• Fixed bug #5495 when doing OVR(SVC(decision_function_shape="ovr")). Fixed by Elvis Dohmatob.
API changes summary

- Attribute \texttt{data\_min}, \texttt{data\_max} and \texttt{data\_range} in \texttt{preprocessing.MinMaxScaler} are deprecated and won’t be available from 0.19. Instead, the class now exposes \texttt{data\_min\_}, \texttt{data\_max\_} and \texttt{data\_range\_}. By Giorgio Patrini.

- All Scaler classes now have an \texttt{scale\_} attribute, the feature-wise rescaling applied by their \texttt{transform} methods. The old attribute \texttt{std\_} in \texttt{preprocessing.StandardScaler} is deprecated and superseded by \texttt{scale\_}; it won’t be available in 0.19. By Giorgio Patrini.

- \texttt{svm.SVC} and \texttt{svm.NuSVC} now have an \texttt{decision\_function\_shape} parameter to make their decision function of shape (\texttt{n\_samples}, \texttt{n\_classes}) by setting \texttt{decision\_function\_shape='ovr'}. This will be the default behavior starting in 0.19. By Andreas Müller.

- Passing 1D data arrays as input to estimators is now deprecated as it caused confusion in how the array elements should be interpreted as features or as samples. All data arrays are now expected to be explicitly shaped \texttt{(n\_samples, n\_features)}. By Vighnesh Birodkar.

- \texttt{lda.LDA} and \texttt{qda.QDA} have been moved to \texttt{discriminant\_analysis.LinearDiscriminantAnalysis} and \texttt{discriminant\_analysis.QuadraticDiscriminantAnalysis}.

- The \texttt{store\_covariance} and \texttt{tol} parameters have been moved from the \texttt{fit} method to the constructor in \texttt{discriminant\_analysis.LinearDiscriminantAnalysis} and the \texttt{store\_covariances} and \texttt{tol} parameters have been moved from the \texttt{fit} method to the constructor in \texttt{discriminant\_analysis.LinearDiscriminantAnalysis}.

- Models inheriting from \texttt{_LearntSelectorMixin} will no longer support the \texttt{transform} methods. (i.e, RandomForests, GradientBoosting, LogisticRegression, DecisionTrees, SVMs and SGD related models). Wrap these models around the metatransformer \texttt{feature\_selection.SelectFromModel} to remove features (according to \texttt{coefs\_} or \texttt{feature\_importances\_}) which are below a certain threshold value instead.

- \texttt{cluster.KMeans} re-runs cluster-assignments in case of non-convergence, to ensure consistency of \texttt{predict(X)} and \texttt{labels\_}. By Vighnesh Birodkar.

- Classifier and Regressor models are now tagged as such using the \texttt{\_estimator\_type} attribute.

- Cross-validation iterators always provide indices into training and test set, not boolean masks.

- The \texttt{decision\_function} on all regressors was deprecated and will be removed in 0.19. Use \texttt{predict} instead.

- \texttt{datasets.load\_lfw\_pairs} is deprecated and will be removed in 0.19. Use \texttt{datasets.fetch\_lfw\_pairs} instead.

- The deprecated \texttt{hmm} module was removed.

- The deprecated \texttt{Bootstrap} cross-validation iterator was removed.

- The deprecated \texttt{Ward} and \texttt{WardAgglomerative} classes have been removed. Use \texttt{clustering.AgglomerativeClustering} instead.

- \texttt{cross\_validation.check\_cv} is now a public function.

- The property \texttt{residues\_} of \texttt{linear\_model.LinearRegression} is deprecated and will be removed in 0.19.

- The deprecated \texttt{n\_jobs} parameter of \texttt{linear\_model.LinearRegression} has been moved to the constructor.

- Removed deprecated \texttt{class\_weight} parameter from \texttt{linear\_model.SGDClassifier\_s} \texttt{fit} method. Use the construction parameter instead.
• The deprecated support for the sequence of sequences (or list of lists) multilabel format was removed. To convert to and from the supported binary indicator matrix format, use `MultiLabelBinarizer`.

• The behavior of calling the `inverse_transform` method of `Pipeline.pipeline` will change in 0.19. It will no longer reshape one-dimensional input to two-dimensional input.

• The deprecated attributes `indicator_matrix_`, `multilabel_` and `classes_` of `preprocessing.LabelBinarizer` were removed.

• Using `gamma=0` in `svm.SVC` and `svm.SVR` to automatically set the gamma to `1. / n_features` is deprecated and will be removed in 0.19. Use `gamma="auto"` instead.

### Code Contributors

### 1.7.25 Version 0.16.1

April 14, 2015

#### Changelog

#### Bug fixes

• Allow input data larger than `block_size` in `covariance.LedoitWolf` by Andreas Müller.

• Fix a bug in `isotonic.IsotonicRegression` deduplication that caused unstable result in `calibration.CalibratedClassifierCV` by Jan Hendrik Metzen.

• Fix sorting of labels in `func:preprocessing.label_binarize` by Michael Heilman.
• Fix several stability and convergence issues in `cross_decomposition.CCA` and `cross_decomposition.PLSCanonical` by Andreas Müller.

• Fix a bug in `cluster.KMeans` when `precompute_distances=False` on fortran-ordered data.

• Fix a speed regression in `ensemble.RandomForestClassifier`'s `predict` and `predict_proba` by Andreas Müller.

• Fix a regression where `utils.shuffle` converted lists and dataframes to arrays, by Olivier Grisel.

1.7.26 Version 0.16

March 26, 2015

Highlights

• Speed improvements (notably in `cluster.DBSCAN`), reduced memory requirements, bug-fixes and better default settings.

• Multinomial Logistic regression and a path algorithm in `linear_model.LogisticRegressionCV`.

• Out-of core learning of PCA via `decomposition.IncrementalPCA`.

• Probability calibration of classifiers using `calibration.CalibratedClassifierCV`.

• `cluster.Birch` clustering method for large-scale datasets.

• Scalable approximate nearest neighbors search with Locality-sensitive hashing forests in `neighbors.LSHForest`.

• Improved error messages and better validation when using malformed input data.

• More robust integration with pandas dataframes.

Changelog

New features

• The new `neighbors.LSHForest` implements locality-sensitive hashing for approximate nearest neighbors search. By Maheshakya Wijewardena.

• Added `svm.LinearSVR`. This class uses the liblinear implementation of Support Vector Regression which is much faster for large sample sizes than `svm.SVR` with linear kernel. By Fabian Pedregosa and Qiang Luo.

• Incremental fit for `GaussianNB`.

• Added `sample_weight` support to `dummy.DummyClassifier` and `dummy.DummyRegressor`. By Arnaud Joly.

• Added the `metrics.label_ranking_average_precision_score` metrics. By Arnaud Joly.

• Add the `metrics.coverage_error` metrics. By Arnaud Joly.

• Added `linear_model.LogisticRegressionCV`. By Manoj Kumar, Fabian Pedregosa, Gael Varoquaux and Alexandre Gramfort.

• Added `warm_start` constructor parameter to make it possible for any trained forest model to grow additional trees incrementally. By Laurent Diner.
• Added `sample_weight` support to `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor`. By Peter Prettenhofer.

• Added `decomposition.IncrementalPCA`, an implementation of the PCA algorithm that supports out-of-core learning with a `partial_fit` method. By Kyle Kastner.

• Averaged SGD for `SGDClassifier` and `SGDRegressor` By Danny Sullivan.

• Added `cross_val_predict` function which computes cross-validated estimates. By Luis Pedro Coelho.

• Added `linear_model.TheilSenRegressor`, a robust generalized-median-based estimator. By Florian Wilhelm.

• Added `metrics.median_absolute_error`, a robust metric. By Gael Varoquaux and Florian Wilhelm.

• Add `cluster.Birch`, an online clustering algorithm. By Manoj Kumar, Alexandre Gramfort and Joel Nothman.

• Added shrinkage support to `discriminant_analysis.LinearDiscriminantAnalysis` using two new solvers. By Clemens Brunner and Martin Billinger.

• Added `kernel_ridge.KernelRidge`, an implementation of kernelized ridge regression. By Mathieu Blondel and Jan Hendrik Metzen.

• All solvers in `linear_model.Ridge` now support `sample_weight`. By Mathieu Blondel.

• Added `cross_validation.PredefinedSplit` cross-validation for fixed user-provided cross-validation folds. By Thomas Unterthiner.

• Added `calibration.CalibratedClassifierCV`, an approach for calibrating the predicted probabilities of a classifier. By Alexandre Gramfort, Jan Hendrik Metzen, Mathieu Blondel and Balazs Kegl.

Enhancements

• Add option `return_distance` in `hierarchical.ward_tree` to return distances between nodes for both structured and unstructured versions of the algorithm. By Matteo Visconti di Oleggio Castello. The same option was added in `hierarchical.linkage_tree`. By Manoj Kumar.

• Add support for sample weights in scorer objects. Metrics with sample weight support will automatically benefit from it. By Noel Dawe and Vlad Niculae.

• Added `newton-cg` and `lbfgs` solver support in `linear_model.LogisticRegression`. By Manoj Kumar.

• Add selection="random" parameter to implement stochastic coordinate descent for `linear_model.Lasso`, `linear_model.ElasticNet` and related. By Manoj Kumar.

• Add `sample_weight` parameter to `metrics.jaccard_similarity_score` and `metrics.log_loss`. By Jatin Shah.

• Support sparse multilabel indicator representation in `preprocessing.LabelBinarizer` and `multiclass.OneVsRestClassifier` (by Hamze Alsalhi with thanks to Rohit Sivaprasad), as well as evaluation metrics (by Joel Nothman).

• Add `sample_weight` parameter to `metrics.jaccard_similarity_score`. By Jatin Shah.

• Add support for multiclass in `metrics.hinge_loss`. Added `labels=None` as optional parameter. By Saurabh Jha.

• Add `sample_weight` parameter to `metrics.hinge_loss`. By Saurabh Jha.
• Add `multi_class``multinomial` option in `linear_model.LogisticRegression` to implement a Logistic Regression solver that minimizes the cross-entropy or multinomial loss instead of the default One-vs-Rest setting. Supports `lbfgs` and `newton-cg` solvers. By Lars Buitinck and Manoj Kumar. Solver option `newton-cg` by Simon Wu.

• DictVectorizer can now perform `fit_transform` on an iterable in a single pass, when giving the option `sort=False`. By Dan Blanchard.

• GridSearchCV and RandomizedSearchCV can now be configured to work with estimators that may fail and raise errors on individual folds. This option is controlled by the `error_score` parameter. This does not affect errors raised on re-fit. By Michal Romaniuk.

• Add `digits` parameter to `metrics.classification_report` to allow report to show different precision of floating point numbers. By Ian Gilmore.

• Add a quantile prediction strategy to the `dummy.DummyRegressor`. By Aaron Staple.

• Add `handle_unknown` option to `preprocessing.OneHotEncoder` to handle unknown categorical features more gracefully during transform. By Manoj Kumar.

• Added support for sparse input data to decision trees and their ensembles. By Fares Hedyati and Arnaud Joly.

• Optimized `cluster.AffinityPropagation` by reducing the number of memory allocations of large temporary data-structures. By Antony Lee.

• Parellization of the computation of feature importances in random forest. By Olivier Grisel and Arnaud Joly.

• Add `n_iter_` attribute to estimators that accept a `max_iter` attribute in their constructor. By Manoj Kumar.

• Added decision function for `multiclass.OneVsOneClassifier` By Raghav RV and Kyle Beauchamp.

• `neighbors.kneighbors_graph` and `radius_neighbors_graph` support non-Euclidean metrics. By Manoj Kumar.

• Parameter `connectivity` in `cluster.AgglomerativeClustering` and family now accept callables that return a connectivity matrix. By Manoj Kumar.

• Sparse support for `paired_distances`. By Joel Nothman.

• `cluster.DBSCAN` now supports sparse input and sample weights and has been optimized: the inner loop has been rewritten in Cython and radius neighbors queries are now computed in batch. By Joel Nothman and Lars Buitinck.

• Add `class_weight` parameter to automatically weight samples by class frequency for `ensemble.RandomForestClassifier`, `tree.DecisionTreeClassifier`, `ensemble.ExtraTreesClassifier` and `tree.ExtraTreeClassifier`. By Trevor Stephens.

• `grid_search.RandomizedSearchCV` now does sampling without replacement if all parameters are given as lists. By Andreas Müller.

• Parallelized calculation of `pairwise_distances` is now supported for scipy metrics and custom callables. By Joel Nothman.

• Allow the fitting and scoring of all clustering algorithms in `pipeline.Pipeline`. By Andreas Müller.

• More robust seeding and improved error messages in `cluster.MeanShift` by Andreas Müller.

• Make the stopping criterion for `mixture.GMM`, `mixture.DPGMM` and `mixture.VBGMM` less dependent on the number of samples by thresholding the average log-likelihood change instead of its sum over all samples. By Hervé Bredin.

• The outcome of `manifold.spectral_embedding` was made deterministic by flipping the sign of eigenvectors. By Hasil Sharma.
• Significant performance and memory usage improvements in `preprocessing PolynomialFeatures`. By Eric Martin.

• Numerical stability improvements for `preprocessing StandardScaler` and `preprocessing scale`. By Nicolas Goix

• `svm.SVC` fitted on sparse input now implements `decision_function`. By Rob Zinkov and Andreas Müller.

• `cross_validation.train_test_split` now preserves the input type, instead of converting to numpy arrays.

Documentation improvements

• Added example of using `FeatureUnion` for heterogeneous input. By Matt Terry

• Documentation on scorers was improved, to highlight the handling of loss functions. By Matt Pico.

• A discrepancy between liblinear output and scikit-learn’s wrappers is now noted. By Manoj Kumar.

• Improved documentation generation: examples referring to a class or function are now shown in a gallery on the class/function’s API reference page. By Joel Nothman.

• More explicit documentation of sample generators and of data transformation. By Joel Nothman.

• `sklearn.neighbors.BallTree` and `sklearn.neighbors.KDTree` used to point to empty pages stating that they are aliases of BinaryTree. This has been fixed to show the correct class docs. By Manoj Kumar.

• Added silhouette plots for analysis of KMeans clustering using `metrics.silhouette_samples` and `metrics.silhouette_score`. See Selecting the number of clusters with silhouette analysis on KMeans clustering.

Bug fixes

• Metaestimators now support ducktyping for the presence of `decision_function`, `predict_proba` and other methods. This fixes behavior of `grid_search.GridSearchCV`, `grid_search.RandomizedSearchCV`, `pipeline.Pipeline`, `feature_selection.RFE`, `feature_selection.RFECV` when nested. By Joel Nothman

• The `scoring` attribute of grid-search and cross-validation methods is no longer ignored when a `grid_search.GridSearchCV` is given as a base estimator or the base estimator doesn’t have predict.

• The function `hierarchical.ward_tree` now returns the children in the same order for both the structured and unstructured versions. By Matteo Visconti di Oleggio Castello.

• `feature_selection.RFECV` now correctly handles cases when `step` is not equal to 1. By Nikolay Mayorov

• The `decomposition.PCA` now undoes whitening in its `inverse_transform`. Also, its `components_` now always have unit length. By Michael Eickenberg.

• Fix incomplete download of the dataset when `datasets.download_20newsgroups` is called. By Manoj Kumar.

• Various fixes to the Gaussian processes subpackage by Vincent Dubourg and Jan Hendrik Metzen.

• Calling `partial_fit` with `class_weight='auto'` throws an appropriate error message and suggests a work around. By Danny Sullivan.
• **RBFSampler** with \(\gamma=g\) formerly approximated \(\texttt{rbf\_kernel}\) with \(\gamma=g/2\); the definition of \(\gamma\) is now consistent, which may substantially change your results if you use a fixed value. (If you cross-validated over \(\gamma\), it probably doesn’t matter too much.) By Dougal Sutherland.

• Pipeline object delegate the \texttt{classes\_} attribute to the underlying estimator. It allows, for instance, to make bagging of a pipeline object. By Arnaud Joly

• \texttt{neighbors.NearestCentroid} now uses the median as the centroid when metric is set to \texttt{manhattan}. It was using the mean before. By Manoj Kumar

• Fix numerical stability issues in \texttt{linear\_model.SGDClassifier} and \texttt{linear\_model.SGDRegressor} by clipping large gradients and ensuring that weight decay rescaling is always positive (for large l2 regularization and large learning rate values). By Olivier Grisel

• When \texttt{compute\_full\_tree} is set to “auto”, the full tree is built when \(n\_clusters\) is high and is early stopped when \(n\_clusters\) is low, while the behavior should be vice-versa in \texttt{cluster.AgglomerativeClustering} (and friends). This has been fixed By Manoj Kumar

• Fix lazy centering of data in \texttt{linear\_model.enet\_path} and \texttt{linear\_model.lasso\_path}. It was centered around one. It has been changed to be centered around the origin. By Manoj Kumar

• Fix handling of precomputed affinity matrices in \texttt{cluster.AgglomerativeClustering} when using connectivity constraints. By Cathy Deng

• Correct \texttt{partial\_fit} handling of \texttt{class\_prior} for \texttt{sklearn.naive\_bayes.MultinomialNB} and \texttt{sklearn.naive\_bayes.BernoulliNB}. By Trevor Stephens.

• Fixed a crash in \texttt{metrics.precision\_recall\_fscore\_support} when using unsorted \texttt{labels} in the multi-label setting. By Andreas Müller.

• Avoid skipping the first nearest neighbor in the methods \texttt{radius\_neighbors}, \texttt{kneighbors}, \texttt{kneighbors\_graph} and \texttt{radius\_neighbors\_graph} in \texttt{sklearn.neighbors.NearestNeighbors} and family, when the query data is not the same as fit data. By Manoj Kumar.

• Fix log-density calculation in the \texttt{mixture.GMM} with tied covariance. By Will Dawson

• Fixed a scaling error in \texttt{feature\_selection.SelectFdr} where a factor \texttt{n\_features} was missing. By Andrew Tulloch

• Fix zero division in \texttt{neighbors.KNeighborsRegressor} and related classes when using distance weighting and having identical data points. By Garret-R.

• Fixed round off errors with non positive-definite covariance matrices in \texttt{GMM}. By Alexis Mignon.

• Fixed a error in the computation of conditional probabilities in \texttt{naive\_bayes.BernoulliNB}. By Hanna Wallach.

• Make the method \texttt{radius\_neighbors} of \texttt{neighbors.NearestNeighbors} return the samples lying on the boundary for \texttt{algorithm='brute'}. By Yan Yi.

• Flip sign of \texttt{dual\_coef\_} of \texttt{svm.SVC} to make it consistent with the documentation and \texttt{decision\_function}. By Artem Sobolev.

• Fixed handling of ties in \texttt{isotonic.IsotonicRegression}. We now use the weighted average of targets (secondary method). By Andreas Müller and Michael Bommarito.
API changes summary

- GridSearchCV and cross_val_score and other meta-estimators don’t convert pandas DataFrames into arrays any more, allowing DataFrame specific operations in custom estimators.

- multiclass.fit_ovr, multiclass.predict_ovr, predict_proba_ovr, multiclass.fit_ovo, multiclass.predict_ovo, multiclass.fit_ecoc and multiclass.predict_ecoc are deprecated. Use the underlying estimators instead.

- Nearest neighbors estimators used to take arbitrary keyword arguments and pass these to their distance metric. This will no longer be supported in scikit-learn 0.18; use the metric_params argument instead.

- n_jobs parameter of the fit method shifted to the constructor of the LinearRegression class.

- The predict_proba method of multiclass.OneVsRestClassifier now returns two probabilities per sample in the multiclass case; this is consistent with other estimators and with the method’s documentation, but previous versions accidentally returned only the positive probability. Fixed by Will Lamond and Lars Buitinck.

- Change default value of precompute in ElasticNet and Lasso to False. Setting precompute to “auto” was found to be slower when n_samples > n_features since the computation of the Gram matrix is computationally expensive and outweighs the benefit of fitting the Gram for just one alpha. precompute="auto" is now deprecated and will be removed in 0.18 By Manoj Kumar.

- Expose positive option in linear_model.enet_path and linear_model.enet_path which constrains coefficients to be positive. By Manoj Kumar.

- Users should now supply an explicit average parameter to sklearn.metrics.f1_score, sklearn.metrics.fbeta_score, sklearn.metrics.recall_score and sklearn.metrics.precision_score when performing multiclass or multilabel (i.e. not binary) classification. By Joel Nothman.

- scoring parameter for cross validation now accepts 'f1_micro', 'f1_macro' or 'f1_weighted'. 'f1' is now for binary classification only. Similar changes apply to 'precision' and 'recall'. By Joel Nothman.

- The fit_intercept, normalize and return_models parameters in linear_model.enet_path and linear_model.lasso_path have been removed. They were deprecated since 0.14

- From now onwards, all estimators will uniformly raise NotFittedError (utils.validation.NotFittedError), when any of the predict like methods are called before the model is fit. By Raghav RV.

- Input data validation was refactored for more consistent input validation. The check_arrays function was replaced by check_array and check_X_y. By Andreas Müller.

- Allow X=None in the methods radius_neighbors, kneighbors, kneighbors_graph and radius_neighbors_graph in sklearn.neighbors.NearestNeighbors and family. If set to None, then for every sample this avoids setting the sample itself as the first nearest neighbor. By Manoj Kumar.

- Add parameter include_self in neighbors.kneighbors_graph and neighbors.radius_neighbors_graph which has to be explicitly set by the user. If set to True, then the sample itself is considered as the first nearest neighbor.

- thresh parameter is deprecated in favor of new tol parameter in GMM, DPGMM and VBGMM. See Enhancements section for details. By Hervé Bredin.

- Estimators will treat input with dtype object as numeric when possible. By Andreas Müller

- Estimators now raise ValueError consistently when fitted on empty data (less than 1 sample or less than 1 feature for 2D input). By Olivier Grisel.

`cluster.DBSCAN` now uses a deterministic initialization. The `random_state` parameter is deprecated. By Erich Schubert.

**Code Contributors**

**1.7.27 Version 0.15.2**

September 4, 2014

**Bug fixes**

- Fixed handling of the $p$ parameter of the Minkowski distance that was previously ignored in nearest neighbors models. By Nikolay Mayorov.

- Fixed duplicated alphas in `linear_model.LassoLars` with early stopping on 32 bit Python. By Olivier Grisel and Fabian Pedregosa.

- Fixed the build under Windows when scikit-learn is built with MSVC while NumPy is built with MinGW. By Olivier Grisel and Federico Vaggi.

- Fixed an array index overflow bug in the coordinate descent solver. By Gael Varoquaux.

- Better handling of numpy 1.9 deprecation warnings. By Gael Varoquaux.

- Removed unnecessary numpy 1.9 deprecation copy in `cluster.KMeans`. By Gael Varoquaux.

- Explicitly close open files to avoid `ResourceWarning` under Python 3. By Calvin Giles.
• The transform of `discriminant_analysis.LinearDiscriminantAnalysis` now projects the input on the most discriminant directions. By Martin Billinger.

• Fixed potential overflow in `_tree.safe_realloc` by Lars Buitinck.

• `nose` is non-longer a runtime dependency to import `sklearn`, only for running the tests. By Joel Nothman.

• Many documentation and website fixes by Joel Nothman, Lars Buitinck Matt Pico, and others.

1.7.28 Version 0.15.1

August 1, 2014

Bug fixes

• Made `cross_validation.cross_val_score` use `cross_validation.KFold` instead of `cross_validation.StratifiedKFold` on multi-output classification problems. By Nikolay Mayorov.

• Support unseen labels `preprocessing.LabelBinarizer` to restore the default behavior of 0.14.1 for backward compatibility. By Hamzeh Alsalhi.

• Fixed the `cluster.KMeans` stopping criterion that prevented early convergence detection. By Edward Raff and Gael Varoquaux.

• Fixed the behavior of `multiclass.OneVsOneClassifier` in case of ties at the per-class vote level by computing the correct per-class sum of prediction scores. By Andreas Müller.

• Made `cross_validation.cross_val_score` and `grid_search.GridSearchCV` accept Python lists as input data. This is especially useful for cross-validation and model selection of text processing pipelines. By Andreas Müller.

• Fixed data input checks of most estimators to accept input data that implements the NumPy `__array__` protocol. This is the case for for `pandas.Series` and `pandas.DataFrame` in recent versions of pandas. By Gael Varoquaux.

• Fixed a regression for `linear_model.SGDClassifier` with `class_weight="auto"` on data with non-contiguous labels. By Olivier Grisel.

1.7.29 Version 0.15

July 15, 2014

Highlights

• Many speed and memory improvements all across the code

• Huge speed and memory improvements to random forests (and extra trees) that also benefit better from parallel computing.

• Incremental fit to `BernoulliRBM`

• Added `cluster.AgglomerativeClustering` for hierarchical agglomerative clustering with average linkage, complete linkage and ward strategies.

• Added `linear_model.RANSACRegressor` for robust regression models.
• Added dimensionality reduction with `manifold.TSNE` which can be used to visualize high-dimensional data.

Changelog

New features

• Added `ensemble.BaggingClassifier` and `ensemble.BaggingRegressor` meta-estimators for ensembling any kind of base estimator. See the `Bagging` section of the user guide for details and examples. By Gilles Louppe.

• Added `linear_model.RANSACRegressor` meta-estimator for the robust fitting of regression models. By Johannes Schönberger.

• Added `cluster.AgglomerativeClustering` for hierarchical agglomerative clustering with average linkage, complete linkage and ward strategies, by Nelle Varoquaux and Gael Varoquaux.

• Shorthand constructors `pipeline.make_pipeline` and `pipeline.make_union` were added by Lars Buitinck.

• Shuffle option for `cross_validation.StratifiedKFold`. By Jeffrey Blackburne.

• Incremental learning (`partial_fit`) for Gaussian Naive Bayes by Imran Haque.

• Added `partial_fit` to `BernoulliRBM` By Danny Sullivan.

• Added `learning_curve` utility to chart performance with respect to training size. See `Plotting Learning Curves`. By Alexander Fabisch.

• Add positive option in `LassoCV` and `ElasticNetCV`. By Brian Wignall and Alexandre Gramfort.

• Added `manifold.TSNE`. By Alexander Fabisch.

Enhancements

• Memory improvements of decision trees, by Arnaud Joly.

• Decision trees can now be built in best-first manner by using `max_leaf_nodes` as the stopping criteria. Refactored the tree code to use either a stack or a priority queue for tree building. By Peter Prettenhofer and Gilles Louppe.

• Decision trees can now be fitted on fortran- and c-style arrays, and non-continuous arrays without the need to make a copy. If the input array has a different dtype than `np.float32`, a fortran- style copy will be made since fortran-style memory layout has speed advantages. By Peter Prettenhofer and Gilles Louppe.

• Speed improvement of regression trees by optimizing the the computation of the mean square error criterion. This lead to speed improvement of the tree, forest and gradient boosting tree modules. By Arnaud Joly

• The `img_to_graph` and `grid_to_graph` functions in `sklearn.feature_extraction.image` now return `np.ndarray` instead of `np.matrix` when `return_as=np.ndarray`. See the Notes section for more information on compatibility.
• Changed the internal storage of decision trees to use a struct array. This fixed some small bugs, while improving code and providing a small speed gain. By Joel Nothman.

• Reduce memory usage and overhead when fitting and predicting with forests of randomized trees in parallel with `n_jobs != 1` by leveraging new threading backend of joblib 0.8 and releasing the GIL in the tree fitting Cython code. By Olivier Grisel and Gilles Louppe.

• Speed improvement of the `sklearn.ensemble.gradient_boosting` module. By Gilles Louppe and Peter Prettenhofer.

• Various enhancements to the `sklearn.ensemble.gradient_boosting` module: a `warm_start` argument to fit additional trees, a `max_leaf_nodes` argument to fit GBM style trees, a `monitor` fit argument to inspect the estimator during training, and refactoring of the verbose code. By Peter Prettenhofer.

• Faster `sklearn.ensemble.ExtraTrees` by caching feature values. By Arnaud Joly.

• Faster depth-based tree building algorithm such as decision tree, random forest, extra trees or gradient tree boosting (with depth based growing strategy) by avoiding trying to split on found constant features in the sample subset. By Arnaud Joly.

• Add `min_weight_fraction_leaf` pre-pruning parameter to tree-based methods: the minimum weighted fraction of the input samples required to be at a leaf node. By Noel Dawe.

• Added `metrics.pairwise_distances_argmin_min`, by Philippe Gervais.

• Added predict method to `cluster.AffinityPropagation` and `cluster.MeanShift`, by Mathieu Blondel.

• Vector and matrix multiplications have been optimised throughout the library by Denis Engemann, and Alexandre Gramfort. In particular, they should take less memory with older NumPy versions (prior to 1.7.2).

• Precision-recall and ROC examples now use `train_test_split`, and have more explanation of why these metrics are useful. By Kyle Kastner

• The training algorithm for `decomposition.NMF` is faster for sparse matrices and has much lower memory complexity, meaning it will scale up gracefully to large datasets. By Lars Buitinck.

• Added svd_method option with default value to “randomized” to `decomposition.FactorAnalysis` to save memory and significantly speedup computation by Denis Engemann, and Alexandre Gramfort.

• Changed `cross_validation.StratifiedKFold` to try and preserve as much of the original ordering of samples as possible so as not to hide overfitting on datasets with a non-negligible level of samples dependency. By Daniel Nouri and Olivier Grisel.

• Add multi-output support to `gaussian_process.GaussianProcess` by John Novak.

• Support for precomputed distance matrices in nearest neighbor estimators by Robert Layton and Joel Nothman.

• Norm computations optimized for NumPy 1.6 and later versions by Lars Buitinck. In particular, the k-means algorithm no longer needs a temporary data structure the size of its input.

• `dummy.DummyClassifier` can now be used to predict a constant output value. By Manoj Kumar.

• `dummy.DummyRegressor` has now a strategy parameter which allows to predict the mean, the median of the training set or a constant output value. By Maheshakya Wijewardena.

• Multi-label classification output in multilabel indicator format is now supported by `metrics.roc_auc_score` and `metrics.average_precision_score` by Arnaud Joly.

• Significant performance improvements (more than 100x speedup for large problems) in `isotonic.IsotonicRegression` by Andrew Tulloch.

• Speed and memory usage improvements to the SGD algorithm for linear models: it now uses threads, not separate processes, when `n_jobs>1`. By Lars Buitinck.
• Grid search and cross validation allow NaNs in the input arrays so that preprocessors such as `preprocessing.Imputer` can be trained within the cross validation loop, avoiding potentially skewed results.

• Ridge regression can now deal with sample weights in feature space (only sample space until then). By Michael Eickenberg. Both solutions are provided by the Cholesky solver.

• Several classification and regression metrics now support weighted samples with the new `sample_weight` argument: `metrics.accuracy_score`, `metrics.zero_one_loss`, `metrics.precision_score`, `metrics.average_precision_score`, `metrics.f1_score`, `metrics.fbeta_score`, `metrics.recall_score`, `metrics.roc_auc_score`, `metrics.explained_variance_score`, `metrics.mean_squared_error`, `metrics.mean_absolute_error`, `metrics.r2_score`. By Noel Dawe.

• Speed up of the sample generator `datasets.make_multilabel_classification`. By Joel Nothman.

Documentation improvements

• The `Working With Text Data` tutorial has now been worked in to the main documentation’s tutorial section. Includes exercises and skeletons for tutorial presentation. Original tutorial created by several authors including Olivier Grisel, Lars Buitinck and many others. Tutorial integration into the scikit-learn documentation by Jaques Grobler

• Added `Computational Performance` documentation. Discussion and examples of prediction latency / throughput and different factors that have influence over speed. Additional tips for building faster models and choosing a relevant compromise between speed and predictive power. By Eustache Diemert.

Bug fixes

• Fixed bug in `decomposition.MiniBatchDictionaryLearning`: `partial_fit` was not working properly.

• Fixed bug in `linear_model.stochastic_gradient`: `l1_ratio` was used as (1.0 - l1_ratio).

• Fixed bug in `multiclass.OneVsOneClassifier` with string labels

• Fixed a bug in `LassoCV` and `ElasticNetCV`: they would not pre-compute the Gram matrix with `precompute=True` or `precompute="auto"` and `n_samples > n_features`. By Manoj Kumar.

• Fixed incorrect estimation of the degrees of freedom in `feature_selection.f_regression` when variables are not centered. By Virgile Fritsch.

• Fixed a race condition in parallel processing with `pre_dispatch != "all"` (for instance, in `cross_val_score`). By Olivier Grisel.

• Raise error in `cluster.FeatureAgglomeration` and `cluster.WardAgglomeration` when no samples are given, rather than returning meaningless clustering.

• Fixed bug in `gradient_boosting.GradientBoostingRegressor` with `loss='huber'`: gamma might have not been initialized.

• Fixed feature importances as computed with a forest of randomized trees when fit with `sample_weight != None` and/or with `bootstrap=True`. By Gilles Louppe.
API changes summary

- `sklearn.hmm` is deprecated. Its removal is planned for the 0.17 release.
- Use of `covariance.EllipticEnvelope` has now been removed after deprecation. Please use `covariance.EllipticEnvelope` instead.
- `cluster.Ward` is deprecated. Use `cluster.AgglomerativeClustering` instead.
- `cluster.WardClustering` is deprecated. Use `cluster.AgglomerativeClustering` instead.
- `cross_validation.Bootstrap` is deprecated. `cross_validation.KFold` or `cross_validation.ShuffleSplit` are recommended instead.
- Direct support for the sequence of sequences (or list of lists) multilabel format is deprecated. To convert to and from the supported binary indicator matrix format, use `MultiLabelBinarizer`. By Joel Nothman.
- Add score method to `PCA` following the model of probabilistic PCA and deprecate `ProbabilisticPCA` model whose score implementation is not correct. The computation now also exploits the matrix inversion lemma for faster computation. By Alexandre Gramfort.
- The score method of `FactorAnalysis` now returns the average log-likelihood of the samples. Use `score_samples` to get log-likelihood of each sample. By Alexandre Gramfort.
- Generating boolean masks (the setting `indices=False`) from cross-validation generators is deprecated. Support for masks will be removed in 0.17. The generators have produced arrays of indices by default since 0.10. By Joel Nothman.
- 1-d arrays containing strings with `dtype=object` (as used in Pandas) are now considered valid classification targets. This fixes a regression from version 0.13 in some classifiers. By Joel Nothman.
- Fix wrong `explained_variance_ratio_` attribute in `RandomizedPCA`. By Alexandre Gramfort.
- Fit alphas for each `l1_ratio` instead of `mean_l1_ratio` in `linear_model.ElasticNetCV` and `linear_model.LassoCV`. This changes the shape of `alphas_` from `(n_alphas,)` to `(n_l1_ratio, n_alphas)` if the `l1_ratio` provided is a 1-D array like object of length greater than one. By Manoj Kumar.
- Fix `linear_model.ElasticNetCV` and `linear_model.LassoCV` when fitting intercept and input data is sparse. The automatic grid of alphas was not computed correctly and the scaling with normalize was wrong. By Manoj Kumar.
- Fix wrong maximal number of features drawn (`max_features`) at each split for decision trees, random forests and gradient tree boosting. Previously, the count for the number of drawn features started only after one non constant features in the split. This bug fix will affect computational and generalization performance of those algorithms in the presence of constant features. To get back previous generalization performance, you should modify the value of `max_features`. By Arnaud Joly.
- Fix wrong maximal number of features drawn (`max_features`) at each split for `ensemble.ExtraTreesClassifier` and `ensemble.ExtraTreesRegressor`. Previously, only non constant features in the split was counted as drawn. Now constant features are counted as drawn. Furthermore at least one feature must be non constant in order to make a valid split. This bug fix will affect computational and generalization performance of extra trees in the presence of constant features. To get back previous generalization performance, you should modify the value of `max_features`. By Arnaud Joly.
- Fix `utils.compute_class_weight` when `class_weight="auto"`. Previously it was broken for input of non-integer `dtype` and the weighted array that was returned was wrong. By Manoj Kumar.

1.7. Release History
1.7. Release History
• Missing values with sparse and dense matrices can be imputed with the transformer `preprocessing.Imputer` by Nicolas Trésegnie.

• The core implementation of decisions trees has been rewritten from scratch, allowing for faster tree induction and lower memory consumption in all tree-based estimators. By Gilles Louppe.

• Added `ensemble.AdaBoostClassifier` and `ensemble.AdaBoostRegressor`, by Noel Dawe and Gilles Louppe. See the `AdaBoost` section of the user guide for details and examples.

• Added `grid_search(RandomizedSearchCV)` and `grid_search.ParameterSampler` for randomized hyperparameter optimization. By Andreas Müller.

• Added `biclustering` algorithms (`sklearn.cluster.bicluster.SpectralCoclustering` and `sklearn.cluster.bicluster.SpectralBiclustering`), data generation methods (`sklearn.datasets.make_biclusters` and `sklearn.datasets.make_checkerboard`), and scoring metrics (`sklearn.metrics.consensus_score`). By Kemal Eren.

• Added `Restricted Boltzmann Machines` (`neural_network.BernoulliRBM`). By Yann Dauphin.
• Python 3 support by Justin Vincent, Lars Buitinck, Subhodeep Moitra and Olivier Grisel. All tests now pass under Python 3.3.

• Ability to pass one penalty (alpha value) per target in `linear_model.Ridge`, by @eickenberg and Mathieu Blondel.

• Fixed `sklearn.linear_model.stochastic_gradient.py` L2 regularization issue (minor practical significance). By Norbert Crombach and Mathieu Blondel.

• Added an interactive version of Andreas Müller’s Machine Learning Cheat Sheet (for scikit-learn) to the documentation. See `Choosing the right estimator`. By Jaques Grobler.

• `grid_search.GridSearchCV` and `cross_validation.cross_val_score` now support the use of advanced scoring function such as area under the ROC curve and f-beta scores. See `The scoring parameter: defining model evaluation rules` for details. By Andreas Müller and Lars Buitinck. Passing a function from `sklearn.metrics` as `score_func` is deprecated.

• Multi-label classification output is now supported by `metrics.accuracy_score`, `metrics.zero_one_loss`, `metrics.f1_score`, `metrics.fbeta_score`, `metrics.classification_report`, `metrics.precision_score` and `metrics.recall_score` by Arnaud Joly.

• Two new metrics `metrics.hamming_loss` and `metrics.jaccard_similarity_score` are added with multi-label support by Arnaud Joly.

• Speed and memory usage improvements in `feature_extraction.text.CountVectorizer` and `feature_extraction.text.TfidfVectorizer`, by Jochen Wersdörfer and Roman Sinayev.

• The `min_df` parameter in `feature_extraction.text.CountVectorizer` and `feature_extraction.text.TfidfVectorizer`, which used to be 2, has been reset to 1 to avoid unpleasant surprises (empty vocabularies) for novice users who try it out on tiny document collections. A value of at least 2 is still recommended for practical use.

• `svm.LinearSVC`, `linear_model.SGDClassifier` and `linear_model.SGDRegressor` now have a `sparsify` method that converts their `coef_` into a sparse matrix, meaning stored models trained using these estimators can be made much more compact.

• `linear_model.SGDClassifier` now produces multiclass probability estimates when trained under log loss or modified Huber loss.

• Hyperlinks to documentation in example code on the website by Martin Luessi.

• Fixed bug in `preprocessing.MinMaxScaler` causing incorrect scaling of the features for non-default `feature_range` settings. By Andreas Müller.

• `max_features` in `tree.DecisionTreeClassifier`, `tree.DecisionTreeRegressor` and all derived ensemble estimators now supports percentage values. By Gilles Louppe.

• Performance improvements in `isotonic.IsotonicRegression` by Nelle Varoquaux.

• `metrics.accuracy_score` has an option normalize to return the fraction or the number of correctly classified sample by Arnaud Joly.

• Added `metrics.log_loss` that computes log loss, aka cross-entropy loss. By Jochen Wersdörfer and Lars Buitinck.

• A bug that caused `ensemble.AdaBoostClassifier`’s to output incorrect probabilities has been fixed.

• Feature selectors now share a mixin providing consistent `transform`, `inverse_transform` and `get_support` methods. By Joel Nothman.

• A fitted `grid_search.GridSearchCV` or `grid_search.RandomizedSearchCV` can now generally be pickled. By Joel Nothman.
• Refactored and vectorized implementation of `metrics.roc_curve` and `metrics.precision_recall_curve`. By Joel Nothman.

• The new estimator `sklearn.decomposition.TruncatedSVD` performs dimensionality reduction using SVD on sparse matrices, and can be used for latent semantic analysis (LSA). By Lars Buitinck.

• Added self-contained example of out-of-core learning on text data *Out-of-core classification of text documents*. By Eustache Diemert.

• The default number of components for `sklearn.decomposition.RandomizedPCA` is now correctly documented to be `n_features`. This was the default behavior, so programs using it will continue to work as they did.

• `sklearn.cluster.KMeans` now fits several orders of magnitude faster on sparse data (the speedup depends on the sparsity). By Lars Buitinck.

• Reduce memory footprint of FastICA by Denis Engemann and Alexandre Gramfort.

• Verbose output in `sklearn.ensemble.gradient_boosting` now uses a column format and prints progress in decreasing frequency. It also shows the remaining time. By Peter Prettenhofer.

• `sklearn.ensemble.gradient_boosting` provides out-of-bag improvement `oob_improvement` rather than the OOB score for model selection. An example that shows how to use OOB estimates to select the number of trees was added. By Peter Prettenhofer.

• Most metrics now support string labels for multiclass classification by Arnaud Joly and Lars Buitinck.

• New OrthogonalMatchingPursuitCV class by Alexandre Gramfort and Vlad Niculae.

• Fixed a bug in `sklearn.covariance.GraphLassoCV`: the ‘alphas’ parameter now works as expected when given a list of values. By Philippe Gervais.

• Fixed an important bug in `sklearn.covariance.GraphLassoCV` that prevented all folds provided by a CV object to be used (only the first 3 were used). When providing a CV object, execution time may thus increase significantly compared to the previous version (bug results are correct now). By Philippe Gervais.

• `cross_validation.cross_val_score` and the `grid_search` module is now tested with multi-output data by Arnaud Joly.

• `datasets.make_multilabel_classification` can now return the output in label indicator multi-label format by Arnaud Joly.

• Random state in LibSVM-based estimators (`svm.SVC`, `NuSVC`, `OneClassSVM`, `svm.SVR`, `svm.NuSVR`) can now be controlled. This is useful to ensure consistency in the probability estimates for the classifiers trained with `probability=True`. By Vlad Niculae.

• Out-of-core learning support for discrete naive Bayes classifiers `sklearn.naive_bayes.MultinomialNB` and `sklearn.naive_bayes.BernoulliNB` by adding the `partial_fit` method by Olivier Grisel.

• New website design and navigation by Gilles Louppe, Nelle Varoquaux, Vincent Michel and Andreas Müller.

• Improved documentation on *multi-class, multi-label and multi-output classification* by Yannick Schwartz and Arnaud Joly.

• Better input and error handling in the `metrics` module by Arnaud Joly and Joel Nothman.

• Speed optimization of the `hmm` module by Mikhail Korobov

• Significant speed improvements for `sklearn.cluster.DBSCAN` by cleverless
API changes summary

- The `auc_score` was renamed `roc_auc_score`.
- Testing scikit-learn with `sklearn.test()` is deprecated. Use `nose tests sklearn` from the command line.
- Feature importances in `tree.DecisionTreeClassifier`, `tree.DecisionTreeRegressor` and all derived ensemble estimators are now computed on the fly when accessing the `feature_importances_` attribute. Setting `compute_importances=True` is no longer required. By Gilles Louppe.
- `linear_model.lasso_path` and `linear_model.enet_path` can return its results in the same format as that of `linear_model.lars_path`. This is done by setting the `return_models` parameter to `False`. By Jaques Grobler and Alexandre Gramfort.
- `grid_search.IterGrid` was renamed to `grid_search.ParameterGrid`.
- Fixed bug in `KFold` causing imperfect class balance in some cases. By Alexandre Gramfort and Tadej Janež.
- `sklearn.neighbors.BallTree` has been refactored, and a `sklearn.neighbors.KDTree` has been added which shares the same interface. The Ball Tree now works with a wide variety of distance metrics. Both classes have many new methods, including single-tree and dual-tree queries, breadth-first and depth-first searching, and more advanced queries such as kernel density estimation and 2-point correlation functions. By Jake Vanderplas.
- Support for `scipy.spatial.cKDTree` within neighbors queries has been removed, and the functionality replaced with the new `KDTree` class.
- `sklearn.neighbors.KernelDensity` has been added, which performs efficient kernel density estimation with a variety of kernels.
- `sklearn.decomposition.KernelPCA` now always returns output with `n_components` components, unless the new parameter `remove_zero_eig` is set to `True`. This new behavior is consistent with the way kernel PCA was always documented; previously, the removal of components with zero eigenvalues was tacitly performed on all data.
- `gcv_mode="auto"` no longer tries to perform SVD on a densified sparse matrix in `sklearn.linear_model.RidgeCV`.
- Sparse matrix support in `sklearn.decomposition.RandomizedPCA` is now deprecated in favor of the new `TruncatedSVD`.
- `cross_validation.KFold` and `cross_validation.StratifiedKFold` now enforce `n_folds >= 2` otherwise a `ValueError` is raised. By Olivier Grisel.
- `datasets.load_files`'s `charset` and `charset_errors` parameters were renamed `encoding` and `decode_errors`.
- Attribute `oob_score_` in `sklearn.ensemble.GradientBoostingRegressor` and `sklearn.ensemble.GradientBoostingClassifier` is deprecated and has been replaced by `oob_improvement_`.
- Attributes in `OrthogonalMatchingPursuit` have been deprecated (copy_X, Gram, ...) and `precompute_gram` renamed `precompute` for consistency. See #2224.
- `sklearn.preprocessing.StandardScaler` now converts integer input to float, and raises a warning. Previously it rounded for dense integer input.
- `sklearn.multiclass.OneVsRestClassifier` now has a `decision_function` method. This will return the distance of each sample from the decision boundary for each class, as long as the underlying estimators implement the `decision_function` method. By Kyle Kastner.
- Better input validation, warning on unexpected shapes for y.

1.7. Release History
1.7.31 Version 0.13.1

February 23, 2013

The 0.13.1 release only fixes some bugs and does not add any new functionality.

Changelog

- Fixed a testing error caused by the function `cross_validation.train_test_split` being interpreted as a test by Yaroslav Halchenko.
- Fixed a bug in the reassignment of small clusters in the `cluster.MiniBatchKMeans` by Gael Varoquaux.
- Fixed default value of `gamma` in `decomposition.KernelPCA` by Lars Buitinck.
- Updated joblib to 0.7.0d by Gael Varoquaux.
- Fixed scaling of the deviance in `ensemble.GradientBoostingClassifier` by Peter Prettenhofer.
- Better tie-breaking in `multiclass.OneVsOneClassifier` by Andreas Müller.
- Other small improvements to tests and documentation.

1.7.32 Version 0.13

January 21, 2013

New Estimator Classes

- `decomposition.FactorAnalysis`, a transformer implementing the classical factor analysis, by Christian Osendorfer and Alexandre Gramfort. See Factor Analysis in the user guide.

- `feature_extraction.FeatureHasher`, a transformer implementing the “hashing trick” for fast, low-memory feature extraction from string fields by Lars Buitinck and feature_extraction.text. HashingVectorizer for text documents by Olivier Grisel See Feature hashing and Vectorizing a large text corpus with the hashing trick for the documentation and sample usage.

- `pipeline.FeatureUnion`, a transformer that concatenates results of several other transformers by Andreas Müller. See FeatureUnion: composite feature spaces in the user guide.

- `random_projection.GaussianRandomProjection`, `random_projection.SparseRandomProjection` and the function `random_projection.johnson_lindenstrauss_min_dim`. The first two are transformers implementing Gaussian and sparse random projection matrix by Olivier Grisel and Arnaud Joly. See Random Projection in the user guide.

• **preprocessing.OneHotEncoder**, a transformer that computes binary encodings of categorical features by Andreas Müller. See Encoding categorical features in the user guide.

• **ensemble.RandomTreesEmbedding**, a transformer for creating high-dimensional sparse representations using ensembles of totally random trees by Andreas Müller. See Totally Random Trees Embedding in the user guide.

• **manifold.SpectralEmbedding** and function **manifold.spectral_embedding**, implementing the “laplacian eigenmaps” transformation for non-linear dimensionality reduction by Wei Li. See Spectral Embedding in the user guide.

• **isotonic.IsotonicRegression** by Fabian Pedregosa, Alexandre Gramfort and Nelle Varoquaux,

**Changelog**

• **metrics.zero_one_loss** (formerly **metrics.zero_one**) now has option for normalized output that reports the fraction of misclassifications, rather than the raw number of misclassifications. By Kyle Beauchamp.

• **tree.DecisionTreeClassifier** and all derived ensemble models now support sample weighting, by Noel Dawe and Gilles Louppe.

• Speedup improvement when using bootstrap samples in forests of randomized trees, by Peter Prettenhofer and Gilles Louppe.

• Partial dependence plots for **Gradient Tree Boosting** in **ensemble.partial_dependence.partial_dependence** by Peter Prettenhofer. See Partial Dependence and Individual Conditional Expectation Plots for an example.

• The table of contents on the website has now been made expandable by Jaques Grobler.

• **feature_selection.SelectPercentile** now breaks ties deterministically instead of returning all equally ranked features.

• **feature_selection.SelectKBest** and **feature_selection.SelectPercentile** are more numerically stable since they use scores, rather than p-values, to rank results. This means that they might sometimes select different features than they did previously.

• Ridge regression and ridge classification fitting with **sparse_cg** solver no longer has quadratic memory complexity, by Lars Buitinck and Fabian Pedregosa.

• Ridge regression and ridge classification now support a new fast solver called **lsqr**, by Mathieu Blondel.

• Speed up of **metrics.precision_recall_curve** by Conrad Lee.

• Added support for reading/writing svmlight files with pairwise preference attribute (qid in svmlight file format) in **datasets.dump_svmlight_file** and **datasets.load_svmlight_file** by Fabian Pedregosa.

• Faster and more robust **metrics.confusion_matrix** and Clustering performance evaluation by Wei Li.

• **cross_validation.cross_val_score** now works with precomputed kernels and affinity matrices, by Andreas Müller.

• LARS algorithm made more numerically stable with heuristics to drop regressors too correlated as well as to stop the path when numerical noise becomes predominant, by Gael Varoquaux.

• Faster implementation of **metrics.precision_recall_curve** by Conrad Lee.

• New kernel **metrics.chi2_kernel** by Andreas Müller, often used in computer vision applications.
• Fix of longstanding bug in `naive_bayes.BernoulliNB` fixed by Shaun Jackman.

• Implemented `predict_proba` in `multiclass.OneVsRestClassifier`, by Andrew Winterman.

• Improve consistency in gradient boosting: estimators `ensemble.GradientBoostingRegressor` and `ensemble.GradientBoostingClassifier` use the estimator `tree.DecisionTreeRegressor` instead of the `tree._tree.Tree` data structure by Arnaud Joly.

• Fixed a floating point exception in the `decision trees` module, by Seberg.

• Fix `metrics.roc_curve` fails when `y_true` has only one class by Wei Li.

• Add the `metrics.mean_absolute_error` function which computes the mean absolute error. The `metrics.mean_squared_error`, `metrics.mean_absolute_error` and `metrics.r2_score` metrics support multioutput by Arnaud Joly.

• Fixed `class_weight` support in `svm.LinearSVC` and `linear_model.LogisticRegression` by Andreas Müller. The meaning of `class_weight` was reversed as erroneously higher weight meant less positives of a given class in earlier releases.

• Improve narrative documentation and consistency in `sklearn.metrics` for regression and classification metrics by Arnaud Joly.

• Fixed a bug in `sklearn.svm.SVC` when using csr-matrices with unsorted indices by Xinfan Meng and Andreas Müller.

• MiniBatchKMeans: Add random reassignment of cluster centers with little observations attached to them, by Gael Varoquaux.

**API changes summary**

• Renamed all occurrences of `n_atoms` to `n_components` for consistency. This applies to `decomposition.DictionaryLearning`, `decomposition.MiniBatchDictionaryLearning`, `decomposition.dict_learning`, `decomposition.dict_learning_online`.

• Renamed all occurrences of `max_iters` to `max_iter` for consistency. This applies to `semi_supervised.LabelPropagation` and `semi_supervised.label_propagation.LabelSpreading`.

• Renamed all occurrences of `learn_rate` to `learning_rate` for consistency in `ensemble.BaseGradientBoosting` and `ensemble.GradientBoostingRegressor`.

• The module `sklearn.linear_model.sparse` is gone. Sparse matrix support was already integrated into the “regular” linear models.

• `sklearn.metrics.mean_square_error`, which incorrectly returned the accumulated error, was removed. Use `mean_squared_error` instead.

• Passing `class_weight` parameters to `fit` methods is no longer supported. Pass them to estimator constructors instead.

• GMMs no longer have `decode` and `rvs` methods. Use the `score`, `predict` or `sample` methods instead.

• The `solver` fit option in Ridge regression and classification is now deprecated and will be removed in v0.14. Use the constructor option instead.

• `feature_extraction.text.DictVectorizer` now returns sparse matrices in the CSR format, instead of COO.

• Renamed `k` in `cross_validation.KFold` and `cross_validation.StratifiedKFold` to `n_folds`, renamed `n_bootstraps` to `n_iter` in `cross_validation.Bootstrap`.
Renamed all occurrences of `n_iterations` to `n_iter` for consistency. This applies to `cross_validation.ShuffleSplit`, `cross_validation.StratifiedShuffleSplit`, `utils.randomized_range_finder` and `utils.randomized_svd`.

Replaced `rho` in `linear_model.ElasticNet` and `linear_model.SGDClassifier` by `l1_ratio`. The `rho` parameter had different meanings; `l1_ratio` was introduced to avoid confusion. It has the same meaning as previously `rho` in `linear_model.ElasticNet` and `(1-rho)` in `linear_model.SGDClassifier`.

`linear_model.LassoLars` and `linear_model.Lars` now store a list of paths in the case of multiple targets, rather than an array of paths.

The attribute `gmm` of `hmm.GMMHMM` was renamed to `gmm_` to adhere more strictly with the API.

`cluster.spectral_embedding` was moved to `manifold.spectral_embedding`.

Renamed `eig_tol` in `manifold.spectral_embedding`, `cluster.SpectralClustering` to `eigen_tol`, renamed `mode` to `eigen_solver`.

Renamed `mode` in `manifold.spectral_embedding` and `cluster.SpectralClustering` to `eigen_solver`.

classes_ and `n_classes_` attributes of `tree.DecisionTreeClassifier` and all derived ensemble models are now flat in case of single output problems and nested in case of multi-output problems.

`svm.SVC` and `svm.NuSVC` now provide a `classes_` attribute and support arbitrary dtypes for labels `y`. Also, the dtype returned by `predict` now reflects the dtype of `y` during `fit` (used to be `np.float`).

Changed default `test_size` in `cross_validation.train_test_split` to `None`, added possibility to infer `test_size` from `train_size` in `cross_validation.ShuffleSplit` and `cross_validation.StratifiedShuffleSplit`.

Renamed function `sklearn.metrics.zero_one` to `sklearn.metrics.zero_one_loss`. Be aware that the default behavior in `sklearn.metrics.zero_one_loss` is different from `sklearn.metrics.zero_one`: normalize=False is changed to normalize=True.

Renamed function `metrics.zero_one_score` to `metrics.accuracy_score`.

`datasets.make_circles` now has the same number of inner and outer points.

In the Naive Bayes classifiers, the `class_prior` parameter was moved from `fit` to `__init__`.

- 143 Arnaud Joly
- 137 Peter Prettenhofer
- 131 Gael Varoquaux
- 117 Mathieu Blondel
- 108 Lars Buitinck
1.7.33 Version 0.12.1

October 8, 2012

The 0.12.1 release is a bug-fix release with no additional features, but is instead a set of bug fixes

Changelog

- Improved numerical stability in spectral embedding by Gael Varoquaux
- Doctest under windows 64bit by Gael Varoquaux
- Documentation fixes for elastic net by Andreas Müller and Alexandre Gramfort
- Proper behavior with fortran-ordered NumPy arrays by Gael Varoquaux
- Make GridSearchCV work with non-CSR sparse matrix by Lars Buitinck
- Fix parallel computing in MDS by Gael Varoquaux
• Fix Unicode support in count vectorizer by Andreas Müller
• Fix MinCovDet breaking with X.shape = (3, 1) by Virgile Fritsch
• Fix clone of SGD objects by Peter Prettenhofer
• Stabilize GMM by Virgile Fritsch

• 1 Gilles Louppe
• 1 Mathieu Blondel

1.7.34 Version 0.12

September 4, 2012

Changelog

• Various speed improvements of the decision trees module, by Gilles Louppe.
• GradientBoostingRegressor and GradientBoostingClassifier now support feature subsampling via the max_features argument, by Peter Prettenhofer.
• Added Huber and Quantile loss functions to GradientBoostingRegressor, by Peter Prettenhofer.
• Decision trees and forests of randomized trees now support multi-output classification and regression problems, by Gilles Louppe.
• Added LabelEncoder, a simple utility class to normalize labels or transform non-numerical labels, by Mathieu Blondel.
• Added the epsilon-insensitive loss and the ability to make probabilistic predictions with the modified huber loss in Stochastic Gradient Descent, by Mathieu Blondel.
• Added Multi-dimensional Scaling (MDS), by Nelle Varoquaux.
• SVMlight file format loader now detects compressed (gzip/bzip2) files and decompresses them on the fly, by Lars Buitinck.
• SVMlight file format serializer now preserves double precision floating point values, by Olivier Grisel.
• A common testing framework for all estimators was added, by Andreas Müller.
• Understandable error messages for estimators that do not accept sparse input by Gael Varoquaux
• Speedups in hierarchical clustering by Gael Varoquaux. In particular building the tree now supports early stopping. This is useful when the number of clusters is not small compared to the number of samples.
• Add MultiTaskLasso and MultiTaskElasticNet for joint feature selection, by Alexandre Gramfort.
• Added `metrics.auc_score` and `metrics.average_precision_score` convenience functions by Andreas Müller.

• Improved sparse matrix support in the Feature selection module by Andreas Müller.

• New word boundaries-aware character n-gram analyzer for the Text feature extraction module by @kernc.

• Fixed bug in spectral clustering that led to single point clusters by Andreas Müller.

• In `CountVectorizer`, added an option to ignore infrequent words, `min_df` by Andreas Müller.

• Add support for multiple targets in some linear models (ElasticNet, Lasso and OrthogonalMatchingPursuit) by Vlad Niculae and Alexandre Gramfort.

• Fixes in `ProbabilisticPCA` score function by Wei Li.

• Fixed feature importance computation in Gradient Tree Boosting.

API changes summary

• The old `scikits.learn` package has disappeared; all code should import from `sklearn` instead, which was introduced in 0.9.

• In `metrics.roc_curve`, the `thresholds` array is now returned with it’s order reversed, in order to keep it consistent with the order of the returned `fpr` and `tpr`.

• In `hmm` objects, like `GaussianHMM`, `MultinomialHMM`, etc., all parameters must be passed to the object when initialising it and not through `fit`. Now `fit` will only accept the data as an input parameter.

• For all SVM classes, a faulty behavior of `gamma` was fixed. Previously, the default gamma value was only computed the first time `fit` was called and then stored. It is now recalculated on every call to `fit`.

• All `Base` classes are now abstract meta classes so that they can not be instantiated.

• `cluster.ward_tree` now also returns the parent array. This is necessary for early-stopping in which case the tree is not completely built.

• In `CountVectorizer` the parameters `min_n` and `max_n` were joined to the parameter `n_gram_range` to enable grid-searching both at once.

• In `CountVectorizer`, words that appear only in one document are now ignored by default. To reproduce the previous behavior, set `min_df=1`.

• Fixed API inconsistency: `linear_model.SGDClassifier.predict_proba` now returns 2d array when fit on two classes.

• Fixed API inconsistency: `discriminant_analysis.QuadraticDiscriminantAnalysis.decision_function` and `discriminant_analysis.LinearDiscriminantAnalysis.decision_function` now return 1d arrays when fit on two classes.

• Grid of alphas used for fitting `LassoCV` and `ElasticNetCV` is now stored in the attribute `alphas_` rather than overriding the init parameter `alphas`.

• Linear models when alpha is estimated by cross-validation store the estimated value in the `alpha_` attribute rather than just `alpha` or `best_alpha`.

• `GradientBoostingClassifier` now supports `staged_predict_proba`, and `staged_predict`.

• `SVC` and other sparse SVM classes are now deprecated. The all classes in the Support Vector Machines module now automatically select the sparse or dense representation base on the input.

• All clustering algorithms now interpret the array `X` given to `fit` as input data, in particular `SpectralClustering` and `AffinityPropagation` which previously expected affinity matrices.
• For clustering algorithms that take the desired number of clusters as a parameter, this parameter is now called `n_clusters`.

1.7.35 Version 0.11

May 7, 2012

Changelog

Highlights

- Gradient boosted regression trees (Gradient Tree Boosting) for classification and regression by Peter Prettenhofer and Scott White.
- Simple dict-based feature loader with support for categorical variables (DictVectorizer) by Lars Buitinck.
- Added Matthews correlation coefficient (metrics.matthews_corrcoef) and added macro and micro average options to precision_score, metrics.recall_score and f1_score by Satrajit Ghosh.
- Out of Bag Estimates of generalization error for Ensemble methods by Andreas Müller.
- Randomized sparse linear models for feature selection, by Alexandre Gramfort and Gael Varoquaux
- Label Propagation for semi-supervised learning, by Clay Woolam. Note the semi-supervised API is still work in progress, and may change.
- Added BIC/AIC model selection to classical Gaussian mixture models and unified the API with the remainder of scikit-learn, by Bertrand Thirion
- Added StratifiedShuffleSplit, which is a ShuffleSplit with balanced splits, by Yannick Schwartz.
- NearestCentroid classifier added, along with a shrink_threshold parameter, which implements shrunken centroid classification, by Robert Layton.
Other changes

- Merged dense and sparse implementations of Stochastic Gradient Descent module and exposed utility extension types for sequential datasets `seq_dataset` and weight vectors `weight_vector` by Peter Prettenhofer.
- Added `partial_fit` (support for online/minibatch learning) and `warm_start` to the Stochastic Gradient Descent module by Mathieu Blondel.
- Dense and sparse implementations of Support Vector Machines classes and `LogisticRegression` merged by Lars Buitinck.
- Regressors can now be used as base estimator in the Multiclass and multioutput algorithms module by Mathieu Blondel.
- Added `n_jobs` option to `metrics.pairwise.pairwise_distances` and `metrics.pairwise.pairwise_kernels` for parallel computation, by Mathieu Blondel.
- K-means can now be run in parallel, using the `n_jobs` argument to either K-means or KMeans, by Robert Layton.
- Improved Cross-validation: evaluating estimator performance and Tuning the hyper-parameters of an estimator documentation and introduced the new `cross_validation.train_test_split` helper function by Olivier Grisel
- SVC members `coef_` and `intercept_` changed sign for consistency with `decision_function`; for `kernel==linear`, `coef_` was fixed in the one-vs-one case, by Andreas Müller.
- Performance improvements to efficient leave-one-out cross-validated Ridge regression, esp. for the `n_samples > n_features` case, in `RidgeCV`, by Reuben Fletcher-Costin.
- Refactoring and simplification of the Text feature extraction API and fixed a bug that caused possible negative IDF, by Olivier Grisel.
- Beam pruning option in `_BaseHMM` module has been removed since it is difficult to Cythonize. If you are interested in contributing a Cython version, you can use the python version in the git history as a reference.
- Classes in Nearest Neighbors now support arbitrary Minkowski metric for nearest neighbors searches. The metric can be specified by argument `p`.

API changes summary

- **EllipticEnvelope** is now deprecated - Please use **EllipticEnvelope** instead.
- **NeighborsClassifier** and **NeighborsRegressor** are gone in the module Nearest Neighbors. Use the classes `KNeighborsClassifier`, `RadiusNeighborsClassifier`, `KNeighborsRegressor` and/or `RadiusNeighborsRegressor` instead.
- Sparse classes in the Stochastic Gradient Descent module are now deprecated.
- In GMM, DP-GMM and VB-GMM, parameters must be passed to an object when initialising it and not through `fit`. Now `fit` will only accept the data as an input parameter.
- methods `rvs` and `decode` in GMM module are now deprecated. `sample` and `score` or `predict` should be used instead.
- attribute `_scores` and `_pvalues` in univariate feature selection objects are now deprecated. `scores_` or `pvalues_` should be used instead.
- In LogisticRegression, LinearSVC, SVC and NuSVC, the `class_weight` parameter is now an initialization parameter, not a parameter to fit. This makes grid searches over this parameter possible.
• LFW data is now always shape (n_samples, n_features) to be consistent with the Olivetti faces dataset. Use images and pairs attribute to access the natural images shapes instead.

• In LinearSVC, the meaning of the multi_class parameter changed. Options now are 'ovr' and 'crammer_singer', with 'ovr' being the default. This does not change the default behavior but hopefully is less confusing.

• Class Vectorizer is deprecated and replaced by TfidfVectorizer.

• The preprocessor / analyzer nested structure for text feature extraction has been removed. All those features are now directly passed as flat constructor arguments to TfidfVectorizer and CountVectorizer, in particular the following parameters are now used:
  • analyzer can be 'word' or 'char' to switch the default analysis scheme, or use a specific python callable (as previously).
  • tokenizer and preprocessor have been introduced to make it still possible to customize those steps with the new API.
  • input explicitly control how to interpret the sequence passed to fit and predict: filenames, file objects or direct (byte or Unicode) strings.
  • charset decoding is explicit and strict by default.
  • the vocabulary, fitted or not is now stored in the vocabulary_ attribute to be consistent with the project conventions.

• Class TfidfVectorizer now derives directly from CountVectorizer to make grid search trivial.

• methods rvs in _BaseHMM module are now deprecated. sample should be used instead.

• Beam pruning option in _BaseHMM module is removed since it is difficult to be Cythonized. If you are interested, you can look in the history codes by git.

• The SVMlight format loader now supports files with both zero-based and one-based column indices, since both occur “in the wild”.

• Arguments in class ShuffleSplit are now consistent with StratifiedShuffleSplit. Arguments test_fraction and train_fraction are deprecated and renamed to test_size and train_size and can accept both float and int.

• Arguments in class Bootstrap are now consistent with StratifiedShuffleSplit. Arguments n_test and n_train are deprecated and renamed to test_size and train_size and can accept both float and int.

• Argument p added to classes in Nearest Neighbors to specify an arbitrary Minkowski metric for nearest neighbors searches.

People

• 282 Andreas Müller

• 114 Mathieu Blondel
• 103 Clay Woolam
• 96 Lars Buitinck
1.7.36 Version 0.10

January 11, 2012

Changelog

- Python 2.5 compatibility was dropped; the minimum Python version needed to use scikit-learn is now 2.6.
- Sparse inverse covariance estimation using the graph Lasso, with associated cross-validated estimator, by Gael Varoquaux
- New Tree module by Brian Holt, Peter Prettenhofer, Satrajit Ghosh and Gilles Louppe. The module comes with complete documentation and examples.
- Fixed a bug in the RFE module by Gilles Louppe (issue #378).
- Fixed a memory leak in Support Vector Machines module by Brian Holt (issue #367).
- Faster tests by Fabian Pedregosa and others.
- Silhouette Coefficient cluster analysis evaluation metric added as silhouette_score by Robert Layton.
- Fixed a bug in K-means in the handling of the n_init parameter: the clustering algorithm used to be run n_init times but the last solution was retained instead of the best solution by Olivier Grisel.
-Minor refactoring in Stochastic Gradient Descent module; consolidated dense and sparse predict methods; Enhanced test time performance by converting model parameters to fortran-style arrays after fitting (only multi-class).
- Adjusted Mutual Information metric added as adjusted_mutual_info_score by Robert Layton.
- Models like SVC/SVR/LinearSVC/LogisticRegression from libsvm/liblinear now support scaling of C regularization parameter by the number of samples by Alexandre Gramfort.
- New Ensemble Methods module by Gilles Louppe and Brian Holt. The module comes with the random forest algorithm and the extra-trees method, along with documentation and examples.
- Novelty and Outlier Detection: outlier and novelty detection, by Virgile Fritsch.
- Kernel Approximation: a transform implementing kernel approximation for fast SGD on non-linear kernels by Andreas Müller.
- Fixed a bug due to atom swapping in Orthogonal Matching Pursuit (OMP) by Vlad Niculae.
- Sparse coding with a precomputed dictionary by Vlad Niculae.
- Mini Batch K-Means performance improvements by Olivier Grisel.
- K-means support for sparse matrices by Mathieu Blondel.
- Improved documentation for developers and for the sklearn.utils module, by Jake Vanderplas.
- Vectorized 20newsgroups dataset loader (fetch_20newsgroups_vectorized) by Mathieu Blondel.
• *Multiclass and multioutput algorithms* by Lars Buitinck.
• Utilities for fast computation of mean and variance for sparse matrices by Mathieu Blondel.
• Make *scale* and *Scaler* work on sparse matrices by Olivier Grisel
• Feature importances using decision trees and/or forest of trees, by Gilles Louppe.
• Parallel implementation of forests of randomized trees by Gilles Louppe.
• *ShuffleSplit* can subsample the train sets as well as the test sets by Olivier Grisel.
• Errors in the build of the documentation fixed by Andreas Müller.

### API changes summary

Here are the code migration instructions when upgrading from scikit-learn version 0.9:

- Some estimators that may overwrite their inputs to save memory previously had `overwrite_` parameters; these have been replaced with `copy_` parameters with exactly the opposite meaning.
  
  This particularly affects some of the estimators in `linear_model`. The default behavior is still to copy everything passed in.

- The SVMlight dataset loader `load_svmlight_file` no longer supports loading two files at once; use `load_svmlight_files` instead. Also, the (unused) `buffer_mb` parameter is gone.

- Sparse estimators in the *Stochastic Gradient Descent* module use dense parameter vector `coef_` instead of `sparse_coef_`. This significantly improves test time performance.

- The *Covariance estimation* module now has a robust estimator of covariance, the Minimum Covariance Determinant estimator.

- Cluster evaluation metrics in `metrics.cluster` have been refactored but the changes are backwards compatible. They have been moved to the `metrics.cluster.supervised`, along with `metrics.cluster.unsupervised` which contains the Silhouette Coefficient.

- The `permutation_test_score` function now behaves the same way as `cross_val_score` (i.e. uses the mean score across the folds.)

- Cross Validation generators now use integer indices (`indices=True`) by default instead of boolean masks. This make it more intuitive to use with sparse matrix data.

- The functions used for sparse coding, `sparse_encode` and `sparse_encode_parallel` have been combined into `sparse_encode`, and the shapes of the arrays have been transposed for consistency with the matrix factorization setting, as opposed to the regression setting.

- Fixed an off-by-one error in the SVMlight/LibSVM file format handling; files generated using `dump_svmlight_file` should be re-generated. (They should continue to work, but accidentally had one extra column of zeros prepended.)

- `BaseDictionaryLearning` class replaced by `SparseCodingMixin`.

- `fast_svd` has been renamed `randomized_svd` and the default oversampling is now fixed to 10 additional random vectors instead of doubling the number of components to extract. The new behavior follows the reference paper.

1.7.37 Version 0.9

September 21, 2011

scikit-learn 0.9 was released on September 2011, three months after the 0.8 release and includes the new modules *Manifold learning, The Dirichlet Process* as well as several new algorithms and documentation improvements.

This release also includes the dictionary-learning work developed by Vlad Niculae as part of the Google Summer of Code program.
Manifold Learning with 1000 points, 10 neighbors

Original space

Projection by PCA

Projection by KPCA

Original space after inverse transfo
Changelog

• New Manifold learning module by Jake Vanderplas and Fabian Pedregosa.

• New Dirichlet Process Gaussian Mixture Model by Alexandre Passos

• Nearest Neighbors module refactoring by Jake Vanderplas: general refactoring, support for sparse matrices in input, speed and documentation improvements. See the next section for a full list of API changes.

• Improvements on the Feature selection module by Gilles Louppe: refactoring of the RFE classes, documentation rewrite, increased efficiency and minor API changes.

• Sparse principal components analysis (SparsePCA and MiniBatchSparsePCA) by Vlad Niculae, Gael Varoquaux and Alexandre Gramfort

• Printing an estimator now behaves independently of architectures and Python version thanks to Jean Kossaifi.

• Loader for libsvm/svmlight format by Mathieu Blondel and Lars Buitinck

• Documentation improvements: thumbnails in example gallery by Fabian Pedregosa.

• Important bugfixes in Support Vector Machines module (segfaults, bad performance) by Fabian Pedregosa.

• Added Multinomial Naive Bayes and Bernoulli Naive Bayes by Lars Buitinck

• Text feature extraction optimizations by Lars Buitinck

• Chi-Square feature selection (feature_selection.univariate_selection.chi2) by Lars Buitinck.

• Generated datasets module refactoring by Gilles Louppe

• Multiclass and multioutput algorithms by Mathieu Blondel

• Ball tree rewrite by Jake Vanderplas

• Implementation of DBSCAN algorithm by Robert Layton

• Kmeans predict and transform by Robert Layton

• Preprocessing module refactoring by Olivier Grisel

• Faster mean shift by Conrad Lee

• New Bootstrap, Random permutations cross-validation a.k.a. Shuffle & Split and various other improvements in cross validation schemes by Olivier Grisel and Gael Varoquaux

• Adjusted Rand index and V-Measure clustering evaluation metrics by Olivier Grisel

• Added Orthogonal Matching Pursuit by Vlad Niculae

• Added 2D-patch extractor utilities in the Feature extraction module by Vlad Niculae

• Implementation of LassoLarsCV (cross-validated Lasso solver using the Lars algorithm) and LassoLarsIC (BIC/AIC model selection in Lars) by Gael Varoquaux and Alexandre Gramfort

• Scalability improvements to metrics.roc_curve by Olivier Hervieu

• Distance helper functions metrics.pairwise.pairwise_distances and metrics.pairwise.pairwise_kernels by Robert Layton

• Mini-Batch K-Means by Nelle Varoquaux and Peter Prettenhofer.

• mldata utilities by Pietro Berkes.

• The Olivetti faces dataset by David Warde-Farley.
API changes summary

Here are the code migration instructions when upgrading from scikit-learn version 0.8:

- The `scikits.learn` package was renamed `sklearn`. There is still a `scikits.learn` package alias for backward compatibility.

  Third-party projects with a dependency on scikit-learn 0.9+ should upgrade their codebase. For instance, under Linux / MacOSX just run (make a backup first!):

  ```bash
  find -name "*.py" | xargs sed -i 's/\bscikits.learn\b\ssl\sklearn/g'
  ```

- Estimators no longer accept model parameters as `fit` arguments: instead all parameters must be only be passed as constructor arguments or using the now public `set_params` method inherited from `BaseEstimator`.

  Some estimators can still accept keyword arguments on the `fit` but this is restricted to data-dependent values (e.g. a Gram matrix or an affinity matrix that are precomputed from the `X` data matrix.

- The `cross_val` package has been renamed to `cross_validation` although there is also a `cross_val` package alias in place for backward compatibility.

  Third-party projects with a dependency on scikit-learn 0.9+ should upgrade their codebase. For instance, under Linux / MacOSX just run (make a backup first!):

  ```bash
  find -name "*.py" | xargs sed -i 's/\bcross_val\b\bcross_validation/g'
  ```

- The `score_func` argument of the `sklearn.cross_validation.cross_val_score` function is now expected to accept `y_test` and `y_predicted` as only arguments for classification and regression tasks or `X_test` for unsupervised estimators.

- The `gamma` parameter for support vector machine algorithms is set to `1 / n_features` by default, instead of `1 / n_samples`.

- The `sklearn.hmm` has been marked as orphaned: it will be removed from scikit-learn in version 0.11 unless someone steps up to contribute documentation, examples and fix lurking numerical stability issues.

- `sklearn.neighbors` has been made into a submodule. The two previously available estimators, `NeighborsClassifier` and `NeighborsRegressor` have been marked as deprecated. Their functionality has been divided among five new classes: `NearestNeighbors` for unsupervised neighbors searches, `KNeighborsClassifier` & `RadiusNeighborsClassifier` for supervised classification problems, and `KNeighborsRegressor` & `RadiusNeighborsRegressor` for supervised regression problems.

- `sklearn.ball_tree.BallTree` has been moved to `sklearn.neighbors.BallTree`. Using the former will generate a warning.

- `sklearn.linear_model.LARS()` and related classes (`LassoLARS`, `LassoLARSCV`, etc.) have been renamed to `sklearn.linear_model.Lars()`.

- All distance metrics and kernels in `sklearn.metrics.pairwise` now have a `Y` parameter, which by default is `None`. If not given, the result is the distance (or kernel similarity) between each sample in `Y`. If given, the result is the pairwise distance (or kernel similarity) between samples in `X` to `Y`.

- `sklearn.metrics.pairwise.l1_distance` is now called `manhattan_distance`, and by default returns the pairwise distance. For the component wise distance, set the parameter `sum_over_features` to `False`.

Backward compatibility package aliases and other deprecated classes and functions will be removed in version 0.11.

1.7.38 Version 0.8

May 11, 2011

scikit-learn 0.8 was released on May 2011, one month after the first “international” scikit-learn coding sprint and is marked by the inclusion of important modules: Hierarchical clustering, Cross decomposition, Non-negative matrix factorization (NMF or NNMF), initial support for Python 3 and by important enhancements and bug fixes.

Changelog

Several new modules were introduced during this release:

• New Hierarchical clustering module by Vincent Michel, Bertrand Thirion, Alexandre Gramfort and Gael Varoquaux.
• Kernel PCA implementation by Mathieu Blondel
• The Labeled Faces in the Wild face recognition dataset by Olivier Grisel.
• New Cross decomposition module by Edouard Duchesnay.
• Non-negative matrix factorization (NMF or NNMF) module Vlad Niculae
• Implementation of the Oracle Approximating Shrinkage algorithm by Virgile Fritsch in the Covariance estimation module.

Some other modules benefited from significant improvements or cleanups.

• Initial support for Python 3: builds and imports cleanly, some modules are usable while others have failing tests by Fabian Pedregosa.
• PCA is now usable from the Pipeline object by Olivier Grisel.
• Guide How to optimize for speed by Olivier Grisel.
• Fixes for memory leaks in libsvm bindings, 64-bit safer BallTree by Lars Buitinck.
• bug and style fixing in K-means algorithm by Jan Schlüter.
• Add attribute converged to Gaussian Mixture Models by Vincent Schut.
• Implemented transform, predict_log_proba in LinearDiscriminantAnalysis By Mathieu Blondel.
• Refactoring in the Support Vector Machines module and bug fixes by Fabian Pedregosa, Gael Varoquaux and Amit Aides.
• Refactored SGD module (removed code duplication, better variable naming), added interface for sample weight by Peter Prettenhofer.
• Wrapped BallTree with Cython by Thouis (Ray) Jones.
• Added function svm.l1_min_c by Paolo Losi.
• Typos, doc style, etc. by Yaroslav Halchenko, Gael Varoquaux, Olivier Grisel, Yann Malet, Nicolas Pinto, Lars Buitinck and Fabian Pedregosa.

1.7.39 Version 0.7

March 2, 2011

scikit-learn 0.7 was released in March 2011, roughly three months after the 0.6 release. This release is marked by the speed improvements in existing algorithms like k-Nearest Neighbors and K-Means algorithm and by the inclusion of an efficient algorithm for computing the Ridge Generalized Cross Validation solution. Unlike the preceding release, no new modules were added to this release.
Changelog

- Performance improvements for Gaussian Mixture Model sampling [Jan Schlüter].
- Implementation of efficient leave-one-out cross-validated Ridge in `RidgeCV` [Mathieu Blondel]
- Better handling of collinearity and early stopping in `linear_model.lars_path` [Alexandre Gramfort and Fabian Pedregosa].
- Fixes for liblinear ordering of labels and sign of coefficients [Dan Yamins, Paolo Losi, Mathieu Blondel and Fabian Pedregosa].
- Performance improvements for Nearest Neighbors algorithm in high-dimensional spaces [Fabian Pedregosa].
- Performance improvements for `KMeans` [Gael Varoquaux and James Bergstra].
- Sanity checks for SVM-based classes [Mathieu Blondel].
- Refactoring of `NeighborsClassifier` and `neighbors.kneighbors_graph`: added different algorithms for the k-Nearest Neighbor Search and implemented a more stable algorithm for finding barycenter weights. Also added some developer documentation for this module, see notes_neighbors for more information [Fabian Pedregosa].
- Documentation improvements: Added `RandomizedPCA` and `LogisticRegression` to the class reference. Also added references of matrices used for clustering and other fixes [Gael Varoquaux, Fabian Pedregosa, Mathieu Blondel, Olivier Grisel, Virgile Fritsch, Emmanuelle Gouillart]
- Binded decision_function in classes that make use of liblinear, dense and sparse variants, like `LinearSVC` or `LogisticRegression` [Fabian Pedregosa].
- Performance and API improvements to `metrics.euclidean_distances` and to `RandomizedPCA` [James Bergstra].
- Fix compilation issues under NetBSD [Kamel Ibn Hassen Derouiche]
- Allow input sequences of different lengths in `GaussianHMM` [Ron Weiss].
- Fix bug in affinity propagation caused by incorrect indexing [Xinfan Meng]

People

- 2 Vincent Dubourg
- 1 Emmanuelle Gouillart
scikit-learn 0.6 was released on December 2010. It is marked by the inclusion of several new modules and a general renaming of old ones. It is also marked by the inclusion of new example, including applications to real-world datasets.

Changelog

- New stochastic gradient descent module by Peter Prettenhofer. The module comes with complete documentation and examples.
- Improved svm module: memory consumption has been reduced by 50%, heuristic to automatically set class weights, possibility to assign weights to samples (see SVM: Weighted samples for an example).
- New Gaussian Processes module by Vincent Dubourg. This module also has great documentation and some very neat examples. See example_gaussian_process_plot_gp_regression.py or example_gaussian_process_plot_gp_probabilistic_classification_after_regression.py for a taste of what can be done.
- It is now possible to use liblinear’s Multi-class SVC (option multi_class in LinearSVC)
- New features and performance improvements of text feature extraction.
- Improved sparse matrix support, both in main classes (GridSearchCV) as in modules sklearn.svm.sparse and sklearn.linear_model.sparse.
- Lots of cool new examples and a new section that uses real-world datasets was created. These include: Faces recognition example using eigenfaces and SVMs, Species distribution modeling, Libsvm GUI, Wikipedia principal eigenvector and others.
- Faster Least Angle Regression algorithm. It is now 2x faster than the R version on worst case and up to 10x times faster on some cases.
- Faster coordinate descent algorithm. In particular, the full path version of lasso (linear_model.lasso_path) is more than 200x times faster than before.
- It is now possible to get probability estimates from a LogisticRegression model.
- module renaming: the glm module has been renamed to linear_model, the gmm module has been included into the more general mixture model and the sgd module has been included in linear_model.
- Lots of bug fixes and documentation improvements.

1.7.41 Version 0.5

October 11, 2010

Changelog

New classes

- Support for sparse matrices in some classifiers of modules `svm` and `linear_model` (see `SVC`, `SVR`, `LinearSVC`, `Lasso`, `ElasticNet`)
- New `Pipeline` object to compose different estimators.
- Recursive Feature Elimination routines in module `Feature selection`.
- Addition of various classes capable of cross validation in the linear_model module (`LassoCV`, `ElasticNetCV`, etc.).
- New, more efficient LARS algorithm implementation. The Lasso variant of the algorithm is also implemented. See `lars_path`, `Lars` and `LassoLars`.
- New Hidden Markov Models module (see classes `GaussianHMM`, `MultinomialHMM`, `GMMHMM`)
- New module `feature_extraction` (see `class reference`)
- New FastICA algorithm in module `sklearn.fastica"
Documentation

- Improved documentation for many modules, now separating narrative documentation from the class reference. As an example, see documentation for the SVM module and the complete class reference.

Fixes

- API changes: adhere variable names to PEP-8, give more meaningful names.
- Fixes for svm module to run on a shared memory context (multiprocessing).
- It is again possible to generate latex (and thus PDF) from the sphinx docs.

Examples

- new examples using some of the mlcomp datasets: sphx_glr_auto_examples_mlcomp_sparse_document_classification.py (since removed) and Classification of text documents using sparse features
- Many more examples. See here the full list of examples.

External dependencies

- Joblib is now a dependency of this package, although it is shipped with (sklearn.externals.joblib).

Removed modules

- Module ann (Artificial Neural Networks) has been removed from the distribution. Users wanting this sort of algorithms should take a look into pybrain.

Misc

- New sphinx theme for the web page.

Authors

The following is a list of authors for this release, preceded by number of commits:

- 262 Fabian Pedregosa
- 240 Gael Varoquaux
- 149 Alexandre Gramfort
- 116 Olivier Grisel
- 40 Vincent Michel
- 38 Ron Weiss
- 23 Matthieu Perrot
- 10 Bertrand Thirion
- 7 Yaroslav Halchenko
- 9 VirgileFritsch
1.7.42 Version 0.4

August 26, 2010

Changelog

Major changes in this release include:

- Coordinate Descent algorithm (Lasso, ElasticNet) refactoring & speed improvements (roughly 100x times faster).
- Coordinate Descent Refactoring (and bug fixing) for consistency with R’s package GLMNET.
- New metrics module.
- New GMM module contributed by Ron Weiss.
- Implementation of the LARS algorithm (without Lasso variant for now).
- feature_selection module redesign.
- Migration to GIT as version control system.
- Removal of obsolete attrselect module.
- Rename of private compiled extensions (added underscore).
- Removal of legacy unmaintained code.
- Documentation improvements (both docstring and rst).
- Improvement of the build system to (optionally) link with MKL. Also, provide a lite BLAS implementation in case no system-wide BLAS is found.
- Lots of new examples.
- Many, many bug fixes . . .

Authors

The committer list for this release is the following (preceded by number of commits):

- 143 Fabian Pedregosa
- 35 Alexandre Gramfort
- 34 Olivier Grisel
- 11 Gael Varoquaux
- 5 Yaroslav Halchenko
- 2 Vincent Michel
- 1 Chris Filo Gorgolewski
1.7.43 Earlier versions

Earlier versions included contributions by Fred Mailhot, David Cooke, David Huard, Dave Morrill, Ed Schofield, Travis Oliphant, Pearu Peterson.

1.8 Roadmap

1.8.1 Purpose of this document

This document lists general directions that core contributors are interested to see developed in scikit-learn. The fact that an item is listed here is in no way a promise that it will happen, as resources are limited. Rather, it is an indication that help is welcomed on this topic.

1.8.2 Statement of purpose: Scikit-learn in 2018

Eleven years after the inception of Scikit-learn, much has changed in the world of machine learning. Key changes include:

- Computational tools: The exploitation of GPUs, distributed programming frameworks like Scala/Spark, etc.
- High-level Python libraries for experimentation, processing and data management: Jupyter notebook, Cython, Pandas, Dask, Numba, ...
- Changes in the focus of machine learning research: artificial intelligence applications (where input structure is key) with deep learning, representation learning, reinforcement learning, domain transfer, etc.

A more subtle change over the last decade is that, due to changing interests in ML, PhD students in machine learning are more likely to contribute to PyTorch, Dask, etc. than to Scikit-learn, so our contributor pool is very different to a decade ago.

Scikit-learn remains very popular in practice for trying out canonical machine learning techniques, particularly for applications in experimental science and in data science. A lot of what we provide is now very mature. But it can be costly to maintain, and we cannot therefore include arbitrary new implementations. Yet Scikit-learn is also essential in defining an API framework for the development of interoperable machine learning components external to the core library.

Thus our main goals in this era are to:

- continue maintaining a high-quality, well-documented collection of canonical tools for data processing and machine learning within the current scope (i.e. rectangular data largely invariant to column and row order; predicting targets with simple structure)
- improve the ease for users to develop and publish external components
- improve inter-operability with modern data science tools (e.g. Pandas, Dask) and infrastructures (e.g. distributed processing)

Many of the more fine-grained goals can be found under the API tag on the issue tracker.
1.8.3 Architectural / general goals

The list is numbered not as an indication of the order of priority, but to make referring to specific points easier. Please add new entries only at the bottom. Note that the crossed out entries are already done, and we try to keep the document up to date as we work on these issues.

1. Improved handling of Pandas DataFrames
   - document current handling
   - column reordering issue #7242
   - avoiding unnecessary conversion to ndarray #12147
   - returning DataFrames from transformers #5523
   - getting DataFrames from dataset loaders #10733, #13902
   - Sparse currently not considered #12800

2. Improved handling of categorical features
   - Tree-based models should be able to handle both continuous and categorical features #12866 and #15550.
   - In dataset loaders #13902
   - As generic transformers to be used with ColumnTransforms (e.g. ordinal encoding supervised by correlation with target variable) #5853, #11805
   - Handling mixtures of categorical and continuous variables

3. Improved handling of missing data
   - Making sure meta-estimators are lenient towards missing data, #15319
   - Non-trivial imputers #11977, #12852
   - Learners directly handling missing data #13911
   - An amputation sample generator to make parts of a dataset go missing #6284

4. More didactic documentation
   - More and more options have been added to scikit-learn. As a result, the documentation is crowded which makes it hard for beginners to get the big picture. Some work could be done in prioritizing the information.

5. Passing around information that is not (X, y): Sample properties
   - We need to be able to pass sample weights to scorers in cross validation.
   - We should have standard/generalised ways of passing sample-wise properties around in meta-estimators. #4497 #7646

6. Passing around information that is not (X, y): Feature properties
   - Feature names or descriptions should ideally be available to fit for, e.g. . #6425 #6424
   - Per-feature handling (e.g. “is this a nominal / ordinal / English language text?”) should also not need to be provided to estimator constructors, ideally, but should be available as metadata alongside X. #8480

7. Passing around information that is not (X, y): Target information
   - We have problems getting the full set of classes to all components when the data is split/sampled. #6231 #8100
   - We have no way to handle a mixture of categorical and continuous targets.

8. Make it easier for external users to write Scikit-learn-compatible components
• More flexible estimator checks that do not select by estimator name #6599 #6715
• Example of how to develop an estimator or a meta-estimator, #14582
• More self-sufficient running of scikit-learn-contrib or a similar resource

9. Support resampling and sample reduction
• Allow subsampling of majority classes (in a pipeline?) #3855
• Implement random forests with resampling #8732

10. Better interfaces for interactive development
• __repr__ and HTML visualisations of estimators #6323 and #14180.
• Include plotting tools, not just as examples. #9173

11. Improved tools for model diagnostics and basic inference
• alternative feature importances implementations, #13146
• better ways to handle validation sets when fitting
• better ways to find thresholds / create decision rules #8614

12. Better tools for selecting hyperparameters with transductive estimators
• Grid search and cross validation are not applicable to most clustering tasks. Stability-based selection is more relevant.

13. Better support for manual and automatic pipeline building
• Easier way to construct complex pipelines and valid search spaces #7608 #5082 #8243
• provide search ranges for common estimators??
• cf. searchgrid

14. Improved tracking of fitting
•Verbose is not very friendly and should use a standard logging library #6929, #78
• Callbacks or a similar system would facilitate logging and early stopping

15. Distributed parallelism
• Accept data which complies with __array_function__

16. A way forward for more out of core
• Dask enables easy out-of-core computation. While the Dask model probably cannot be adaptable to all machine-learning algorithms, most machine learning is on smaller data than ETL, hence we can maybe adapt to very large scale while supporting only a fraction of the patterns.

17. Support for working with pre-trained models
• Estimator “freezing”. In particular, right now it’s impossible to clone a CalibratedClassifierCV with prefit. #8370, #6451

18. Backwards-compatible de/serialization of some estimators
• Currently serialization (with pickle) breaks across versions. While we may not be able to get around other limitations of pickle re security etc, it would be great to offer cross-version safety from version 1.0. Note: Gael and Olivier think that this can cause heavy maintenance burden and we should manage the trade-offs. A possible alternative is presented in the following point.

19. Documentation and tooling for model lifecycle management
• Document good practices for model deployments and lifecycle: before deploying a model: snapshot the code versions (numpy, scipy, scikit-learn, custom code repo), the training script and an alias on how to retrieve historical training data + snapshot a copy of a small validation set + snapshot of the predictions (predicted probabilities for classifiers) on that validation set.

• Document and tools to make it easy to manage upgrade of scikit-learn versions:
  – Try to load the old pickle, if it works, use the validation set prediction snapshot to detect that the serialized model still behave the same;
  – If joblib.load / pickle.load not work, use the versioned control training script + historical training set to retrain the model and use the validation set prediction snapshot to assert that it is possible to recover the previous predictive performance: if this is not the case there is probably a bug in scikit-learn that needs to be reported.

20. Everything in Scikit-learn should probably conform to our API contract. We are still in the process of making decisions on some of these related issues.

• Pipeline <pipeline.Pipeline> and FeatureUnion modify their input parameters in fit. Fixing this requires making sure we have a good grasp of their use cases to make sure all current functionality is maintained. #8157 #7382

21. (Optional) Improve scikit-learn common tests suite to make sure that (at least for frequently used) models have stable predictions across-versions (to be discussed);

• Extend documentation to mention how to deploy models in Python-free environments for instance ONNX. and use the above best practices to assess predictive consistency between scikit-learn and ONNX prediction functions on validation set.

• Document good practices to detect temporal distribution drift for deployed model and good practices for re-training on fresh data without causing catastrophic predictive performance regressions.

1.8.4 Subpackage-specific goals

sklearn.ensemble

• a stacking implementation, #11047

sklearn.cluster

• kmeans variants for non-Euclidean distances, if we can show these have benefits beyond hierarchical clustering.

sklearn.model_selection

• multi-metric scoring is slow #9326

• perhaps we want to be able to get back more than multiple metrics

• the handling of random states in CV splitters is a poor design and contradicts the validation of similar parameters in estimators, #15177

• exploit warm-starting and path algorithms so the benefits of EstimatorCV objects can be accessed via GridSearchCV and used in Pipelines. #1626

• Cross-validation should be able to be replaced by OOB estimates whenever a cross-validation iterator is used.

• Redundant computations in pipelines should be avoided (related to point above) cf daskml

sklearn.neighbors

• Ability to substitute a custom/approximate/precomputed nearest neighbors implementation for ours in all/most contexts that nearest neighbors are used for learning. #10463

sklearn.pipeline
• Performance issues with `Pipeline.memory`
• see “Everything in Scikit-learn should conform to our API contract” above

1.9 Scikit-learn governance and decision-making

The purpose of this document is to formalize the governance process used by the scikit-learn project, to clarify how decisions are made and how the various elements of our community interact. This document establishes a decision-making structure that takes into account feedback from all members of the community and strives to find consensus, while avoiding any deadlocks.

This is a meritocratic, consensus-based community project. Anyone with an interest in the project can join the community, contribute to the project design and participate in the decision making process. This document describes how that participation takes place and how to set about earning merit within the project community.

1.9.1 Roles And Responsibilities

Contributors

Contributors are community members who contribute in concrete ways to the project. Anyone can become a contributor, and contributions can take many forms – not only code – as detailed in the contributors guide.

Triage team

The triage team is composed of community members who have permission on github to label and close issues. Their work is crucial to improve the communication in the project and limit the crowding of the issue tracker.

Similarly to what has been decided in the python project, any contributor may become a member of the scikit-learn triage team, after showing some continuity in participating to scikit-learn development (with pull requests and reviews). Any core developer is welcome to propose a scikit-learn contributor to join the triage team. Other core developers are then consulted: while it is expected that most acceptances will be unanimous, a two-thirds majority is enough. Every new triager will be announced in the mailing list. Triagers are welcome to participate in monthly core developer meetings.

Core developers

Core developers are community members who have shown that they are dedicated to the continued development of the project through ongoing engagement with the community. They have shown they can be trusted to maintain scikit-learn with care. Being a core developer allows contributors to more easily carry on with their project related activities by giving them direct access to the project’s repository and is represented as being an organization member on the scikit-learn GitHub organization. Core developers are expected to review code contributions, can merge approved pull requests, can cast votes for and against merging a pull-request, and can be involved in deciding major changes to the API.

New core developers can be nominated by any existing core developers. Once they have been nominated, there will be a vote by the current core developers. Voting on new core developers is one of the few activities that takes place on the project’s private management list. While it is expected that most votes will be unanimous, a two-thirds majority of the cast votes is enough. The vote needs to be open for at least 1 week.

Core developers that have not contributed to the project (commits or GitHub comments) in the past 12 months will be asked if they want to become emeritus core developers and recant their commit and voting rights until they become active again. The list of core developers, active and emeritus (with dates at which they became active) is public on the scikit-learn website.
Technical Committee

The Technical Committee (TC) members are core developers who have additional responsibilities to ensure the smooth running of the project. TC members are expected to participate in strategic planning, and approve changes to the governance model. The purpose of the TC is to ensure a smooth progress from the big-picture perspective. Indeed changes that impact the full project require a synthetic analysis and a consensus that is both explicit and informed. In cases that the core developer community (which includes the TC members) fails to reach such a consensus in the required time frame, the TC is the entity to resolve the issue. Membership of the TC is by nomination by a core developer. A nomination will result in discussion which cannot take more than a month and then a vote by the core developers which will open for a week. TC membership votes are subject to a two-third majority of all cast votes as well as a simple majority approval of all the current TC members. TC members who do not actively engage with the TC duties are expected to resign.

The Technical Committee of scikit-learn consists of Alexandre Gramfort, Olivier Grisel, Adrin Jalali, Andreas Müller, Joel Nothman, Hanmin Qin, Gaël Varoquaux, and Roman Yurchak.

1.9.2 Decision Making Process

Decisions about the future of the project are made through discussion with all members of the community. All non-sensitive project management discussion takes place on the project contributors’ mailing list and the issue tracker. Occasionally, sensitive discussion occurs on a private list.

Scikit-learn uses a “consensus seeking” process for making decisions. The group tries to find a resolution that has no open objections among core developers. At any point during the discussion, any core-developer can call for a vote, which will conclude one month from the call for the vote. Any vote must be backed by a SLEP `<slep>`. If no option can gather two thirds of the votes cast, the decision is escalated to the TC, which in turn will use consensus seeking with the fallback option of a simple majority vote if no consensus can be found within a month. This is what we hereafter may refer to as “the decision making process”.

Decisions (in addition to adding core developers and TC membership as above) are made according to the following rules:

- **Minor Documentation changes**, such as typo fixes, or addition / correction of a sentence, but no change of the scikit-learn.org landing page or the “about” page: Requires +1 by a core developer, no -1 by a core developer (lazy consensus), happens on the issue or pull request page. Core developers are expected to give “reasonable time” to others to give their opinion on the pull request if they’re not confident others would agree.

- **Code changes and major documentation changes** require +1 by two core developers, no -1 by a core developer (lazy consensus), happens on the issue of pull-request page.

- **Changes to the API principles and changes to dependencies or supported versions** happen via a Enhancement proposals (SLEPs) and follows the decision-making process outlined above.

- **Changes to the governance model** use the same decision process outlined above.

If a veto -1 vote is cast on a lazy consensus, the proposer can appeal to the community and core developers and the change can be approved or rejected using the decision making procedure outlined above.
1.9.3 Enhancement proposals (SLEPs)

For all votes, a proposal must have been made public and discussed before the vote. Such proposal must be a consolidated document, in the form of a ‘Scikit-Learn Enhancement Proposal’ (SLEP), rather than a long discussion on an issue. A SLEP must be submitted as a pull-request to enhancement proposals using the SLEP template.
2.1 An introduction to machine learning with scikit-learn

Section contents

In this section, we introduce the machine learning vocabulary that we use throughout scikit-learn and give a simple learning example.

2.1.1 Machine learning: the problem setting

In general, a learning problem considers a set of \( n \) samples of data and then tries to predict properties of unknown data. If each sample is more than a single number and, for instance, a multi-dimensional entry (aka multivariate data), it is said to have several attributes or features.

Learning problems fall into a few categories:

- **supervised learning**, in which the data comes with additional attributes that we want to predict (Click here to go to the scikit-learn supervised learning page). This problem can be either:
  - **classification**: samples belong to two or more classes and we want to learn from already labeled data how to predict the class of unlabeled data. An example of a classification problem would be handwritten digit recognition, in which the aim is to assign each input vector to one of a finite number of discrete categories. Another way to think of classification is as a discrete (as opposed to continuous) form of supervised learning where one has a limited number of categories and for each of the \( n \) samples provided, one is to try to label them with the correct category or class.
  - **regression**: if the desired output consists of one or more continuous variables, then the task is called regression. An example of a regression problem would be the prediction of the length of a salmon as a function of its age and weight.

- **unsupervised learning**, in which the training data consists of a set of input vectors \( x \) without any corresponding target values. The goal in such problems may be to discover groups of similar examples within the data, where it is called clustering, or to determine the distribution of data within the input space, known as density estimation, or to project the data from a high-dimensional space down to two or three dimensions for the purpose of visualization (Click here to go to the Scikit-Learn unsupervised learning page).
Training set and testing set

Machine learning is about learning some properties of a data set and then testing those properties against another data set. A common practice in machine learning is to evaluate an algorithm by splitting a data set into two. We call one of those sets the training set, on which we learn some properties; we call the other set the testing set, on which we test the learned properties.

2.1.2 Loading an example dataset

scikit-learn comes with a few standard datasets, for instance the iris and digits datasets for classification and the diabetes dataset for regression.

In the following, we start a Python interpreter from our shell and then load the iris and digits datasets. Our notational convention is that $\$\ denote the shell prompt while >>> denotes the Python interpreter prompt:

```
$ python
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> digits = datasets.load_digits()
```

A dataset is a dictionary-like object that holds all the data and some metadata about the data. This data is stored in the .data member, which is a n_samples, n_features array. In the case of supervised problem, one or more response variables are stored in the .target member. More details on the different datasets can be found in the dedicated section.

For instance, in the case of the digits dataset, digits.data gives access to the features that can be used to classify the digits samples:

```
>>> print(digits.data)
[[ 0.  0.  5. ...  0.  0.  0.]
 [ 0.  0.  0. ... 10.  0.  0.]
 [ 0.  0.  0. ... 16.  9.  0.]
...
 [ 0.  0.  1. ...  6.  0.  0.]
 [ 0.  0.  2. ... 12.  0.  0.]
 [ 0.  0. 10. ... 12.  1.  0.]]
```

and digits.target gives the ground truth for the digit dataset, that is the number corresponding to each digit image that we are trying to learn:

```
>>> digits.target
array([0, 1, 2, ..., 8, 9, 8])
```

Shape of the data arrays

The data is always a 2D array, shape (n_samples, n_features), although the original data may have had a different shape. In the case of the digits, each original sample is an image of shape (8, 8) and can be accessed using:

```
>>> digits.images[0]
array([[ 0.,  0.,  5., ...,  9.,  1.,  0.,  0.],
      [ 0.,  0., 13., ..., 10., 15.,  5.,  0.],
      [ 0.,  3., 15.,  2.,  0., 11.,  8.,  0.],
      [ 0.,  4., 12.,  0.,  0.,  8.,  8.,  0.],
      [ 0., 13.,  2.,  0.,  0., 11.,  8.,  0.],
      [ 0.,  5., 13.,  0.,  0.,  8.,  8.,  0.],
      [ 0.,  0.,  1.,  0.,  0., 11.,  8.,  0.],
      [ 0.,  0.,  1., ...,  9., 15.,  5.,  0.],
      [ 0.,  0.,  5., ...,  9.,  1.,  0.,  0.],
      [ 0.,  0.,  0. ...,  16. 9.  0.]])
```
The simple example on this dataset illustrates how starting from the original problem one can shape the data for consumption in scikit-learn.

2.1.3 Learning and predicting

In the case of the digits dataset, the task is to predict, given an image, which digit it represents. We are given samples of each of the 10 possible classes (the digits zero through nine) on which we fit an estimator to be able to predict the classes to which unseen samples belong.

In scikit-learn, an estimator for classification is a Python object that implements the methods fit(X, y) and predict(T).

An example of an estimator is the class sklearn.svm.SVC, which implements support vector classification. The estimator’s constructor takes as arguments the model’s parameters.

For now, we will consider the estimator as a black box:

```python
>>> from sklearn import svm
>>> clf = svm.SVC(gamma=0.001, C=100.)
```

Choosing the parameters of the model

In this example, we set the value of gamma manually. To find good values for these parameters, we can use tools such as grid search and cross validation.

The clf (for classifier) estimator instance is first fitted to the model; that is, it must learn from the model. This is done by passing our training set to the fit method. For the training set, we’ll use all the images from our dataset, except for the last image, which we’ll reserve for our predicting. We select the training set with the [:-1] Python syntax, which produces a new array that contains all but the last item from digits.data:

```python
>>> clf.fit(digits.data[:-1], digits.target[:-1])
SVC(C=100.0, gamma=0.001)
```

Now you can predict new values. In this case, you’ll predict using the last image from digits.data. By predicting, you’ll determine the image from the training set that best matches the last image.

```python
>>> clf.predict(digits.data[-1:])
array([8])
```

The corresponding image is:
As you can see, it is a challenging task: after all, the images are of poor resolution. Do you agree with the classifier?

A complete example of this classification problem is available as an example that you can run and study: Recognizing hand-written digits.

2.1.4 Conventions

scikit-learn estimators follow certain rules to make their behavior more predictive. These are described in more detail in the Glossary of Common Terms and API Elements.

Type casting

Unless otherwise specified, input will be cast to float64:

```python
>>> import numpy as np
>>> from sklearn import random_projection

>>> rng = np.random.RandomState(0)
>>> X = rng.rand(10, 2000)
>>> X = np.array(X, dtype='float32')
>>> X.dtype
'dtype('float32')

>>> transformer = random_projection.GaussianRandomProjection()
>>> X_new = transformer.fit_transform(X)
>>> X_new.dtype
'dtype('float64')
```

In this example, X is float32, which is cast to float64 by fit_transform(X).

Regression targets are cast to float64 and classification targets are maintained:

```python
>>> from sklearn import datasets
>>> from sklearn.svm import SVC

>>> iris = datasets.load_iris()
>>> clf = SVC()
>>> clf.fit(iris.data, iris.target)
SVC()

>>> list(clf.predict(iris.data[:3]))
[0, 0, 0]

>>> clf.fit(iris.data, iris.target_names[iris.target])
SVC()
```

(continues on next page)
Here, the first predict() returns an integer array, since iris.target (an integer array) was used in fit. The second predict() returns a string array, since iris.target_names was for fitting.

Refitting and updating parameters

Hyper-parameters of an estimator can be updated after it has been constructed via the set_params() method. Calling fit() more than once will overwrite what was learned by any previous fit():

```python
>>> import numpy as np
>>> from sklearn.datasets import load_iris
>>> from sklearn.svm import SVC

>>> X, y = load_iris(return_X_y=True)

>>> clf = SVC()
>>> clf.set_params(kernel='linear').fit(X, y)
SVC(kernel='linear')

>>> clf.predict(X[:5])
array([0, 0, 0, 0, 0])

>>> clf.set_params(kernel='rbf').fit(X, y)
SVC()

>>> clf.predict(X[:5])
array([0, 0, 0, 0, 0])
```

Here, the default kernel rbf is first changed to linear via SVC.set_params() after the estimator has been constructed, and changed back to rbf to refit the estimator and to make a second prediction.

Multiclass vs. multilabel fitting

When using multiclass classifiers, the learning and prediction task that is performed is dependent on the format of the target data fit upon:

```python
>>> from sklearn.svm import SVC
>>> from sklearn.multiclass import OneVsRestClassifier
>>> from sklearn.preprocessing import LabelBinarizer

>>> X = [[1, 2], [2, 4], [4, 5], [3, 2], [3, 1]]
>>> y = [0, 0, 1, 1, 2]

>>> classif = OneVsRestClassifier(estimator=SVC(random_state=0))

>>> classif.fit(X, y).predict(X)
array([1, 0, 0, 0, 1])
```

In the above case, the classifier is fit on a 1d array of multiclass labels and the predict() method therefore provides corresponding multiclass predictions. It is also possible to fit upon a 2d array of binary label indicators:

```python
>>> y = LabelBinarizer().fit_transform(y)
>>> classif.fit(X, y).predict(X)
array([[1, 0, 0],
       [1, 0, 0],
       [0, 1, 0],
       [0, 0, 1],
       [0, 0, 1]])
```
Here, the classifier is fit() on a 2d binary label representation of y, using the LabelBinarizer. In this case predict() returns a 2d array representing the corresponding multilabel predictions.

Note that the fourth and fifth instances returned all zeroes, indicating that they matched none of the three labels fit upon. With multilabel outputs, it is similarly possible for an instance to be assigned multiple labels:

```python
>>> from sklearn.preprocessing import MultiLabelBinarizer
>>> y = [[0, 1], [0, 2], [1, 3], [0, 2, 3], [2, 4]]
>>> y = MultiLabelBinarizer().fit_transform(y)
>>> classif.fit(X, y).predict(X)
array([[1, 1, 0, 0, 0],
      [1, 0, 1, 0, 0],
      [0, 1, 0, 1, 0],
      [1, 0, 1, 0, 0],
      [1, 0, 1, 0, 0]])
```

In this case, the classifier is fit upon instances each assigned multiple labels. The MultiLabelBinarizer is used to binarize the 2d array of multilabels to fit upon. As a result, predict() returns a 2d array with multiple predicted labels for each instance.

### 2.2 A tutorial on statistical-learning for scientific data processing

#### Statistical learning

Machine learning is a technique with a growing importance, as the size of the datasets experimental sciences are facing is rapidly growing. Problems it tackles range from building a prediction function linking different observations, to classifying observations, or learning the structure in an unlabeled dataset.

This tutorial will explore statistical learning, the use of machine learning techniques with the goal of statistical inference: drawing conclusions on the data at hand.

Scikit-learn is a Python module integrating classic machine learning algorithms in the tightly-knit world of scientific Python packages (NumPy, SciPy, matplotlib).

#### 2.2.1 Statistical learning: the setting and the estimator object in scikit-learn

#### Datasets

Scikit-learn deals with learning information from one or more datasets that are represented as 2D arrays. They can be understood as a list of multi-dimensional observations. We say that the first axis of these arrays is the samples axis, while the second is the features axis.

A simple example shipped with scikit-learn: iris dataset

```python
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> data = iris.data
```
It is made of 150 observations of irises, each described by 4 features: their sepal and petal length and width, as detailed in iris.DESCRIPT.

When the data is not initially in the \((n_{\text{samples}}, n_{\text{features}})\) shape, it needs to be preprocessed in order to be used by scikit-learn.

### An example of reshaping data would be the digits dataset

The digits dataset is made of 1797 8x8 images of hand-written digits.

```python
>>> digits = datasets.load_digits()
```

```python
>>> digits.images.shape
(1797, 8, 8)
```

```python
>>> import matplotlib.pyplot as plt
```

```python
>>> plt.imshow(digits.images[-1], cmap=plt.cm.gray_r)
<matplotlib.image.AxesImage object at ...>
```

To use this dataset with scikit-learn, we transform each 8x8 image into a feature vector of length 64.

```python
>>> data = digits.images.reshape(...)  
>>> (digits.images.shape[0], -1)
...)
```

```python
```
Estimators objects

Fitting data: the main API implemented by scikit-learn is that of the estimator. An estimator is any object that learns from data; it may be a classification, regression or clustering algorithm or a transformer that extracts/filters useful features from raw data.

All estimator objects expose a `fit` method that takes a dataset (usually a 2-d array):

```python
>>> estimator.fit(data)
```

Estimator parameters: All the parameters of an estimator can be set when it is instantiated or by modifying the corresponding attribute:

```python
>>> estimator = Estimator(param1=1, param2=2)
>>> estimator.param1
1
```

Estimated parameters: When data is fitted with an estimator, parameters are estimated from the data at hand. All the estimated parameters are attributes of the estimator object ending by an underscore:

```python
>>> estimator.estimated_param_
```

2.2.2 Supervised learning: predicting an output variable from high-dimensional observations

The problem solved in supervised learning

Supervised learning consists in learning the link between two datasets: the observed data $X$ and an external variable $y$ that we are trying to predict, usually called “target” or “labels”. Most often, $y$ is a 1D array of length $n_{\text{samples}}$.

All supervised estimators in scikit-learn implement a `fit(X, y)` method to fit the model and a `predict(X)` method that, given unlabeled observations $X$, returns the predicted labels $y$.

Vocabulary: classification and regression

If the prediction task is to classify the observations in a set of finite labels, in other words to “name” the objects observed, the task is said to be a classification task. On the other hand, if the goal is to predict a continuous target variable, it is said to be a regression task.

When doing classification in scikit-learn, $y$ is a vector of integers or strings.

Note: See the Introduction to machine learning with scikit-learn Tutorial for a quick run-through on the basic machine learning vocabulary used within scikit-learn.
Nearest neighbor and the curse of dimensionality

Classifying irises:

The iris dataset is a classification task consisting in identifying 3 different types of irises (Setosa, Versicolour, and Virginica) from their petal and sepal length and width:

```python
>>> import numpy as np
>>> from sklearn import datasets
>>> iris_X, iris_y = datasets.load_iris(return_X_y=True)
>>> np.unique(iris_y)
array([0, 1, 2])
```

k-Nearest neighbors classifier

The simplest possible classifier is the nearest neighbor: given a new observation \(X_{\text{test}}\), find in the training set (i.e. the data used to train the estimator) the observation with the closest feature vector. (Please see the Nearest Neighbors section of the online Scikit-learn documentation for more information about this type of classifier.)

Training set and testing set

While experimenting with any learning algorithm, it is important not to test the prediction of an estimator on the data used to fit the estimator as this would not be evaluating the performance of the estimator on new data. This is why datasets are often split into train and test data.

KNN (k nearest neighbors) classification example:
### Split iris data in train and test data

```python
np.random.seed(0)
indices = np.random.permutation(len(iris_X))
iris_X_train = iris_X[indices[:-10]]
iris_y_train = iris_y[indices[:-10]]
iris_X_test = iris_X[indices[-10:]]
iris_y_test = iris_y[indices[-10:]]
```

### Create and fit a nearest-neighbor classifier

```python
from sklearn.neighbors import KNeighborsClassifier
knn = KNeighborsClassifier()
knn.fit(iris_X_train, iris_y_train)
knn.predict(iris_X_test)
```

```python
array([1, 2, 1, 0, 0, 0, 2, 1, 2, 0])
```

### The curse of dimensionality

For an estimator to be effective, you need the distance between neighboring points to be less than some value $d$, which depends on the problem. In one dimension, this requires on average $n \sim \frac{1}{d}$ points. In the context of the above $k$-NN example, if the data is described by just one feature with values ranging from 0 to 1 and with $n$ training observations, then new data will be no further away than $1/n$. Therefore, the nearest neighbor decision rule will be efficient as soon as $1/n$ is small compared to the scale of between-class feature variations.

If the number of features is $p$, you now require $n \sim \frac{1}{d^p}$ points. Let’s say that we require 10 points in one dimension: now $10^p$ points are required in $p$ dimensions to pave the $[0, 1]$ space. As $p$ becomes large, the number of training points...
required for a good estimator grows exponentially. For example, if each point is just a single number (8 bytes), then an effective $k$-NN estimator in a paltry $p \sim 20$ dimensions would require more training data than the current estimated size of the entire internet ($\pm 1000$ Exabytes or so).

This is called the curse of dimensionality and is a core problem that machine learning addresses.

**Linear model: from regression to sparsity**

**Diabetes dataset**

The diabetes dataset consists of 10 physiological variables (age, sex, weight, blood pressure) measure on 442 patients, and an indication of disease progression after one year:

```python
>>> diabetes_X, diabetes_y = datasets.load_diabetes(return_X_y=True)
>>> diabetes_X_train = diabetes_X[:-20]
>>> diabetes_X_test = diabetes_X[-20:]
>>> diabetes_y_train = diabetes_y[:-20]
>>> diabetes_y_test = diabetes_y[-20:]
```

The task at hand is to predict disease progression from physiological variables.

**Linear regression**

`LinearRegression`, in its simplest form, fits a linear model to the data set by adjusting a set of parameters in order to make the sum of the squared residuals of the model as small as possible.

Linear models: $y = X\beta + \epsilon$

- $X$: data
- $y$: target variable
- $\beta$: Coefficients
- $\epsilon$: Observation noise
>>> from sklearn import linear_model
>>> regr = linear_model.LinearRegression()
>>> regr.fit(diabetes_X_train, diabetes_y_train)
LinearRegression()
>>> print(regr.coef_)
[ 0.30349955 -237.63931533 510.53060544 327.73698041 -814.13170937
  492.81458798 102.84845219 184.60648906 743.51961675 76.09517222]

>>> # The mean square error
>>> np.mean((regr.predict(diabetes_X_test) - diabetes_y_test)**2)
2004.56760268...

>>> # Explained variance score: 1 is perfect prediction
>>> # and 0 means that there is no linear relationship
>>> # between X and y.
>>> regr.score(diabetes_X_test, diabetes_y_test)
0.5850753022690...

Shrinkage

If there are few data points per dimension, noise in the observations induces high variance:

>>> X = np.c_[ .5, 1].T
>>> y = [.5, 1]
>>> test = np.c_[ 0, 2].T
>>> regr = linear_model.LinearRegression()

>>> import matplotlib.pyplot as plt
>>> plt.figure()

>>> np.random.seed(0)
>>> for _ in range(6):
...    this_X = .1 * np.random.normal(size=(2, 1)) + X
...    regr.fit(this_X, y)
...    plt.plot(test, regr.predict(test))
...    plt.scatter(this_X, y, s=3)
A solution in high-dimensional statistical learning is to shrink the regression coefficients to zero: any two randomly chosen set of observations are likely to be uncorrelated. This is called Ridge regression:

```python
>>> regr = linear_model.Ridge(alpha=.1)

>>> plt.figure()

>>> np.random.seed(0)

>>> for _ in range(6):
...     this_X = .1 * np.random.normal(size=(2, 1)) + X
...     regr.fit(this_X, y)
...     plt.plot(test, regr.predict(test))
...     plt.scatter(this_X, y, s=3)
```

This is an example of bias/variance tradeoff: the larger the ridge alpha parameter, the higher the bias and the lower the variance.

We can choose alpha to minimize left out error, this time using the diabetes dataset rather than our synthetic data:
```python
>>> alphas = np.logspace(-4, -1, 6)
>>> print([regr.set_params(alpha=alpha)
... .fit(diabetes_X_train, diabetes_y_train)
... .score(diabetes_X_test, diabetes_y_test)
... for alpha in alphas])
[0.5851110683883..., 0.5852073015444..., 0.5854677540698..., 0.5855512036503..., 0.5830717085554..., 0.57058999437...]
```

**Note:** Capturing in the fitted parameters noise that prevents the model to generalize to new data is called overfitting. The bias introduced by the ridge regression is called a regularization.

**Sparsity**

**Fitting only features 1 and 2**

![Diagram showing the effect of fitting only features 1 and 2](image)

**Note:** A representation of the full diabetes dataset would involve 11 dimensions (10 feature dimensions and one of the target variable). It is hard to develop an intuition on such representation, but it may be useful to keep in mind that it would be a fairly empty space.

We can see that, although feature 2 has a strong coefficient on the full model, it conveys little information on $y$ when considered with feature 1.

To improve the conditioning of the problem (i.e. mitigating the *The curse of dimensionality*), it would be interesting to select only the informative features and set non-informative ones, like feature 2 to 0. Ridge regression will decrease their contribution, but not set them to zero. Another penalization approach, called *Lasso* (least absolute shrinkage and
selection operator), can set some coefficients to zero. Such methods are called **sparse method** and sparsity can be seen as an application of Occam’s razor: *prefer simpler models.*

```python
>>> regr = linear_model.Lasso()
>>> scores = [regr.set_params(alpha=alpha)
... .fit(diabetes_X_train, diabetes_y_train)
... .score(diabetes_X_test, diabetes_y_test)
...  for alpha in alphas]
>>> best_alpha = alphas[scores.index(max(scores))]
>>> regr.alpha = best_alpha
>>> regr.fit(diabetes_X_train, diabetes_y_train)
Lasso(alpha=0.025118864315095794)
```

```plaintext
[ 0. -212.437... 517.194... 313.779... -160.830...
 -0. -187.195... 69.382... 508.660... 71.842...]
```

### Different algorithms for the same problem

Different algorithms can be used to solve the same mathematical problem. For instance the `Lasso` object in scikit-learn solves the lasso regression problem using a coordinate descent method, that is efficient on large datasets. However, scikit-learn also provides the `LassoLars` object using the LARS algorithm, which is very efficient for problems in which the weight vector estimated is very sparse (i.e. problems with very few observations).

### Classification

For classification, as in the labeling iris task, linear regression is not the right approach as it will give too much weight to data far from the decision frontier. A linear approach is to fit a sigmoid function or **logistic** function:

(y) sigmoid\((X \beta - \text{offset}) + \epsilon = \frac{1}{1 + \exp(-X \beta + \text{offset})} + \epsilon

```python
>>> log = linear_model.LogisticRegression(C=1e5)
>>> log.fit(iris_X_train, iris_y_train)
LogisticRegression(C=100000.0)
```

This is known as **LogisticRegression.**
Multiclass classification

If you have several classes to predict, an option often used is to fit one-versus-all classifiers and then use a voting heuristic for the final decision.

Shrinkage and sparsity with logistic regression

The \( C \) parameter controls the amount of regularization in the `LogisticRegression` object: a large value for \( C \) results in less regularization. `penalty="l2"` gives Shrinkage (i.e. non-sparse coefficients), while `penalty="l1"` gives Sparsity.

Exercise

Try classifying the digits dataset with nearest neighbors and a linear model. Leave out the last 10% and test prediction performance on these observations.

```python
from sklearn import datasets, neighbors, linear_model

X_digits, y_digits = datasets.load_digits(return_X_y=True)
X_digits = X_digits / X_digits.max()

A solution can be downloaded here.
```

Support vector machines (SVMs)

Linear SVMs

`Support Vector Machines` belong to the discriminant model family: they try to find a combination of samples to build a plane maximizing the margin between the two classes. Regularization is set by the \( C \) parameter: a small value for \( C \) means the margin is calculated using many or all of the observations around the separating line (more regularization); a large value for \( C \) means the margin is calculated on observations close to the separating line (less regularization).
Fig. 1: Unregularized SVM

Fig. 2: Regularized SVM (default)
Example:

- *Plot different SVM classifiers in the iris dataset*

SVMs can be used in regression—*SVR* (Support Vector Regression)—, or in classification—*SVC* (Support Vector Classification).

```python
>>> from sklearn import svm
>>> svc = svm.SVC(kernel='linear')
>>> svc.fit(iris_X_train, iris_y_train)
SVC(kernel='linear')
```

**Warning:** Normalizing data

For many estimators, including the SVMs, having datasets with unit standard deviation for each feature is important to get good prediction.

**Using kernels**

Classes are not always linearly separable in feature space. The solution is to build a decision function that is not linear but may be polynomial instead. This is done using the *kernel trick* that can be seen as creating a decision energy by positioning *kernels* on observations:

**Linear kernel**

```python
>>> svc = svm.SVC(kernel='linear')
```
Polynomial kernel

```python
>>> svc = svm.SVC(kernel='poly',
...     degree=3)
>>> # degree: polynomial degree
```

RBF kernel (Radial Basis Function)

```python
>>> svc = svm.SVC(kernel='rbf')
>>> # gamma: inverse of size of
>>> # radial kernel
```
Interactive example

See the SVM GUI to download svm_gui.py; add data points of both classes with right and left button, fit the model and change parameters and data.

Exercise

Try classifying classes 1 and 2 from the iris dataset with SVMs, with the 2 first features. Leave out 10% of each class and test prediction performance on these observations.

Warning: the classes are ordered, do not leave out the last 10%, you would be testing on only one class.

Hint: You can use the decision_function method on a grid to get intuitions.

```python
iris = datasets.load_iris()
X = iris.data
y = iris.target

X = X[y != 0, :2]
y = y[y != 0]
```

A solution can be downloaded here
2.2.3 Model selection: choosing estimators and their parameters

Score, and cross-validated scores

As we have seen, every estimator exposes a score method that can judge the quality of the fit (or the prediction) on new data. Bigger is better.

```python
>>> from sklearn import datasets, svm
>>> X_digits, y_digits = datasets.load_digits(return_X_y=True)
>>> svc = svm.SVC(C=1, kernel='linear')
>>> svc.fit(X_digits[:-100], y_digits[:-100]).score(X_digits[-100:], y_digits[-100:]
0.98
```

To get a better measure of prediction accuracy (which we can use as a proxy for goodness of fit of the model), we can successively split the data in folds that we use for training and testing:

```python
>>> import numpy as np
>>> X_folds = np.array_split(X_digits, 3)
>>> y_folds = np.array_split(y_digits, 3)
>>> scores = list()
>>> for k in range(3):
...   # We use 'list' to copy, in order to 'pop' later on
...   X_train = list(X_folds)
...   X_train.pop(k)
...   X_train = np.concatenate(X_train)
...   y_train = list(y_folds)
...   y_train.pop(k)
...   y_train = np.concatenate(y_train)
...   scores.append(svc.fit(X_train, y_train).score(X_test, y_test))
>>> print(scores)
[0.934..., 0.956..., 0.939...]
```

This is called a KFold cross-validation.

Cross-validation generators

Scikit-learn has a collection of classes which can be used to generate lists of train/test indices for popular cross-validation strategies.

They expose a split method which accepts the input dataset to be split and yields the train/test set indices for each iteration of the chosen cross-validation strategy.

This example shows an example usage of the split method.

```python
>>> from sklearn.model_selection import KFold, cross_val_score
>>> X = ["a", "a", "a", "b", "b", "c", "c", "c", "c", "c"]
>>> k_fold = KFold(n_splits=5)
>>> for train_indices, test_indices in k_fold.split(X):
...   print(f'Train: {train_indices} | test: {test_indices}
Train: [2 3 4 5 6 7 8 9] | test: [0 1]
Train: [0 1 4 5 6 7 8 9] | test: [2 3]
Train: [0 1 2 3 6 7 8 9] | test: [4 5]
Train: [0 1 2 3 4 5 8 9] | test: [6 7]
Train: [0 1 2 3 4 5 6 7] | test: [8 9]
```

The cross-validation can then be performed easily:
The cross-validation score can be directly calculated using the `cross_val_score` helper. Given an estimator, the cross-validation object and the input dataset, the `cross_val_score` splits the data repeatedly into a training and a testing set, trains the estimator using the training set and computes the scores based on the testing set for each iteration of cross-validation.

By default the estimator’s `score` method is used to compute the individual scores.

Refer the `metrics module` to learn more on the available scoring methods.

n_jobs=-1 means that the computation will be dispatched on all the CPUs of the computer.

Alternatively, the `scoring` argument can be provided to specify an alternative scoring method.

Cross-validation generators

<table>
<thead>
<tr>
<th>KFold (n_splits, shuffle, random_state)</th>
<th>StratifiedKFold (n_splits, shuffle, random_state)</th>
<th>GroupKFold (n_splits)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Splits it into K folds, trains on K-1 and then tests on the left-out.</td>
<td>Same as K-Fold but preserves the class distribution within each fold.</td>
<td>Ensures that the same group is not in both testing and training sets.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>ShuffleSplit (n_splits, test_size, train_size, random_state)</th>
<th>StratifiedShuffleSplit</th>
<th>GroupShuffleSplit</th>
</tr>
</thead>
<tbody>
<tr>
<td>Generates train/test indices based on random permutation.</td>
<td>Same as shuffle split but preserves the class distribution within each iteration.</td>
<td>Ensures that the same group is not in both testing and training sets.</td>
</tr>
</tbody>
</table>

Exercise

On the digits dataset, plot the cross-validation score of a `SVC` estimator with an linear kernel as a function of parameter C (use a logarithmic grid of points, from 1 to 10).

```python
import numpy as np
from sklearn.model_selection import cross_val_score
from sklearn import datasets, svm
```
scikit-learn provides an object that, given data, computes the score during the fit of an estimator on a parameter grid and chooses the parameters to maximize the cross-validation score. This object takes an estimator during the construction and exposes an estimator API:

```python
>>> from sklearn.model_selection import GridSearchCV, cross_val_score
>>> Cs = np.logspace(-6, -1, 10)
>>> clf = GridSearchCV(estimator=svc, param_grid=dict(C=Cs),
...                     n_jobs=-1)
>>> clf.fit(X_digits[:1000], y_digits[:1000])
GridSearchCV(cv=None,...
>>> clf.best_score_
0.925...
```
By default, the `GridSearchCV` uses a 5-fold cross-validation. However, if it detects that a classifier is passed, rather than a regressor, it uses a stratified 5-fold.

```
>>> clf.best_estimator_.C
0.0077...
>>> # Prediction performance on test set is not as good as on train set
>>> clf.score(X_digits[1000:], y_digits[1000:])
0.943...
```

Nested cross-validation

```
>>> cross_val_score(clf, X_digits, y_digits)
array([0.938..., 0.963..., 0.944...])
```

Two cross-validation loops are performed in parallel: one by the `GridSearchCV` estimator to set `gamma` and the other one by `cross_val_score` to measure the prediction performance of the estimator. The resulting scores are unbiased estimates of the prediction score on new data.

Warning: You cannot nest objects with parallel computing (n_jobs different than 1).

Cross-validated estimators

Cross-validation to set a parameter can be done more efficiently on an algorithm-by-algorithm basis. This is why, for certain estimators, scikit-learn exposes `Cross-validation: evaluating estimator performance` estimators that set their parameter automatically by cross-validation:

```
>>> from sklearn import linear_model, datasets
>>> lasso = linear_model.LassoCV()
>>> X_diabetes, y_diabetes = datasets.load_diabetes(return_X_y=True)
>>> lasso.fit(X_diabetes, y_diabetes)
LassoCV()
>>> # The estimator chose automatically its lambda:
>>> lasso.alpha_
0.00375...
```

These estimators are called similarly to their counterparts, with ‘CV’ appended to their name.

Exercise

On the diabetes dataset, find the optimal regularization parameter alpha.

Bonus: How much can you trust the selection of alpha?

```
from sklearn import datasets
from sklearn.linear_model import LassoCV
from sklearn.linear_model import Lasso
from sklearn.model_selection import KFold
from sklearn.model_selection import GridSearchCV

X, y = datasets.load_diabetes(return_X_y=True)
X = X[:150]
```
Cross-validation on diabetes Dataset Exercise

2.2.4 Unsupervised learning: seeking representations of the data

Clustering: grouping observations together

The problem solved in clustering

Given the iris dataset, if we knew that there were 3 types of iris, but did not have access to a taxonomist to label them: we could try a clustering task: split the observations into well-separated group called clusters.

K-means clustering

Note that there exist a lot of different clustering criteria and associated algorithms. The simplest clustering algorithm is K-means.

```python
>>> from sklearn import cluster, datasets
>>> X_iris, y_iris = datasets.load_iris(return_X_y=True)
>>> k_means = cluster.KMeans(n_clusters=3)
>>> k_means.fit(X_iris)
KMeans(n_clusters=3)
>>> print(k_means.labels_[::10])
[1 1 1 1 0 0 0 2 2 2 2]
>>> print(y_iris[::10])
[0 0 0 0 0 1 1 1 1 2 2 2 2]
```

Warning: There is absolutely no guarantee of recovering a ground truth. First, choosing the right number of clusters is hard. Second, the algorithm is sensitive to initialization, and can fall into local minima, although scikit-learn employs several tricks to mitigate this issue.
Don’t over-interpret clustering results

Application example: vector quantization

Clustering in general and KMeans, in particular, can be seen as a way of choosing a small number of exemplars to
compress the information. The problem is sometimes known as vector quantization. For instance, this can be used to posterize an image:

```python
>>> import scipy as sp
>>> try:
...     face = sp.face(gray=True)
... except AttributeError:
...     from scipy import misc
...     face = misc.face(gray=True)
>>> X = face.reshape((-1, 1))  # We need an (n_sample, n_feature) array
>>> k_means = cluster.KMeans(n_clusters=5, n_init=1)
>>> k_means.fit(X)
KMeans(n_clusters=5, n_init=1)
>>> values = k_means.cluster_centers_.squeeze()
>>> labels = k_means.labels_
>>> face_compressed = np.choose(labels, values)
>>> face_compressed.shape = face.shape
```

![Raw image](image1.png)

2.2. A tutorial on statistical-learning for scientific data processing 223
Hierarchical agglomerative clustering: Ward

A Hierarchical clustering method is a type of cluster analysis that aims to build a hierarchy of clusters. In general, the various approaches of this technique are either:

- **Agglomerative** - bottom-up approaches: each observation starts in its own cluster, and clusters are iteratively merged in such a way to minimize a linkage criterion. This approach is particularly interesting when the clusters of interest are made of only a few observations. When the number of clusters is large, it is much more computationally efficient than k-means.

- **Divisive** - top-down approaches: all observations start in one cluster, which is iteratively split as one moves down the hierarchy. For estimating large numbers of clusters, this approach is both slow (due to all observations starting as one cluster, which it splits recursively) and statistically ill-posed.
Connectivity-constrained clustering

With agglomerative clustering, it is possible to specify which samples can be clustered together by giving a connectivity graph. Graphs in scikit-learn are represented by their adjacency matrix. Often, a sparse matrix is used. This can be useful, for instance, to retrieve connected regions (sometimes also referred to as connected components) when clustering an image.

```python
>>> from skimage.data import coins
>>> from scipy.ndimage.filters import gaussian_filter
>>> from skimage.transform import rescale

rescaled_coins = rescale(...
    gaussian_filter(coins(), sigma=2),
    0.2, mode='reflect', anti_aliasing=False, multichannel=False
... )
>>> X = np.reshape(rescaled_coins, (-1, 1))

We need a vectorized version of the image. 'rescaled_coins' is a down-scaled version of the coins image to speed up the process:

```python
>>> from sklearn.feature_extraction import grid_to_graph

connectivity = grid_to_graph(*rescaled_coins.shape)
```

Define the graph structure of the data. Pixels connected to their neighbors:

```python
>>> n_clusters = 27 # number of regions
>>> from sklearn.cluster import AgglomerativeClustering

ward = AgglomerativeClustering(n_clusters=n_clusters, linkage='ward',
    connectivity=connectivity)
>>> ward.fit(X)
AgglomerativeClustering( connectivity=..., n_clusters=27)
>>> label = np.reshape(ward.labels_, rescaled_coins.shape)
```
Feature agglomeration

We have seen that sparsity could be used to mitigate the curse of dimensionality, i.e., an insufficient amount of observations compared to the number of features. Another approach is to merge together similar features: feature agglomeration. This approach can be implemented by clustering in the feature direction, in other words clustering the transposed data.

```python
digits = datasets.load_digits()
digits.images = np.reshape(images, (len(images), -1))
connectivity = grid_to_graph(*digits[0].shape)
agglo = cluster.FeatureAgglomeration(connectivity=connectivity, n_clusters=32)
agglo.fit(X)
X_reduced = agglo.transform(X)
X_approx = agglo.inverse_transform(X_reduced)
images_approx = np.reshape(X_approx, digits.images.shape)
```

Some estimators expose a transform method, for instance to reduce the dimensionality of the dataset.

Decompositions: from a signal to components and loadings

Components and loadings

If X is our multivariate data, then the problem that we are trying to solve is to rewrite it on a different observational basis: we want to learn loadings L and a set of components C such that \( X = L C \). Different criteria exist to choose the components.
Principal component analysis: PCA

Principal component analysis (PCA) selects the successive components that explain the maximum variance in the signal.

The point cloud spanned by the observations above is very flat in one direction: one of the three univariate features can almost be exactly computed using the other two. PCA finds the directions in which the data is not flat.

When used to transform data, PCA can reduce the dimensionality of the data by projecting on a principal subspace.

```python
>>> # Create a signal with only 2 useful dimensions
>>> x1 = np.random.normal(size=100)
>>> x2 = np.random.normal(size=100)
>>> x3 = x1 + x2
>>> X = np.c_[x1, x2, x3]

>>> from sklearn import decomposition
>>> pca = decomposition.PCA()
>>> pca.fit(X)
PCA()

>>> print(pca.explained_variance_)
[ 2.18565811e+00 1.19346747e+00 8.43026679e-32]

>>> # As we can see, only the 2 first components are useful
>>> pca.n_components = 2
>>> X_reduced = pca.fit_transform(X)
>>> X_reduced.shape
(100, 2)
```
Independent Component Analysis: ICA

Independent component analysis (ICA) selects components so that the distribution of their loadings carries a maximum amount of independent information. It is able to recover non-Gaussian independent signals:

```python
>>> # Generate sample data
>>> import numpy as np
>>> from scipy import signal

>>> time = np.linspace(0, 10, 2000)

>>> s1 = np.sin(2 * time)  # Signal 1: sinusoidal signal
>>> s2 = np.sign(np.sin(3 * time))  # Signal 2: square signal
>>> s3 = signal.sawtooth(2 * np.pi * time)  # Signal 3: saw tooth signal

>>> S = np.c_[s1, s2, s3]
>>> S += 0.2 * np.random.normal(size=S.shape)  # Add noise
>>> S /= S.std(axis=0)  # Standardize data

>>> # Mix data
>>> A = np.array([[1, 1, 1], [0.5, 2, 1], [1.5, 1, 2]])  # Mixing matrix

>>> X = np.dot(S, A.T)  # Generate observations

>>> # Compute ICA
>>> ica = decomposition.FastICA()

>>> S_ = ica.fit_transform(X)  # Get the estimated sources

>>> A_ = ica.mixing_.T
>>> np.allclose(X, np.dot(S_, A_) + ica.mean_)
True
```
2.2.5 Putting it all together

Pipelining

We have seen that some estimators can transform data and that some estimators can predict variables. We can also create combined estimators:

```python
import numpy as np
import matplotlib.pyplot as plt
import pandas as pd

from sklearn import datasets
from sklearn.decomposition import PCA
from sklearn.linear_model import LogisticRegression
from sklearn.pipeline import Pipeline
from sklearn.model_selection import GridSearchCV

# Define a pipeline to search for the best combination of PCA truncation
# and classifier regularization.
pca = PCA()
# set the tolerance to a large value to make the example faster
logistic = LogisticRegression(max_iter=10000, tol=0.1)
pipe = Pipeline(steps=[('pca', pca), ('logistic', logistic)])

X_digits, y_digits = datasets.load_digits(return_X_y=True)

# Parameters of pipelines can be set using '__' separated parameter names:
param_grid = {
    'pca__n_components': [5, 15, 30, 45, 64],
    'logistic__C': np.logspace(-4, 4, 4),
}
search = GridSearchCV(pipe, param_grid, n_jobs=-1)
search.fit(X_digits, y_digits)
print("Best parameter (CV score=\%0.3f):" % search.best_score_)
print(search.best_params_)

# Plot the PCA spectrum
pca.fit(X_digits)
fig, (ax0, ax1) = plt.subplots(nrows=2, sharex=True, figsize=(6, 6))
ax0.plot(np.arange(1, pca.n_components_ + 1),
    pca.explained_variance_ratio_, '+', linewidth=2)
ax0.set_ylabel('PCA explained variance ratio')
ax0.axvline(search.best_estimator_.named_steps['pca'].n_components,
    linestyle=':', label='n_components chosen')
ax0.legend(prop=dict(size=12))
```

Open problem: Stock Market Structure

Can we predict the variation in stock prices for Google over a given time frame?

_Learning a graph structure_

### 2.3 Working With Text Data

The goal of this guide is to explore some of the main scikit-learn tools on a single practical task: analyzing a collection of text documents (newsgroups posts) on twenty different topics.

In this section we will see how to:

- load the file contents and the categories
- extract feature vectors suitable for machine learning
- train a linear model to perform categorization
- use a grid search strategy to find a good configuration of both the feature extraction components and the classifier
2.3.1 Tutorial setup

To get started with this tutorial, you must first install *scikit-learn* and all of its required dependencies. Please refer to the *installation instructions* page for more information and for system-specific instructions.

The source of this tutorial can be found within your scikit-learn folder:

```bash
scikit-learn/doc/tutorial/text_analytics/
```

The source can also be found on Github.

The tutorial folder should contain the following sub-folders:

- * .rst files - the source of the tutorial document written with sphinx
- data - folder to put the datasets used during the tutorial
- skeletons - sample incomplete scripts for the exercises
- solutions - solutions of the exercises

You can already copy the skeletons into a new folder somewhere on your hard-drive named `sklearn_tut_workspace` where you will edit your own files for the exercises while keeping the original skeletons intact:

```bash
% cp -r skeletons work_directory/sklearn_tut_workspace
```

Machine learning algorithms need data. Go to each `$TUTORIAL_HOME/data` sub-folder and run the `fetch_data.py` script from there (after having read them first).

For instance:

```bash
% cd $TUTORIAL_HOME/data/languages
% less fetch_data.py
% python fetch_data.py
```

2.3.2 Loading the 20 newsgroups dataset

The dataset is called “Twenty Newsgroups”. Here is the official description, quoted from the website:

> The 20 Newsgroups data set is a collection of approximately 20,000 newsgroup documents, partitioned (nearly) evenly across 20 different newsgroups. To the best of our knowledge, it was originally collected by Ken Lang, probably for his paper “Newsweeder: Learning to filter netnews,” though he does not explicitly mention this collection. The 20 newsgroups collection has become a popular data set for experiments in text applications of machine learning techniques, such as text classification and text clustering.

In the following we will use the built-in dataset loader for 20 newsgroups from scikit-learn. Alternatively, it is possible to download the dataset manually from the website and use the `sklearn.datasets.load_files` function by pointing it to the `20news-bydate-train` sub-folder of the uncompressed archive folder.

In order to get faster execution times for this first example we will work on a partial dataset with only 4 categories out of the 20 available in the dataset:

```python
>>> categories = ['alt.atheism', 'soc.religion.christian',
                 'comp.graphics', 'sci.med']
```

We can now load the list of files matching those categories as follows:
```python
>>> from sklearn.datasets import fetch_20newsgroups
>>> twenty_train = fetch_20newsgroups(subset='train',
... categories=categories, shuffle=True, random_state=42)
```

The returned dataset is a scikit-learn “bunch”: a simple holder object with fields that can be both accessed as python dict keys or object attributes for convenience, for instance the `target_names` holds the list of the requested category names:

```python
>>> twenty_train.target_names
['alt.atheism', 'comp.graphics', 'sci.med', 'soc.religion.christian']
```

The files themselves are loaded in memory in the `data` attribute. For reference the filenames are also available:

```python
>>> len(twenty_train.data)
2257
>>> len(twenty_train.filenames)
2257
```

Let’s print the first lines of the first loaded file:

```python
>>> print("\n".join(twenty_train.data[0].split("\n")[:3]))
From: sd345@city.ac.uk (Michael Collier)
Subject: Converting images to HP LaserJet III?
Nntp-Posting-Host: hampton
```

```python
>>> print(twenty_train.target_names[twenty_train.target[0]])
comp.graphics
```

Supervised learning algorithms will require a category label for each document in the training set. In this case the category is the name of the newsgroup which also happens to be the name of the folder holding the individual documents.

For speed and space efficiency reasons scikit-learn loads the target attribute as an array of integers that corresponds to the index of the category name in the `target_names` list. The category integer id of each sample is stored in the `target` attribute:

```python
>>> twenty_train.target[:10]
array([1, 1, 3, 3, 3, 3, 3, 2, 2, 2])
```

It is possible to get back the category names as follows:

```python
>>> for t in twenty_train.target[:10]:
...     print(twenty_train.target_names[t])
...     print(twenty_train.target_names[t])
...     comp.graphics
comp.graphics
comp.graphics
soc.religion.christian
soc.religion.christian
soc.religion.christian
soc.religion.christian
soc.religion.christian
soc.religion.christian
sci.med
sci.med
sci.med
```

You might have noticed that the samples were shuffled randomly when we called `fetch_20newsgroups(...)`, this is useful if you wish to select only a subset of samples to quickly train a model and get a first idea of the results before re-training on the complete dataset later.
2.3.3 Extracting features from text files

In order to perform machine learning on text documents, we first need to turn the text content into numerical feature vectors.

**Bags of words**

The most intuitive way to do so is to use a bags of words representation:

1. Assign a fixed integer id to each word occurring in any document of the training set (for instance by building a dictionary from words to integer indices).
2. For each document \( i \), count the number of occurrences of each word \( w \) and store it in \( X[i, j] \) as the value of feature \( j \) where \( j \) is the index of word \( w \) in the dictionary.

The bags of words representation implies that \( n_{features} \) is the number of distinct words in the corpus: this number is typically larger than 100,000.

If \( n_{samples} == 10000 \), storing \( X \) as a NumPy array of type float32 would require \( 10000 \times 100000 \times 4 \) bytes = 4GB in RAM which is barely manageable on today’s computers.

Fortunately, most values in \( X \) will be zeros since for a given document less than a few thousand distinct words will be used. For this reason we say that bags of words are typically high-dimensional sparse datasets. We can save a lot of memory by only storing the non-zero parts of the feature vectors in memory. scipy.sparse matrices are data structures that do exactly this, and scikit-learn has built-in support for these structures.

**Tokenizing text with scikit-learn**

Text preprocessing, tokenizing and filtering of stopwords are all included in CountVectorizer, which builds a dictionary of features and transforms documents to feature vectors:

```python
>>> from sklearn.feature_extraction.text import CountVectorizer
>>> count_vect = CountVectorizer()
>>> X_train_counts = count_vect.fit_transform(twenty_train.data)
>>> X_train_counts.shape
(2257, 35788)
```

CountVectorizer supports counts of N-grams of words or consecutive characters. Once fitted, the vectorizer has built a dictionary of feature indices:

```python
>>> count_vect.vocabulary_.get(u'algorith'm)
4690
```

The index value of a word in the vocabulary is linked to its frequency in the whole training corpus.
From occurrences to frequencies

Occurrence count is a good start but there is an issue: longer documents will have higher average count values than shorter documents, even though they might talk about the same topics.

To avoid these potential discrepancies it suffices to divide the number of occurrences of each word in a document by the total number of words in the document: these new features are called \(tf\) for Term Frequencies.

Another refinement on top of \(tf\) is to downscale weights for words that occur in many documents in the corpus and are therefore less informative than those that occur only in a smaller portion of the corpus.

This downscaling is called \(tf\text{-}idf\) for “Term Frequency times Inverse Document Frequency”.

Both \(tf\) and \(tf\text{-}idf\) can be computed as follows using \texttt{TfidfTransformer}:

```python
>>> from sklearn.feature_extraction.text import TfidfTransformer
>>> tfidf_transformer = TfidfTransformer().fit_transform(X_train_counts)
>>> X_train_tfidf.shape
(2257, 35788)
```

In the above example-code, we firstly use the \texttt{fit(..)} method to fit our estimator to the data and secondly the \texttt{transform(..)} method to transform our count-matrix to a \(tf\text{-}idf\) representation. These two steps can be combined to achieve the same end result faster by skipping redundant processing. This is done through using the \texttt{fit_transform(..)} method as shown below, and as mentioned in the note in the previous section:

```python
>>> tfidf_transformer = TfidfTransformer()
>>> X_train_tfidf = tfidf_transformer.fit_transform(X_train_counts)
>>> X_train_tfidf.shape
(2257, 35788)
```

2.3.4 Training a classifier

Now that we have our features, we can train a classifier to try to predict the category of a post. Let’s start with a \textit{naive Bayes} classifier, which provides a nice baseline for this task. \texttt{scikit-learn} includes several variants of this classifier; the one most suitable for word counts is the multinomial variant:

```python
>>> from sklearn.naive_bayes import MultinomialNB
>>> clf = MultinomialNB().fit(X_train_tfidf, twenty_train.target)
```

To try to predict the outcome on a new document we need to extract the features using almost the same feature extracting chain as before. The difference is that we call \texttt{transform} instead of \texttt{fit_transform} on the transformers, since they have already been fit to the training set:

```python
>>> docs_new = ['God is love', 'OpenGL on the GPU is fast']
>>> X_new_counts = count_vect.transform(docs_new)
>>> X_new_tfidf = tfidf_transformer.transform(X_new_counts)
>>> predicted = clf.predict(X_new_tfidf)
```
2.3.5 Building a pipeline

In order to make the vectorizer => transformer => classifier easier to work with, scikit-learn provides a `Pipeline` class that behaves like a compound classifier:

```python
>>> from sklearn.pipeline import Pipeline
>>> text_clf = Pipeline([
...     ('vect', CountVectorizer()),
...     ('tfidf', TfidfTransformer()),
...     ('clf', MultinomialNB()),
... ])  
```

The names `vect`, `tfidf` and `clf` (classifier) are arbitrary. We will use them to perform grid search for suitable hyperparameters below. We can now train the model with a single command:

```python
>>> text_clf.fit(twenty_train.data, twenty_train.target)
```

2.3.6 Evaluation of the performance on the test set

Evaluating the predictive accuracy of the model is equally easy:

```python
>>> import numpy as np
>>> twenty_test = fetch_20newsgroups(subset='test',
...     categories=categories, shuffle=True, random_state=42)
>>> docs_test = twenty_test.data
>>> predicted = text_clf.predict(docs_test)
>>> np.mean(predicted == twenty_test.target)
0.8348...
```

We achieved 83.5% accuracy. Let’s see if we can do better with a linear support vector machine (SVM), which is widely regarded as one of the best text classification algorithms (although it’s also a bit slower than naïve Bayes). We can change the learner by simply plugging a different classifier object into our pipeline:

```python
>>> from sklearn.linear_model import SGDClassifier
>>> text_clf = Pipeline([
...     ('vect', CountVectorizer()),
...     ('tfidf', TfidfTransformer()),
...     ('clf', SGDClassifier(loss='hinge', penalty='l2',
...         alpha=1e-3, random_state=42,
...         max_iter=5, tol=0.0001)),
... ])  
```

```python
>>> text_clf.fit(twenty_train.data, twenty_train.target)
Pipeline(...)
>>> predicted = text_clf.predict(docs_test)
>>> np.mean(predicted == twenty_test.target)
0.9101...
```

We achieved 91.3% accuracy using the SVM. scikit-learn provides further utilities for more detailed performance analysis of the results:

```python
>>> from sklearn import metrics
>>> print(metrics.classification_report(twenty_test.target, predicted,
...     target_names=twenty_test.target_names))
```

(continues on next page)
As expected, the confusion matrix shows that posts from the newsgroups on atheism and Christianity are more often confused for one another than with computer graphics.

### 2.3.7 Parameter tuning using grid search

We’ve already encountered some parameters such as `use_idf` in the `TfidfTransformer`. Classifiers tend to have many parameters as well; e.g., `MultinomialNB` includes a smoothing parameter `alpha` and `SGDClassifier` has a penalty parameter `alpha` and configurable loss and penalty terms in the objective function (see the module documentation, or use the Python `help` function to get a description of these).

Instead of tweaking the parameters of the various components of the chain, it is possible to run an exhaustive search of the best parameters on a grid of possible values. We try out all classifiers on either words or bigrams, with or without idf, and with a penalty parameter of either 0.01 or 0.001 for the linear SVM:

```python
>>> from sklearn.model_selection import GridSearchCV

>>> parameters = {
...     'vect__ngram_range': [(1, 1), (1, 2)],
...     'tfidf__use_idf': (True, False),
...     'clf__alpha': [1e-2, 1e-3],
... }
```

Obviously, such an exhaustive search can be expensive. If we have multiple CPU cores at our disposal, we can tell the grid searcher to try these eight parameter combinations in parallel with the `n_jobs` parameter. If we give this parameter a value of -1, grid search will detect how many cores are installed and use them all:

```python
>>> gs_clf = GridSearchCV(text_clf, parameters, cv=5, n_jobs=-1)
```

The grid search instance behaves like a normal `scikit-learn` model. Let’s perform the search on a smaller subset of the training data to speed up the computation:

```python
>>> gs_clf = gs_clf.fit(twenty_train.data[:400], twenty_train.target[:400])
```

The result of calling `fit` on a `GridSearchCV` object is a classifier that we can use to `predict`:

```python
>>> twenty_train.target_names[gs_clf.predict(['God is love'])[0]]
'soc.religion.christian'
```
The object’s best_score_ and best_params_ attributes store the best mean score and the parameters setting corresponding to that score:

```python
>>> gs_clf.best_score_
0.9...
>>> for param_name in sorted(parameters.keys()):
...     print("%s: %r" % (param_name, gs_clf.best_params_[param_name]))
...
clf__alpha: 0.001
tfidf__use_idf: True
vect__ngram_range: (1, 1)
```

A more detailed summary of the search is available at `gs_clf.cv_results_`. The `cv_results_` parameter can be easily imported into pandas as a DataFrame for further inspection.

### Exercises

To do the exercises, copy the content of the ‘skeletons’ folder as a new folder named ‘workspace’:

```bash
% cp -r skeletons workspace
```

You can then edit the content of the workspace without fear of losing the original exercise instructions.

Then fire an ipython shell and run the work-in-progress script with:

```
[1] %run workspace/exercise_XX_script.py arg1 arg2 arg3
```

If an exception is triggered, use `%debug` to fire-up a post mortem ipdb session.

Refine the implementation and iterate until the exercise is solved.

For each exercise, the skeleton file provides all the necessary import statements, boilerplate code to load the data and sample code to evaluate the predictive accuracy of the model.

#### 2.3.8 Exercise 1: Language identification

- Write a text classification pipeline using a custom preprocessor and CharNGramAnalyzer using data from Wikipedia articles as training set.
- Evaluate the performance on some held out test set.

Ipython command line:

```
%run workspace/exercise_01_language_train_model.py data/languages/paragraphs/
```

#### 2.3.9 Exercise 2: Sentiment Analysis on movie reviews

- Write a text classification pipeline to classify movie reviews as either positive or negative.
- Find a good set of parameters using grid search.
- Evaluate the performance on a held out test set.

Ipython command line:
%run workspace/exercise_02_sentiment.py data/movie_reviews/txt_sentoken/

2.3.10 Exercise 3: CLI text classification utility

Using the results of the previous exercises and the cPickle module of the standard library, write a command line utility that detects the language of some text provided on stdin and estimate the polarity (positive or negative) if the text is written in English.

Bonus point if the utility is able to give a confidence level for its predictions.

2.3.11 Where to from here

Here are a few suggestions to help further your scikit-learn intuition upon the completion of this tutorial:

- Try playing around with the analyzer and token normalisation under CountVectorizer.
- If you don’t have labels, try using Clustering on your problem.
- If you have multiple labels per document, e.g categories, have a look at the Multiclass and multilabel section.
- Try using Truncated SVD for latent semantic analysis.
- Have a look at using Out-of-core Classification to learn from data that would not fit into the computer main memory.
- Have a look at the Hashing Vectorizer as a memory efficient alternative to CountVectorizer.

2.4 Choosing the right estimator

Often the hardest part of solving a machine learning problem can be finding the right estimator for the job.

Different estimators are better suited for different types of data and different problems.

The flowchart below is designed to give users a bit of a rough guide on how to approach problems with regard to which estimators to try on your data.

Click on any estimator in the chart below to see its documentation.

2.5 External Resources, Videos and Talks

For written tutorials, see the Tutorial section of the documentation.

2.5.1 New to Scientific Python?

For those that are still new to the scientific Python ecosystem, we highly recommend the Python Scientific Lecture Notes. This will help you find your footing a bit and will definitely improve your scikit-learn experience. A basic understanding of NumPy arrays is recommended to make the most of scikit-learn.
2.5.2 External Tutorials

There are several online tutorials available which are geared toward specific subject areas:

- Machine Learning for NeuroImaging in Python
- Machine Learning for Astronomical Data Analysis

2.5.3 Videos

- An introduction to scikit-learn Part I and Part II at Scipy 2013 by Gael Varoquaux, Jake Vanderplas and Olivier Grisel. Notebooks on github.
- Introduction to scikit-learn by Gael Varoquaux at ICML 2010
  A three minute video from a very early stage of scikit-learn, explaining the basic idea and approach we are following.
- Introduction to statistical learning with scikit-learn by Gael Varoquaux at SciPy 2011
  An extensive tutorial, consisting of four sessions of one hour. The tutorial covers the basics of machine learning, many algorithms and how to apply them using scikit-learn. The material corresponding is now in the scikit-learn documentation section A tutorial on statistical-learning for scientific data processing.
- Statistical Learning for Text Classification with scikit-learn and NLTK (and slides) by Olivier Grisel at PyCon 2011
  Thirty minute introduction to text classification. Explains how to use NLTK and scikit-learn to solve real-world text classification tasks and compares against cloud-based solutions.
- Introduction to Interactive Predictive Analytics in Python with scikit-learn by Olivier Grisel at PyCon 2012
  3-hours long introduction to prediction tasks using scikit-learn.
- scikit-learn - Machine Learning in Python by Jake Vanderplas at the 2012 PyData workshop at Google
  Interactive demonstration of some scikit-learn features. 75 minutes.
- scikit-learn tutorial by Jake Vanderplas at PyData NYC 2012
  Presentation using the online tutorial, 45 minutes.

Note: Doctest Mode

The code-examples in the above tutorials are written in a python-console format. If you wish to easily execute these examples in IPython, use:

```
doctest_mode
```

in the IPython-console. You can then simply copy and paste the examples directly into IPython without having to worry about removing the >>>> manually.
The purpose of this guide is to illustrate some of the main features that scikit-learn provides. It assumes a very basic working knowledge of machine learning practices (model fitting, predicting, cross-validation, etc.). Please refer to our installation instructions for installing scikit-learn.

Scikit-learn is an open source machine learning library that supports supervised and unsupervised learning. It also provides various tools for model fitting, data preprocessing, model selection and evaluation, and many other utilities.

3.1 Fitting and predicting: estimator basics

Scikit-learn provides dozens of built-in machine learning algorithms and models, called estimators. Each estimator can be fitted to some data using its fit method.

Here is a simple example where we fit a RandomForestClassifier to some very basic data:

```python
>>> from sklearn.ensemble import RandomForestClassifier
>>> clf = RandomForestClassifier(random_state=0)
>>> X = [[1, 2, 3], # 2 samples, 3 features...
... [11, 12, 13]]
>>> y = [0, 1] # classes of each sample
>>> clf.fit(X, y)
RandomForestClassifier(random_state=0)
```

The fit method generally accepts 2 inputs:

- The samples matrix (or design matrix) $X$. The size of $X$ is typically $(n_{samples}, n_{features})$, which means that samples are represented as rows and features are represented as columns.

- The target values $y$ which are real numbers for regression tasks, or integers for classification (or any other discrete set of values). For unsupervised learning tasks, $y$ does not need to be specified. $y$ is usually 1d array where the $i$ th entry corresponds to the target of the $i$ th sample (row) of $X$.

Both $X$ and $y$ are usually expected to be numpy arrays or equivalent array-like data types, though some estimators work with other formats such as sparse matrices.

Once the estimator is fitted, it can be used for predicting target values of new data. You don’t need to re-train the estimator:

```python
>>> clf.predict(X) # predict classes of the training data
array([0, 1])
>>> clf.predict([[4, 5, 6], [14, 15, 16]]) # predict classes of new data
array([0, 1])
```
3.2 Transformers and pre-processors

Machine learning workflows are often composed of different parts. A typical pipeline consists of a pre-processing step that transforms or imputes the data, and a final predictor that predicts target values.

In scikit-learn, pre-processors and transformers follow the same API as the estimator objects (they actually all inherit from the same `BaseEstimator` class). The transformer objects don’t have a `predict` method but rather a `transform` method that outputs a newly transformed sample matrix $X$:

```python
>>> from sklearn.preprocessing import StandardScaler
>>> X = [[0, 15], ...
...      [1, -10]]
>>> # scale data according to computed scaling values
>>> StandardScaler().fit(X).transform(X)
array([[ -1.,  1.],
       [ 1., -1.]])
```

Sometimes, you want to apply different transformations to different features: the `ColumnTransformer` is designed for these use-cases.

3.3 Pipelines: chaining pre-processors and estimators

Transformers and estimators (predictors) can be combined together into a single unifying object: a `Pipeline`. The pipeline offers the same API as a regular estimator: it can be fitted and used for prediction with `fit` and `predict`. As we will see later, using a pipeline will also prevent you from data leakage, i.e. disclosing some testing data in your training data.

In the following example, we `load the Iris dataset`, split it into train and test sets, and compute the accuracy score of a pipeline on the test data:

```python
>>> from sklearn.preprocessing import StandardScaler
>>> from sklearn.linear_model import LogisticRegression
>>> from sklearn.pipeline import make_pipeline
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.metrics import accuracy_score
...
>>> # create a pipeline object
>>> pipe = make_pipeline(
...   StandardScaler(),
...   LogisticRegression()
... )
...
>>> # load the iris dataset and split it into train and test sets
>>> X, y = load_iris(return_X_y=True)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
...
>>> # fit the whole pipeline
>>> pipe.fit(X_train, y_train)
Pipeline(steps=[('standardscaler', StandardScaler()),
               ('logisticregression', LogisticRegression())])
>>> # we can now use it like any other estimator
>>> accuracy_score(pipe.predict(X_test), y_test)
0.97...
```
3.4 Model evaluation

Fitting a model to some data does not entail that it will predict well on unseen data. This needs to be directly evaluated. We have just seen the `train_test_split` helper that splits a dataset into train and test sets, but scikit-learn provides many other tools for model evaluation, in particular for cross-validation.

We here briefly show how to perform a 5-fold cross-validation procedure, using the `cross_validate` helper. Note that it is also possible to manually iterate over the folds, use different data splitting strategies, and use custom scoring functions. Please refer to our User Guide for more details:

```python
>>> from sklearn.datasets import make_regression
>>> from sklearn.linear_model import LinearRegression
>>> from sklearn.model_selection import cross_validate

>>> X, y = make_regression(n_samples=1000, random_state=0)
>>> lr = LinearRegression()

>>> result = cross_validate(lr, X, y)  # defaults to 5-fold CV
>>> result['test_score']  # r_squared score is high because dataset is easy
array([1., 1., 1., 1., 1.])
```

3.5 Automatic parameter searches

All estimators have parameters (often called hyper-parameters in the literature) that can be tuned. The generalization power of an estimator often critically depends on a few parameters. For example a `RandomForestRegressor` has a `n_estimators` parameter that determines the number of trees in the forest, and a `max_depth` parameter that determines the maximum depth of each tree. Quite often, it is not clear what the exact values of these parameters should be since they depend on the data at hand.

Scikit-learn provides tools to automatically find the best parameter combinations (via cross-validation). In the following example, we randomly search over the parameter space of a random forest with a `RandomizedSearchCV` object. When the search is over, the `RandomizedSearchCV` behaves as a `RandomForestRegressor` that has been fitted with the best set of parameters. Read more in the User Guide:

```python
>>> from sklearn.datasets import fetch_california_housing
>>> from sklearn.ensemble import RandomForestRegressor
>>> from sklearn.model_selection import RandomizedSearchCV
>>> from sklearn.model_selection import train_test_split
>>> from scipy.stats import randint

>>> X, y = fetch_california_housing(return_X_y=True)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)

>>> # define the parameter space that will be searched over
>>> param_distributions = {'n_estimators': randint(1, 5),
                          'max_depth': randint(5, 10)}

>>> # now create a searchCV object and fit it to the data
>>> search = RandomizedSearchCV(estimator=RandomForestRegressor(random_state=0),
                              n_iter=5,
                              param_distributions=param_distributions,
                              random_state=0)
>>> search.fit(X_train, y_train)
RandomizedSearchCV(estimator=RandomForestRegressor(random_state=0), n_iter=5,
(continues on next page)
```python
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.model_selection import RandomizedSearchCV

# Define the parameter distributions to search over
param_distributions={'max_depth': ...,
                     'n_estimators': ...},
random_state=0)

>>> search.best_params_
{'max_depth': 9, 'n_estimators': 4}

>>> # the search object now acts like a normal random forest estimator
>>> # with max_depth=9 and n_estimators=4
>>> search.score(X_test, y_test)
0.73...
```

**Note:** In practice, you almost always want to **search over a pipeline**, instead of a single estimator. One of the main reasons is that if you apply a pre-processing step to the whole dataset without using a pipeline, and then perform any kind of cross-validation, you would be breaking the fundamental assumption of independence between training and testing data. Indeed, since you pre-processed the data using the whole dataset, some information about the test sets are available to the train sets. This will lead to over-estimating the generalization power of the estimator (you can read more in this Kaggle post).

Using a pipeline for cross-validation and searching will largely keep you from this common pitfall.

### 3.6 Next steps

We have briefly covered estimator fitting and predicting, pre-processing steps, pipelines, cross-validation tools and automatic hyper-parameter searches. This guide should give you an overview of some of the main features of the library, but there is much more to scikit-learn!

Please refer to our *User Guide* for details on all the tools that we provide. You can also find an exhaustive list of the public API in the *API Reference*.

You can also look at our numerous *examples* that illustrate the use of *scikit-learn* in many different contexts. The *tutorials* also contain additional learning resources.
4.1 Supervised learning

4.1.1 Linear Models

The following are a set of methods intended for regression in which the target value is expected to be a linear combination of the features. In mathematical notation, if \( \hat{y} \) is the predicted value.

\[
\hat{y}(w, x) = w_0 + w_1 x_1 + \ldots + w_p x_p
\]

Across the module, we designate the vector \( w = (w_1, \ldots, w_p) \) as \( \text{coef} \) and \( w_0 \) as \( \text{intercept} \).

To perform classification with generalized linear models, see Logistic regression.

Ordinary Least Squares

LinearRegression fits a linear model with coefficients \( w = (w_1, \ldots, w_p) \) to minimize the residual sum of squares between the observed targets in the dataset, and the targets predicted by the linear approximation. Mathematically it solves a problem of the form:

\[
\min_w \|Xw - y\|_2^2
\]

LinearRegression will take in its fit method arrays X, y and will store the coefficients \( w \) of the linear model in its coef_ member:
The coefficient estimates for Ordinary Least Squares rely on the independence of the features. When features are correlated and the columns of the design matrix $X$ have an approximate linear dependence, the design matrix becomes close to singular and as a result, the least-squares estimate becomes highly sensitive to random errors in the observed target, producing a large variance. This situation of *multicollinearity* can arise, for example, when data are collected without an experimental design.

Examples:

- **Linear Regression Example**

Non-Negative Least Squares

It is possible to constrain all the coefficients to be non-negative, which may be useful when they represent some physical or naturally non-negative quantities (e.g., frequency counts or prices of goods). *LinearRegression* accepts a boolean `positive` parameter: when set to `True` Non Negative Least Squares are then applied.

Examples:

- **Non-negative least squares**

Ordinary Least Squares Complexity

The least squares solution is computed using the singular value decomposition of $X$. If $X$ is a matrix of shape $(n_{\text{samples}}, n_{\text{features}})$ this method has a cost of $O(n_{\text{samples}}n_{\text{features}}^2)$, assuming that $n_{\text{samples}} \geq n_{\text{features}}$.

**Ridge regression and classification**

**Regression**

*Ridge* regression addresses some of the problems of *Ordinary Least Squares* by imposing a penalty on the size of the coefficients. The ridge coefficients minimize a penalized residual sum of squares:

$$
\min_w \|Xw - y\|_2^2 + \alpha \|w\|_2^2
$$

The complexity parameter $\alpha \geq 0$ controls the amount of shrinkage: the larger the value of $\alpha$, the greater the amount of shrinkage and thus the coefficients become more robust to collinearity.

As with other linear models, *Ridge* will take in its `fit` method arrays $X$, $y$ and will store the coefficients $w$ of the linear model in its `coef_` member:
>>> from sklearn import linear_model
>>> reg = linear_model.Ridge(alpha=.5)
>>> reg.fit([[0, 0], [0, 0], [1, 1]], [0, .1, 1])
Ridge(alpha=0.5)
>>> reg.coef_
array([0.34545455, 0.34545455])
>>> reg.intercept_
0.13636...

Classification

The Ridge regressor has a classifier variant: RidgeClassifier. This classifier first converts binary targets to \((-1, 1)\) and then treats the problem as a regression task, optimizing the same objective as above. The predicted class corresponds to the sign of the regressor’s prediction. For multiclass classification, the problem is treated as multi-output regression, and the predicted class corresponds to the output with the highest value.

It might seem questionable to use a (penalized) Least Squares loss to fit a classification model instead of the more traditional logit or hinge losses. However in practice all those models can lead to similar cross-validation scores in terms of accuracy or precision/recall, while the penalized least squares loss used by the RidgeClassifier allows for a very different choice of the numerical solvers with distinct computational performance profiles.

The RidgeClassifier can be significantly faster than e.g. LogisticRegression with a high number of classes, because it is able to compute the projection matrix \((X^T X)^{-1} X^T\) only once.

This classifier is sometimes referred to as a Least Squares Support Vector Machines with a linear kernel.

Examples:

- Plot Ridge coefficients as a function of the regularization
- Classification of text documents using sparse features
- Common pitfalls in interpretation of coefficients of linear models

4.1. Supervised learning
Ridge Complexity

This method has the same order of complexity as *Ordinary Least Squares*.

Setting the regularization parameter: leave-one-out Cross-Validation

*RidgeCV* implements ridge regression with built-in cross-validation of the alpha parameter. The object works in the same way as *GridSearchCV* except that it defaults to Leave-One-Out Cross-Validation:

```python
>>> import numpy as np
>>> from sklearn import linear_model

>>> reg = linear_model.RidgeCV(alphas=np.logspace(-6, 6, 13))
>>> reg.fit([[0, 0], [0, 0], [1, 1]], [0, .1, 1])
RidgeCV(alphas=array([1.e-06, 1.e-05, 1.e-04, 1.e-03, 1.e-02, 1.e-01, 1.e+00, 1.e+01,
    1.e+02, 1.e+03, 1.e+04, 1.e+05, 1.e+06]))

>>> reg.alpha_
0.01
```

Specifying the value of the `cv` attribute will trigger the use of cross-validation with *GridSearchCV*, for example `cv=10` for 10-fold cross-validation, rather than Leave-One-Out Cross-Validation.

Lasso

The *Lasso* is a linear model that estimates sparse coefficients. It is useful in some contexts due to its tendency to prefer solutions with fewer non-zero coefficients, effectively reducing the number of features upon which the given solution is dependent. For this reason Lasso and its variants are fundamental to the field of compressed sensing. Under certain conditions, it can recover the exact set of non-zero coefficients (see *Compressive sensing: tomography reconstruction with L1 prior* (Lasso)).

Mathematically, it consists of a linear model with an added regularization term. The objective function to minimize is:

\[
\min_w \frac{1}{2n_{\text{samples}}} \|Xw - y\|^2_2 + \alpha \|w\|_1
\]

The lasso estimate thus solves the minimization of the least-squares penalty with \(\alpha \|w\|_1\) added, where \(\alpha\) is a constant and \(\|w\|_1\) is the \(\ell_1\)-norm of the coefficient vector.

The implementation in the class *Lasso* uses coordinate descent as the algorithm to fit the coefficients. See *Least Angle Regression* for another implementation:

```python
>>> from sklearn import linear_model

>>> reg = linear_model.Lasso(alpha=0.1)

>>> reg.fit([[0, 0], [1, 1]], [0, 1])
Lasso(alpha=0.1)

>>> reg.predict([[1, 1]])
array([0.8])
```

The function *lasso_path* is useful for lower-level tasks, as it computes the coefficients along the full path of possible values.
Examples:

- Lasso and Elastic Net for Sparse Signals
- Compressive sensing: tomography reconstruction with L1 prior (Lasso)
- Common pitfalls in interpretation of coefficients of linear models

Note: Feature selection with Lasso

As the Lasso regression yields sparse models, it can thus be used to perform feature selection, as detailed in \textit{L1-based feature selection}.

The following two references explain the iterations used in the coordinate descent solver of scikit-learn, as well as the duality gap computation used for convergence control.

References

Setting regularization parameter

The \texttt{alpha} parameter controls the degree of sparsity of the estimated coefficients.

Using cross-validation

scikit-learn exposes objects that set the Lasso \texttt{alpha} parameter by cross-validation: \texttt{LassoCV} and \texttt{LassoLarsCV}. \texttt{LassoLarsCV} is based on the \textit{Least Angle Regression} algorithm explained below.

For high-dimensional datasets with many collinear features, \texttt{LassoCV} is most often preferable. However, \texttt{LassoLarsCV} has the advantage of exploring more relevant values of \texttt{alpha} parameter, and if the number of samples is very small compared to the number of features, it is often faster than \texttt{LassoCV}.
Information-criteria based model selection

Alternatively, the estimator `LassoLarsIC` proposes to use the Akaike information criterion (AIC) and the Bayes Information criterion (BIC). It is a computationally cheaper alternative to find the optimal value of alpha as the regularization path is computed only once instead of k+1 times when using k-fold cross-validation. However, such criteria needs a proper estimation of the degrees of freedom of the solution, are derived for large samples (asymptotic results) and assume the model is correct, i.e. that the data are actually generated by this model. They also tend to break when the problem is badly conditioned (more features than samples).

Examples:

- Lasso model selection: Cross-Validation / AIC / BIC
Comparison with the regularization parameter of SVM

The equivalence between $\alpha$ and the regularization parameter of SVM, $C$, is given by $\alpha = 1 / C$ or $\alpha = 1 / (n_{\text{samples}} \times C)$, depending on the estimator and the exact objective function optimized by the model.

Multi-task Lasso

The `MultiTaskLasso` is a linear model that estimates sparse coefficients for multiple regression problems jointly: $y$ is a 2D array, of shape $(n_{\text{samples}}, n_{\text{tasks}})$. The constraint is that the selected features are the same for all the regression problems, also called tasks.

The following figure compares the location of the non-zero entries in the coefficient matrix $W$ obtained with a simple Lasso or a MultiTaskLasso. The Lasso estimates yield scattered non-zeros while the non-zeros of the MultiTaskLasso are full columns.

Fitting a time-series model, imposing that any active feature be active at all times.

Examples:

- `Joint feature selection with multi-task Lasso`

Mathematically, it consists of a linear model trained with a mixed $\ell_1 \ell_2$-norm for regularization. The objective function
to minimize is:

$$\min_w \frac{1}{2n_{\text{samples}}} \|XW - Y\|_\text{Fro}^2 + \alpha \|W\|_1$$

where Fro indicates the Frobenius norm

$$\|A\|_\text{Fro} = \sqrt{\sum_{ij} a_{ij}^2}$$

and $\ell_1 \ell_2$ reads

$$\|A\|_1 = \sum_i \sqrt{\sum_j a_{ij}^2}.$$ 

The implementation in the class `MultiTaskLasso` uses coordinate descent as the algorithm to fit the coefficients.

**Elastic-Net**

`ElasticNet` is a linear regression model trained with both $\ell_1$ and $\ell_2$-norm regularization of the coefficients. This combination allows for learning a sparse model where few of the weights are non-zero like `Lasso`, while still maintaining the regularization properties of `Ridge`. We control the convex combination of $\ell_1$ and $\ell_2$ using the `l1_ratio` parameter.

Elastic-net is useful when there are multiple features which are correlated with one another. Lasso is likely to pick one of these at random, while elastic-net is likely to pick both.

A practical advantage of trading-off between Lasso and Ridge is that it allows Elastic-Net to inherit some of Ridge’s stability under rotation.

The objective function to minimize is in this case

$$\min_w \frac{1}{2n_{\text{samples}}} \|Xw - y\|_2^2 + \alpha \rho \|w\|_1 + \frac{\alpha(1 - \rho)}{2} \|w\|_2^2$$

The class `ElasticNetCV` can be used to set the parameters `alpha` ($\alpha$) and `l1_ratio` ($\rho$) by cross-validation.
Examples:

- Lasso and Elastic Net for Sparse Signals
- Lasso and Elastic Net

The following two references explain the iterations used in the coordinate descent solver of scikit-learn, as well as the duality gap computation used for convergence control.

References

Multi-task Elastic-Net

The MultiTaskElasticNet is an elastic-net model that estimates sparse coefficients for multiple regression problems jointly: $Y$ is a 2D array of shape $(n\_samples, n\_tasks)$. The constraint is that the selected features are the same for all the regression problems, also called tasks.

Mathematically, it consists of a linear model trained with a mixed $\ell_1 \ell_2$-norm and $\ell_2$-norm for regularization. The objective function to minimize is:

$$\min_W \frac{1}{2n\_samples} ||XW - Y||^2_{\text{Fro}} + \alpha \rho ||W||_{21} + \frac{\alpha (1 - \rho)}{2} ||W||^2_{\text{Fro}}$$

The implementation in the class MultiTaskElasticNet uses coordinate descent as the algorithm to fit the coefficients.

The class MultiTaskElasticNetCV can be used to set the parameters $\text{alpha}$ ($\alpha$) and $\text{l1\_ratio}$ ($\rho$) by cross-validation.

Least Angle Regression

Least-angle regression (LARS) is a regression algorithm for high-dimensional data, developed by Bradley Efron, Trevor Hastie, Iain Johnstone and Robert Tibshirani. LARS is similar to forward stepwise regression. At each step, it finds the feature most correlated with the target. When there are multiple features having equal correlation, instead of continuing along the same feature, it proceeds in a direction equiangular between the features.

The advantages of LARS are:

- It is numerically efficient in contexts where the number of features is significantly greater than the number of samples.
- It is computationally just as fast as forward selection and has the same order of complexity as ordinary least squares.
- It produces a full piecewise linear solution path, which is useful in cross-validation or similar attempts to tune the model.
- If two features are almost equally correlated with the target, then their coefficients should increase at approximately the same rate. The algorithm thus behaves as intuition would expect, and also is more stable.
• It is easily modified to produce solutions for other estimators, like the Lasso.

The disadvantages of the LARS method include:

• Because LARS is based upon an iterative refitting of the residuals, it would appear to be especially sensitive to the effects of noise. This problem is discussed in detail by Weisberg in the discussion section of the Efron et al. (2004) Annals of Statistics article.

The LARS model can be used using estimator `Lars`, or its low-level implementation `lars_path` or `lars_path_gram`.

**LARS Lasso**

`LassoLars` is a lasso model implemented using the LARS algorithm, and unlike the implementation based on coordinate descent, this yields the exact solution, which is piecewise linear as a function of the norm of its coefficients.

```python
>>> from sklearn import linear_model
>>> reg = linear_model.LassoLars(alpha=.1)
>>> reg.fit([[0, 0], [1, 1]], [0, 1])
LassoLars(alpha=0.1)
>>> reg.coef_
array([0.717157..., 0.])
```

**Examples:**

• *Lasso path using LARS*

The Lars algorithm provides the full path of the coefficients along the regularization parameter almost for free, thus a common operation is to retrieve the path with one of the functions `lars_path` or `lars_path_gram`.
Mathematical formulation

The algorithm is similar to forward stepwise regression, but instead of including features at each step, the estimated coefficients are increased in a direction equiangular to each one's correlations with the residual.

Instead of giving a vector result, the LARS solution consists of a curve denoting the solution for each value of the $\ell_1$ norm of the parameter vector. The full coefficients path is stored in the array `coef_path_`, which has size (n_features, max_features+1). The first column is always zero.

References:

- Original Algorithm is detailed in the paper Least Angle Regression by Hastie et al.

Orthogonal Matching Pursuit (OMP)

`OrthogonalMatchingPursuit` and `orthogonal_mp` implements the OMP algorithm for approximating the fit of a linear model with constraints imposed on the number of non-zero coefficients (ie. the $\ell_0$ pseudo-norm).

Being a forward feature selection method like Least Angle Regression, orthogonal matching pursuit can approximate the optimum solution vector with a fixed number of non-zero elements:

$$\arg \min_w \|y - Xw\|_2^2 \text{ subject to } \|w\|_0 \leq n_{\text{nonzero\_coeffs}}$$

Alternatively, orthogonal matching pursuit can target a specific error instead of a specific number of non-zero coefficients. This can be expressed as:

$$\arg \min_w \|w\|_0 \text{ subject to } \|y - Xw\|_2^2 \leq \text{tol}$$

OMP is based on a greedy algorithm that includes at each step the atom most highly correlated with the current residual. It is similar to the simpler matching pursuit (MP) method, but better in that at each iteration, the residual is recomputed using an orthogonal projection on the space of the previously chosen dictionary elements.

Examples:

- Orthogonal Matching Pursuit

Bayesian Regression

Bayesian regression techniques can be used to include regularization parameters in the estimation procedure: the regularization parameter is not set in a hard sense but tuned to the data at hand.

This can be done by introducing uninformative priors over the hyper parameters of the model. The $\ell_2$ regularization used in Ridge regression and classification is equivalent to finding a maximum a posteriori estimation under a Gaussian prior over the coefficients $w$ with precision $\lambda^{-1}$. Instead of setting $\text{lambda}$ manually, it is possible to treat it as a random variable to be estimated from the data.

To obtain a fully probabilistic model, the output $y$ is assumed to be Gaussian distributed around $Xw$:

$$p(y|X, w, \alpha) = \mathcal{N}(y|Xw, \alpha)$$

where $\alpha$ is again treated as a random variable that is to be estimated from the data.

The advantages of Bayesian Regression are:

- It adapts to the data at hand.
- It can be used to include regularization parameters in the estimation procedure.

The disadvantages of Bayesian regression include:

- Inference of the model can be time consuming.

References

- A good introduction to Bayesian methods is given in C. Bishop: Pattern Recognition and Machine learning
- Original Algorithm is detailed in the book Bayesian learning for neural networks by Radford M. Neal

Bayesian Ridge Regression

$\text{BayesianRidge}$ estimates a probabilistic model of the regression problem as described above. The prior for the coefficient $w$ is given by a spherical Gaussian:

$$p(w|\lambda) = \mathcal{N}(w|0, \lambda^{-1}I_p)$$

The priors over $\alpha$ and $\lambda$ are chosen to be gamma distributions, the conjugate prior for the precision of the Gaussian. The resulting model is called $\text{Bayesian Ridge Regression}$, and is similar to the classical $\text{Ridge}$.

The parameters $w$, $\alpha$ and $\lambda$ are estimated jointly during the fit of the model, the regularization parameters $\alpha$ and $\lambda$ being estimated by maximizing the log marginal likelihood. The scikit-learn implementation is based on the algorithm described in Appendix A of (Tipping, 2001) where the update of the parameters $\alpha$ and $\lambda$ is done as suggested in (MacKay, 1992). The initial value of the maximization procedure can be set with the hyperparameters $\text{alpha_init}$ and $\text{lambda_init}$.

There are four more hyperparameters, $\alpha_1$, $\alpha_2$, $\lambda_1$ and $\lambda_2$ of the gamma prior distributions over $\alpha$ and $\lambda$. These are usually chosen to be non-informative. By default $\alpha_1 = \alpha_2 = \lambda_1 = \lambda_2 = 10^{-6}$.

Bayesian Ridge Regression is used for regression:

```python
>>> from sklearn import linear_model
>>> X = [[0., 0.], [1., 1.], [2., 2.], [3., 3.]]
>>> Y = [0., 1., 2., 3.]
```
>>> reg = linear_model.BayesianRidge()
>>> reg.fit(X, Y)
BayesianRidge()

After being fitted, the model can then be used to predict new values:

```python
>>> reg.predict([[1, 0.0]])
array([0.50000013])
```

The coefficients \( w \) of the model can be accessed:

```python
>>> reg.coef_
array([0.49999993, 0.49999993])
```

Due to the Bayesian framework, the weights found are slightly different to the ones found by Ordinary Least Squares. However, Bayesian Ridge Regression is more robust to ill-posed problems.

**Examples:**

- *Bayesian Ridge Regression*
- *Curve Fitting with Bayesian Ridge Regression*

Automatic Relevance Determination - ARD

ARDRegression is very similar to Bayesian Ridge Regression, but can lead to sparser coefficients $w^{12}$. ARDRegression poses a different prior over $w$, by dropping the assumption of the Gaussian being spherical. Instead, the distribution over $w$ is assumed to be an axis-parallel, elliptical Gaussian distribution.

This means each coefficient $w_i$ is drawn from a Gaussian distribution, centered on zero and with a precision $\lambda_i$:

$$p(w|\lambda) = \mathcal{N}(w|0, A^{-1})$$

with $\text{diag}(A) = \lambda = \{\lambda_1, ..., \lambda_p\}$.

In contrast to Bayesian Ridge Regression, each coordinate of $w_i$ has its own standard deviation $\lambda_i$. The prior over all $\lambda_i$ is chosen to be the same gamma distribution given by hyperparameters $\lambda_1$ and $\lambda_2$.

ARD is also known in the literature as Sparse Bayesian Learning and Relevance Vector Machine$^{14}$.

Examples:

- Automatic Relevance Determination Regression (ARD)

Logistic regression

Logistic regression, despite its name, is a linear model for classification rather than regression. Logistic regression is also known in the literature as logit regression, maximum-entropy classification (MaxEnt) or the log-linear classifier. In this model, the probabilities describing the possible outcomes of a single trial are modeled using a logistic function.

Logistic regression is implemented in `LogisticRegression`. This implementation can fit binary, One-vs-Rest, or multinomial logistic regression with optional $\ell_1$, $\ell_2$ or Elastic-Net regularization.

Note: Regularization is applied by default, which is common in machine learning but not in statistics. Another advantage of regularization is that it improves numerical stability. No regularization amounts to setting $C$ to a very high value.

As an optimization problem, binary class $\ell_2$ penalized logistic regression minimizes the following cost function:

$$
\min_{w,c} \frac{1}{2} w^T w + C \sum_{i=1}^{n} \log(\exp(-y_i(X_i^T w + c)) + 1).
$$

Similarly, $\ell_1$ regularized logistic regression solves the following optimization problem:

$$
\min_{w,c} \|w\|_1 + C \sum_{i=1}^{n} \log(\exp(-y_i(X_i^T w + c)) + 1).
$$

Elastic-Net regularization is a combination of $\ell_1$ and $\ell_2$, and minimizes the following cost function:

$$
\min_{w,c} \frac{1 - \rho}{2} w^T w + \rho \|w\|_1 + C \sum_{i=1}^{n} \log(\exp(-y_i(X_i^T w + c)) + 1),
$$

where $\rho$ controls the strength of $\ell_1$ regularization vs. $\ell_2$ regularization (it corresponds to the `l1_ratio` parameter).

Note that, in this notation, it’s assumed that the target $y_i$ takes values in the set $-1,1$ at trial $i$. We can also see that Elastic-Net is equivalent to $\ell_1$ when $\rho = 1$ and equivalent to $\ell_2$ when $\rho = 0$.

The solvers implemented in the class `LogisticRegression` are “liblinear”, “newton-cg”, “lbfgs”, “sag” and “saga”:

The solver “liblinear” uses a coordinate descent (CD) algorithm, and relies on the excellent C++ LIBLINEAR library, which is shipped with scikit-learn. However, the CD algorithm implemented in liblinear cannot learn a true multinomial (multiclass) model; instead, the optimization problem is decomposed in a “one-vs-rest” fashion so separate binary classifiers are trained for all classes. This happens under the hood, so `LogisticRegression` instances using this solver behave as multiclass classifiers. For $\ell_1$ regularization, `sklearn.svm.l1_min_c` allows to calculate the lower bound for $C$ in order to get a non “null” (all feature weights to zero) model.

The “lbfgs”, “sag” and “newton-cg” solvers only support $\ell_2$ regularization or no regularization, and are found to converge faster for some high-dimensional data. Setting `multi_class` to “multinomial” with these solvers learns a true multinomial logistic regression model\(^5\), which means that its probability estimates should be better calibrated than the default “one-vs-rest” setting.

\(^5\) Christopher M. Bishop: Pattern Recognition and Machine Learning, Chapter 4.3.4
The “sag” solver uses Stochastic Average Gradient descent\(^6\). It is faster than other solvers for large datasets, when both the number of samples and the number of features are large.

The “saga” solver\(^7\) is a variant of “sag” that also supports the non-smooth penalty="l1". This is therefore the solver of choice for sparse multinomial logistic regression. It is also the only solver that supports penalty="elasticnet".

The “lbfgs” is an optimization algorithm that approximates the Broyden–Fletcher–Goldfarb–Shanno algorithm\(^8\), which belongs to quasi-Newton methods. The “lbfgs” solver is recommended for use for small data-sets but for larger datasets its performance suffers.\(^9\)

The following table summarizes the penalties supported by each solver:

<table>
<thead>

</tbody>
</table>

The “lbfgs” solver is used by default for its robustness. For large datasets the “saga” solver is usually faster. For large dataset, you may also consider using \texttt{SGDClassifier} with ‘log’ loss, which might be even faster but requires more tuning.

### Examples:

- \texttt{L1 Penalty and Sparsity in Logistic Regression}
- \texttt{Regularization path of L1- Logistic Regression}
- \texttt{Plot multinomial and One-vs-Rest Logistic Regression}
- \texttt{Multiclass sparse logistic regression on 20newsgroups}
- \texttt{MNIST classification using multinomial logistic + L1}

### Differences from liblinear:

There might be a difference in the scores obtained between \texttt{LogisticRegression} with solver=liblinear or \texttt{LinearSVC} and the external liblinear library directly, when fit\_intercept=False and the fit coef\_ (or) the data to be predicted are zeroes. This is because for the sample(s) with decision\_function zero, \texttt{LogisticRegression} and \texttt{LinearSVC} predict the negative class, while liblinear predicts the positive class. Note that a model with fit\_intercept=False and having many samples with decision\_function zero,\(^6\) Mark Schmidt, Nicolas Le Roux, and Francis Bach: Minimizing Finite Sums with the Stochastic Average Gradient.\(^7\) Aaron Defazio, Francis Bach, Simon Lacoste-Julien: SAGA: A Fast Incremental Gradient Method With Support for Non-Strongly Convex Composite Objectives.\(^8\) https://en.wikipedia.org/wiki/Broyden%E2%80%93Fletcher%E2%80%93Goldfarb%E2%80%93Shanno_algorithm\(^9\) “Performance Evaluation of Lbfgs vs other solvers”
is likely to be a underfit, bad model and you are advised to set `fit_intercept=True` and increase the intercept_scaling.

**Note: Feature selection with sparse logistic regression**

A logistic regression with $\ell_1$ penalty yields sparse models, and can thus be used to perform feature selection, as detailed in *LI-based feature selection.*

**Note: P-value estimation**

It is possible to obtain the p-values and confidence intervals for coefficients in cases of regression without penalization. The `statsmodels` package <https://pypi.org/project/statsmodels/> natively supports this. Within sklearn, one could use bootstrapping instead as well.

`LogisticRegressionCV` implements Logistic Regression with built-in cross-validation support, to find the optimal $C$ and $\text{l1\_ratio}$ parameters according to the `scoring` attribute. The "newton-cg", "sag", "saga" and "lbfgs" solvers are found to be faster for high-dimensional dense data, due to warm-starting (see Glossary).

**References:**

**Generalized Linear Regression**

Generalized Linear Models (GLM) extend linear models in two ways$^{10}$. First, the predicted values $\hat{y}$ are linked to a linear combination of the input variables $X$ via an inverse link function $h$ as

$$\hat{y}(w, X) = h(Xw).$$

Secondly, the squared loss function is replaced by the unit deviance $d$ of a distribution in the exponential family (or more precisely, a reproductive exponential dispersion model (EDM)$^{11}$).

The minimization problem becomes:

$$\min_w \frac{1}{2n_{\text{samples}}} \sum_i d(y_i, \hat{y}_i) + \frac{\alpha}{2} ||w||_2,$$

where $\alpha$ is the L2 regularization penalty. When sample weights are provided, the average becomes a weighted average.

The following table lists some specific EDMs and their unit deviance (all of these are instances of the Tweedie family):

<table>
<thead>
<tr>
<th>Distribution</th>
<th>Target Domain</th>
<th>Unit Deviance $d(y, \hat{y})$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Normal</td>
<td>$y \in (-\infty, \infty)$</td>
<td>$(y - \hat{y})^2$</td>
</tr>
<tr>
<td>Poisson</td>
<td>$y \in [0, \infty)$</td>
<td>$2(y \log \frac{y}{\hat{y}} - y + \hat{y})$</td>
</tr>
<tr>
<td>Gamma</td>
<td>$y \in (0, \infty)$</td>
<td>$2[\log \frac{y}{\hat{y}} + \frac{\hat{y}}{y} - 1]$</td>
</tr>
<tr>
<td>Inverse Gaussian</td>
<td>$y \in (0, \infty)$</td>
<td>$\frac{(y-\hat{y})^2}{y^2}$</td>
</tr>
</tbody>
</table>

The Probability Density Functions (PDF) of these distributions are illustrated in the following figure,

---

Fig. 1: PDF of a random variable Y following Poisson, Tweedie (power=1.5) and Gamma distributions with different mean values ($\mu$). Observe the point mass at $Y = 0$ for the Poisson distribution and the Tweedie (power=1.5) distribution, but not for the Gamma distribution which has a strictly positive target domain.

The choice of the distribution depends on the problem at hand:

- If the target values $y$ are counts (non-negative integer valued) or relative frequencies (non-negative), you might use a Poisson deviance with log-link.
- If the target values are positive valued and skewed, you might try a Gamma deviance with log-link.
- If the target values seem to be heavier tailed than a Gamma distribution, you might try an Inverse Gaussian deviance (or even higher variance powers of the Tweedie family).

Examples of use cases include:

- Agriculture / weather modeling: number of rain events per year (Poisson), amount of rainfall per event (Gamma), total rainfall per year (Tweedie / Compound Poisson Gamma).
- Risk modeling / insurance policy pricing: number of claim events / policyholder per year (Poisson), cost per event (Gamma), total cost per policyholder per year (Tweedie / Compound Poisson Gamma).
- Predictive maintenance: number of production interruption events per year (Poisson), duration of interruption (Gamma), total interruption time per year (Tweedie / Compound Poisson Gamma).

References:

Usage

*TweedieRegressor* implements a generalized linear model for the Tweedie distribution, that allows to model any of the above mentioned distributions using the appropriate *power* parameter. In particular:

- *power* = 0: Normal distribution. Specific estimators such as *Ridge, ElasticNet* are generally more appropriate in this case.
- *power* = 1: Poisson distribution. *PoissonRegressor* is exposed for convenience. However, it is strictly equivalent to *TweedieRegressor* (*power*=1, *link*='log').
- *power* = 2: Gamma distribution. *GammaRegressor* is exposed for convenience. However, it is strictly equivalent to *TweedieRegressor* (*power*=2, *link*='log').
- *power* = 3: Inverse Gaussian distribution.
The link function is determined by the $\text{link}$ parameter.

Usage example:

```python
>>> from sklearn.linear_model import TweedieRegressor
>>> reg = TweedieRegressor(power=1, alpha=0.5, link='log')
>>> reg.fit([[0, 0], [0, 1], [2, 2]], [0, 1, 2])
TweedieRegressor(alpha=0.5, link='log', power=1)
>>> reg.coef_
array([0.2463..., 0.4337...])
>>> reg.intercept_
-0.7638...
```

Examples:
- Poisson regression and non-normal loss
- Tweedie regression on insurance claims

Practical considerations

The feature matrix $X$ should be standardized before fitting. This ensures that the penalty treats features equally.

Since the linear predictor $Xw$ can be negative and Poisson, Gamma and Inverse Gaussian distributions don’t support negative values, it is necessary to apply an inverse link function that guarantees the non-negativeness. For example with $\text{link}='\text{log}'$, the inverse link function becomes $h(Xw) = \exp(Xw)$.

If you want to model a relative frequency, i.e. counts per exposure (time, volume, ...) you can do so by using a Poisson distribution and passing $y = \frac{\text{counts}}{\text{exposure}}$ as target values together with exposure as sample weights. For a concrete example see e.g. Tweedie regression on insurance claims.

When performing cross-validation for the $\text{power}$ parameter of TweedieRegressor, it is advisable to specify an explicit scoring function, because the default scorer TweedieRegressor.score is a function of $\text{power}$ itself.

Stochastic Gradient Descent - SGD

Stochastic gradient descent is a simple yet very efficient approach to fit linear models. It is particularly useful when the number of samples (and the number of features) is very large. The partial_fit method allows online/out-of-core learning.

The classes SGDClassifier and SGDRegressor provide functionality to fit linear models for classification and regression using different (convex) loss functions and different penalties. E.g., with $\text{loss}='\text{log}'$, SGDClassifier fits a logistic regression model, while with $\text{loss}='\text{hinge}'$ it fits a linear support vector machine (SVM).

- Stochastic Gradient Descent
Perceptron

The *Perceptron* is another simple classification algorithm suitable for large scale learning. By default:

- It does not require a learning rate.
- It is not regularized (penalized).
- It updates its model only on mistakes.

The last characteristic implies that the Perceptron is slightly faster to train than SGD with the hinge loss and that the resulting models are sparser.

Passive Aggressive Algorithms

The passive-aggressive algorithms are a family of algorithms for large-scale learning. They are similar to the Perceptron in that they do not require a learning rate. However, contrary to the Perceptron, they include a regularization parameter $C$.

For classification, *PassiveAggressiveClassifier* can be used with loss='hinge' (PA-I) or loss='squared_hinge' (PA-II). For regression, *PassiveAggressiveRegressor* can be used with loss='epsilon_insensitive' (PA-I) or loss='squared_epsilon_insensitive' (PA-II).

Robustness regression: outliers and modeling errors

Robust regression aims to fit a regression model in the presence of corrupt data: either outliers, or error in the model.
Different scenario and useful concepts

There are different things to keep in mind when dealing with data corrupted by outliers:

- **Outliers in X or in y?**

  ![Outliers in X or in y](image)

- **Fraction of outliers versus amplitude of error**

  The number of outlying points matters, but also how much they are outliers.

  ![Small outliers vs Large outliers](image)

An important notion of robust fitting is that of breakdown point: the fraction of data that can be outlying for the fit to start missing the inlying data.

Note that in general, robust fitting in high-dimensional setting (large \( n_{\text{features}} \)) is very hard. The robust models here will probably not work in these settings.

**Trade-offs: which estimator?**

Scikit-learn provides 3 robust regression estimators: **RANSAC**, **Theil Sen**, and **HuberRegressor**.
**HuberRegressor** should be faster than **RANSAC** and **Theil Sen** unless the number of samples are very large, i.e \( n_{\text{samples}} \gg n_{\text{features}} \). This is because **RANSAC** and **Theil Sen** fit on smaller subsets of the data. However, both **Theil Sen** and **RANSAC** are unlikely to be as robust as **HuberRegressor** for the default parameters.

- **RANSAC** is faster than **Theil Sen** and scales much better with the number of samples.
- **RANSAC** will deal better with large outliers in the \( y \) direction (most common situation).
- **Theil Sen** will cope better with medium-size outliers in the \( X \) direction, but this property will disappear in high-dimensional settings.

When in doubt, use **RANSAC**.

**RANSAC: RANdom SAmple Consensus**

RANSAC (RANdom SAmple Consensus) fits a model from random subsets of inliers from the complete data set.

RANSAC is a non-deterministic algorithm producing only a reasonable result with a certain probability, which is dependent on the number of iterations (see `max_trials` parameter). It is typically used for linear and non-linear regression problems and is especially popular in the field of photogrammetric computer vision.

The algorithm splits the complete input sample data into a set of inliers, which may be subject to noise, and outliers, which are e.g. caused by erroneous measurements or invalid hypotheses about the data. The resulting model is then estimated only from the determined inliers.

![RANSAC Example](image)

**Details of the algorithm**

Each iteration performs the following steps:

1. Select `min_samples` random samples from the original data and check whether the set of data is valid (see `is_data_valid`).

2. Fit a model to the random subset (`base_estimator.fit`) and check whether the estimated model is valid (see `is_model_valid`).

3. Classify all data as inliers or outliers by calculating the residuals to the estimated model (`base_estimator.predict(X) - y`) - all data samples with absolute residuals smaller than the residual_threshold are considered as inliers.
4. Save fitted model as best model if number of inlier samples is maximal. In case the current estimated model has the same number of inliers, it is only considered as the best model if it has better score.

These steps are performed either a maximum number of times (max_trials) or until one of the special stop criteria are met (see stop_n_inliers and stop_score). The final model is estimated using all inlier samples (consensus set) of the previously determined best model.

The is_data_valid and is_model_valid functions allow to identify and reject degenerate combinations of random sub-samples. If the estimated model is not needed for identifying degenerate cases, is_data_valid should be used as it is called prior to fitting the model and thus leading to better computational performance.

**Examples:**

- Robust linear model estimation using RANSAC
- Robust linear estimator fitting

**References:**

**Theil-Sen estimator: generalized-median-based estimator**

The TheilSenRegressor estimator uses a generalization of the median in multiple dimensions. It is thus robust to multivariate outliers. Note however that the robustness of the estimator decreases quickly with the dimensionality of the problem. It loses its robustness properties and becomes no better than an ordinary least squares in high dimension.

**Examples:**

- Theil-Sen Regression
- Robust linear estimator fitting

**References:**

- [https://en.wikipedia.org/wiki/Theil%E2%80%93Sen_estimator](https://en.wikipedia.org/wiki/Theil%E2%80%93Sen_estimator)
Theoretical considerations

*TheilSenRegressor* is comparable to the *Ordinary Least Squares (OLS)* in terms of asymptotic efficiency and as an unbiased estimator. In contrast to OLS, Theil-Sen is a non-parametric method which means it makes no assumption about the underlying distribution of the data. Since Theil-Sen is a median-based estimator, it is more robust against corrupted data aka outliers. In univariate setting, Theil-Sen has a breakdown point of about 29.3% in case of a simple linear regression which means that it can tolerate arbitrary corrupted data of up to 29.3%.

The implementation of *TheilSenRegressor* in scikit-learn follows a generalization to a multivariate linear regression model\(^\text{12}\) using the spatial median which is a generalization of the median to multiple dimensions\(^\text{13}\).

In terms of time and space complexity, Theil-Sen scales according to

\[
\binom{n_{\text{samples}}}{n_{\text{subsamples}}}
\]

which makes it infeasible to be applied exhaustively to problems with a large number of samples and features. Therefore, the magnitude of a subpopulation can be chosen to limit the time and space complexity by considering only a random subset of all possible combinations.

Examples:

- *Theil-Sen Regression*

References:

\(^{12}\) Xin Dang, Hanxiang Peng, Xueqin Wang and Heping Zhang: *Theil-Sen Estimators in a Multiple Linear Regression Model.*

Huber Regression

The `HuberRegressor` is different to `Ridge` because it applies a linear loss to samples that are classified as outliers. A sample is classified as an inlier if the absolute error of that sample is lesser than a certain threshold. It differs from `TheilSenRegressor` and `RANSACRegressor` because it does not ignore the effect of the outliers but gives a lesser weight to them.

![Comparison of HuberRegressor vs Ridge](image)

The loss function that `HuberRegressor` minimizes is given by

$$
\min_{w, \sigma} \sum_{i=1}^{n} \left( \sigma + H_\epsilon \left( \frac{X_i w - y_i}{\sigma} \right) \sigma \right) + \alpha ||w||^2
$$

where

$$
H_\epsilon(z) = \begin{cases} 
  z^2, & \text{if } |z| < \epsilon, \\
  2\epsilon|z| - \epsilon^2, & \text{otherwise}
\end{cases}
$$

It is advised to set the parameter `epsilon` to 1.35 to achieve 95% statistical efficiency.

Notes

The `HuberRegressor` differs from using `SGDRegressor` with loss set to `huber` in the following ways.

- `HuberRegressor` is scaling invariant. Once `epsilon` is set, scaling `X` and `y` down or up by different values would produce the same robustness to outliers as before. as compared to `SGDRegressor` where `epsilon` has to be set again when `X` and `y` are scaled.

- `HuberRegressor` should be more efficient to use on data with small number of samples while `SGDRegressor` needs a number of passes on the training data to produce the same robustness.

Examples:

- `HuberRegressor` vs `Ridge` on dataset with strong outliers

References:

- Peter J. Huber, Elvezio M. Ronchetti: Robust Statistics, Concomitant scale estimates, pg 172
Note that this estimator is different from the R implementation of Robust Regression (http://www.ats.ucla.edu/stat/r/dae/rreg.htm) because the R implementation does a weighted least squares implementation with weights given to each sample on the basis of how much the residual is greater than a certain threshold.

**Polynomial regression: extending linear models with basis functions**

One common pattern within machine learning is to use linear models trained on nonlinear functions of the data. This approach maintains the generally fast performance of linear methods, while allowing them to fit a much wider range of data.

For example, a simple linear regression can be extended by constructing polynomial features from the coefficients. In the standard linear regression case, you might have a model that looks like this for two-dimensional data:

\[
\hat{y}(w, x) = w_0 + w_1 x_1 + w_2 x_2
\]

If we want to fit a paraboloid to the data instead of a plane, we can combine the features in second-order polynomials, so that the model looks like this:

\[
\hat{y}(w, x) = w_0 + w_1 x_1 + w_2 x_2 + w_3 x_1 x_2 + w_4 x_1^2 + w_5 x_2^2
\]

The (sometimes surprising) observation is that this is still a linear model: to see this, imagine creating a new set of features

\[
z = [x_1, x_2, x_1 x_2, x_1^2, x_2^2]
\]

With this re-labeling of the data, our problem can be written

\[
\hat{y}(w, z) = w_0 + w_1 z_1 + w_2 z_2 + w_3 z_3 + w_4 z_4 + w_5 z_5
\]

We see that the resulting polynomial regression is in the same class of linear models we considered above (i.e. the model is linear in \( w \)) and can be solved by the same techniques. By considering linear fits within a higher-dimensional space built with these basis functions, the model has the flexibility to fit a much broader range of data.

Here is an example of applying this idea to one-dimensional data, using polynomial features of varying degrees:

![Polynomial regression example](image)

This figure is created using the `PolynomialFeatures` transformer, which transforms an input data matrix into a new data matrix of a given degree. It can be used as follows:
>>> from sklearn.preprocessing import PolynomialFeatures
>>> import numpy as np

>>> X = np.arange(6).reshape(3, 2)
>>> X
array([[0, 1],
       [2, 3],
       [4, 5]])

>>> poly = PolynomialFeatures(degree=2)
>>> poly.fit_transform(X)
array([[ 1.,  0.,  1.,  0.,  0.,  1.],
       [ 1.,  2.,  3.,  4.,  6.,  9.],
       [ 1.,  4.,  5., 16., 20., 25.]])

The features of \( X \) have been transformed from \( [x_1, x_2] \) to \( [1, x_1, x_2, x_1^2, x_1x_2, x_2^2] \), and can now be used within any linear model.

This sort of preprocessing can be streamlined with the \textit{Pipeline} tools. A single object representing a simple polynomial regression can be created and used as follows:

```python
>>> from sklearn.preprocessing import PolynomialFeatures
>>> from sklearn.linear_model import LinearRegression
>>> from sklearn.pipeline import Pipeline
>>> import numpy as np

>>> model = Pipeline([('poly', PolynomialFeatures(degree=3)),
                    ('linear', LinearRegression(fit_intercept=False))])

>>> # fit to an order-3 polynomial data
>>> x = np.arange(5)
>>> y = 3 - 2 * x + x ** 2 - x ** 3
>>> model = model.fit(x[:, np.newaxis], y)
>>> model.named_steps['linear'].coef_
array([ 3., -2., 1., -1.])
```

The linear model trained on polynomial features is able to exactly recover the input polynomial coefficients.

In some cases it’s not necessary to include higher powers of any single feature, but only the so-called interaction features that multiply together at most \( d \) distinct features. These can be gotten from \textit{PolynomialFeatures} with the setting interaction_only=True.

For example, when dealing with boolean features, \( x_i^n = x_i \) for all \( n \) and is therefore useless; but \( x_ix_j \) represents the conjunction of two booleans. This way, we can solve the XOR problem with a linear classifier:

```python
>>> from sklearn.linear_model import Perceptron
>>> from sklearn.preprocessing import PolynomialFeatures

>>> X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]])
>>> y = X[:, 0] ^ X[:, 1]
>>> y
array([0, 1, 1, 0])

>>> X = PolynomialFeatures(interaction_only=True).fit_transform(X).astype(int)
>>> X
array([[1, 0, 0, 0],
       [1, 0, 1, 0],
       [1, 1, 0, 0],
       [1, 1, 1, 1]])

>>> clf = Perceptron(fit_intercept=False, max_iter=10, tol=None, ...
                   shuffle=False).fit(X, y)
```

And the classifier “predictions” are perfect:
4.1.2 Linear and Quadratic Discriminant Analysis

Linear Discriminant Analysis (LinearDiscriminantAnalysis) and Quadratic Discriminant Analysis (QuadraticDiscriminantAnalysis) are two classic classifiers, with, as their names suggest, a linear and a quadratic decision surface, respectively.

These classifiers are attractive because they have closed-form solutions that can be easily computed, are inherently multiclass, have proven to work well in practice, and have no hyperparameters to tune.

The plot shows decision boundaries for Linear Discriminant Analysis and Quadratic Discriminant Analysis. The bottom row demonstrates that Linear Discriminant Analysis can only learn linear boundaries, while Quadratic Discriminant Analysis can learn quadratic boundaries and is therefore more flexible.

Examples:
Linear and Quadratic Discriminant Analysis with covariance ellipsoid: Comparison of LDA and QDA on synthetic data.

Dimensionality reduction using Linear Discriminant Analysis

LinearDiscriminantAnalysis can be used to perform supervised dimensionality reduction, by projecting the input data to a linear subspace consisting of the directions which maximize the separation between classes (in a precise sense discussed in the mathematics section below). The dimension of the output is necessarily less than the number of classes, so this is in general a rather strong dimensionality reduction, and only makes sense in a multiclass setting.

This is implemented in the transform method. The desired dimensionality can be set using the n_components parameter. This parameter has no influence on the fit and predict methods.

Examples:

Comparison of LDA and PCA 2D projection of Iris dataset: Comparison of LDA and PCA for dimensionality reduction of the Iris dataset

Mathematical formulation of the LDA and QDA classifiers

Both LDA and QDA can be derived from simple probabilistic models which model the class conditional distribution of the data $P(X|y = k)$ for each class $k$. Predictions can then be obtained by using Bayes’ rule, for each training sample $x \in \mathbb{R}^d$:

$$P(y = k|x) = \frac{P(x|y = k)P(y = k)}{P(x)} = \frac{P(x|y = k)P(y = k)}{\sum_l P(x|y = l) \cdot P(y = l)}$$

and we select the class $k$ which maximizes this posterior probability.

More specifically, for linear and quadratic discriminant analysis, $P(x|y)$ is modeled as a multivariate Gaussian distribution with density:

$$P(x|y = k) = \frac{1}{(2\pi)^{d/2}|\Sigma_k|^{1/2}} \exp \left( -\frac{1}{2}(x - \mu_k)^T \Sigma_k^{-1}(x - \mu_k) \right)$$

where $d$ is the number of features.

QDA

According to the model above, the log of the posterior is:

$$\log P(y = k|x) = \log P(x|y = k) + \log P(y = k) + Cst$$

$$= -\frac{1}{2} \log |\Sigma_k| - \frac{1}{2}(x - \mu_k)^T \Sigma_k^{-1}(x - \mu_k) + \log P(y = k) + Cst,$$

where the constant term $Cst$ corresponds to the denominator $P(x)$, in addition to other constant terms from the Gaussian. The predicted class is the one that maximises this log-posterior.

Note: Relation with Gaussian Naive Bayes

If in the QDA model one assumes that the covariance matrices are diagonal, then the inputs are assumed to be conditionally independent in each class, and the resulting classifier is equivalent to the Gaussian Naive Bayes classifier naive_bayes.GaussianNB.
LDA

LDA is a special case of QDA, where the Gaussians for each class are assumed to share the same covariance matrix: \( \Sigma_k = \Sigma \) for all \( k \). This reduces the log posterior to:

\[
\log P(y = k|x) = -\frac{1}{2}(x - \mu_k)^T \Sigma^{-1}(x - \mu_k) + \log P(y = k) + Cst.
\]

The term \((x - \mu_k)^T \Sigma^{-1}(x - \mu_k)\) corresponds to the Mahalanobis Distance between the sample \( x \) and the mean \( \mu_k \). The Mahalanobis distance tells how close \( x \) is from \( \mu_k \), while also accounting for the variance of each feature. We can thus interpret LDA as assigning \( x \) to the class whose mean is the closest in terms of Mahalanobis distance, while also accounting for the class prior probabilities.

The log-posterior of LDA can also be written\(^3\) as:

\[
\log P(y = k|x) = \omega_k x + \omega_{k0} + Cst.
\]

where \( \omega_k = \Sigma^{-1} \mu_k \) and \( \omega_{k0} = -\frac{1}{2} \mu_k^T \Sigma^{-1} \mu_k + \log P(y = k) \). These quantities correspond to the coef_ and intercept_ attributes, respectively.

From the above formula, it is clear that LDA has a linear decision surface. In the case of QDA, there are no assumptions on the covariance matrices \( \Sigma_k \) of the Gaussians, leading to quadratic decision surfaces. See\(^1\) for more details.

**Mathematical formulation of LDA dimensionality reduction**

First note that the K means \( \mu_k \) are vectors in \( \mathbb{R}^d \), and they lie in an affine subspace \( H \) of dimension at least \( K - 1 \) (2 points lie on a line, 3 points lie on a plane, etc).

As mentioned above, we can interpret LDA as assigning \( x \) to the class whose mean \( \mu_k \) is the closest in terms of Mahalanobis distance, while also accounting for the class prior probabilities. Alternatively, LDA is equivalent to first sphering the data so that the covariance matrix is the identity, and then assigning \( x \) to the closest mean in terms of Euclidean distance (still accounting for the class priors).

Computing Euclidean distances in this d-dimensional space is equivalent to first projecting the data points into \( H \), and computing the distances there (since the other dimensions will contribute equally to each class in terms of distance).

In other words, if \( x \) is closest to \( \mu_k \) in the original space, it will also be the case in \( H \). This shows that, implicit in the LDA classifier, there is a dimensionality reduction by linear projection onto a \( K - 1 \) dimensional space.

We can reduce the dimension even more, to a chosen \( L \), by projecting onto the linear subspace \( H_L \) which maximizes the variance of the \( \mu_k \) after projection (in effect, we are doing a form of PCA for the transformed class means \( \mu_k^* \)). This \( L \) corresponds to the n_components parameter used in the transform method. See\(^1\) for more details.

**Shrinkage and Covariance Estimator**

Shrinkage is a form of regularization used to improve the estimation of covariance matrices in situations where the number of training samples is small compared to the number of features. In this scenario, the empirical sample covariance is a poor estimator, and shrinkage helps improving the generalization performance of the classifier. Shrinkage LDA can be used by setting the shrinkage parameter of the LinearDiscriminantAnalysis class to ‘auto’. This automatically determines the optimal shrinkage parameter in an analytic way following the lemma introduced by Ledoit and Wolf\(^2\). Note that currently shrinkage only works when setting the solver parameter to ‘lsqr’ or ‘eigen’.

The shrinkage parameter can also be manually set between 0 and 1. In particular, a value of 0 corresponds to no shrinkage (which means the empirical covariance matrix will be used) and a value of 1 corresponds to complete

---

\(^3\) R. O. Duda, P. E. Hart, D. G. Stork. Pattern Classification (Second Edition), section 2.6.2.

shrinkage (which means that the diagonal matrix of variances will be used as an estimate for the covariance matrix). Setting this parameter to a value between these two extrema will estimate a shrunk version of the covariance matrix.

The shrunk Ledoit and Wolf estimator of covariance may not always be the best choice. For example if the distribution of the data is normally distributed, the Oracle Shrinking Approximating estimator `sklearn.covariance. OAS` yields a smaller Mean Squared Error than the one given by Ledoit and Wolf’s formula used with shrinkage="auto". In LDA, the data are assumed to be gaussian conditionally to the class. If these assumptions hold, using LDA with the OAS estimator of covariance will yield a better classification accuracy than if Ledoit and Wolf or the empirical covariance estimator is used.

The covariance estimator can be chosen using with the covariance_estimator parameter of the `discriminant_analysis.LinearDiscriminantAnalysis` class. A covariance estimator should have a fit method and a covariance_attribute like all covariance estimators in the `sklearn.covariance` module.

![Linear Discriminant Analysis vs. Shrinkage Linear Discriminant Analysis vs. OAS Linear Discriminant Analysis (1 discriminative feature)](image)

Examples:

*Normal, Ledoit-Wolf and OAS Linear Discriminant Analysis for classification*: Comparison of LDA classifiers with Empirical, Ledoit Wolf and OAS covariance estimator.

**Estimation algorithms**

Using LDA and QDA requires computing the log-posterior which depends on the class priors $P(y = k)$, the class means $\mu_k$, and the covariance matrices.

The ‘svd’ solver is the default solver used for `LinearDiscriminantAnalysis`, and it is the only available solver for `QuadraticDiscriminantAnalysis`. It can perform both classification and transform (for LDA). As it does not rely on the calculation of the covariance matrix, the ‘svd’ solver may be preferable in situations where the number of features is large. The ‘svd’ solver cannot be used with shrinkage. For QDA, the use of the SVD solver relies on the fact that the covariance matrix $\Sigma_k$ is, by definition, equal to $\frac{1}{n-1} X_k^T X_k = V S^2 V^T$ where $V$ comes from the SVD of the (centered) matrix: $X_k = U S V^T$. It turns out that we can compute the log-posterior above without having to
explicitly compute $\Sigma$: computing $S$ and $V$ via the SVD of $X$ is enough. For LDA, two SVDs are computed: the SVD of the centered input matrix $X$ and the SVD of the class-wise mean vectors.

The ‘lsqr’ solver is an efficient algorithm that only works for classification. It needs to explicitly compute the covariance matrix $\Sigma$, and supports shrinkage and custom covariance estimators. This solver computes the coefficients $\omega_k = \Sigma^{-1}\mu_k$ by solving for $\Sigma \omega = \mu_k$, thus avoiding the explicit computation of the inverse $\Sigma^{-1}$.

The ‘eigen’ solver is based on the optimization of the between class scatter to within class scatter ratio. It can be used for both classification and transform, and it supports shrinkage. However, the ‘eigen’ solver needs to compute the covariance matrix, so it might not be suitable for situations with a high number of features.

References:

4.1.3 Kernel ridge regression

Kernel ridge regression (KRR) [M2012] combines Ridge regression and classification (linear least squares with l2-norm regularization) with the kernel trick. It thus learns a linear function in the space induced by the respective kernel and the data. For non-linear kernels, this corresponds to a non-linear function in the original space.

The form of the model learned by KernelRidge is identical to support vector regression (SVR). However, different loss functions are used: KRR uses squared error loss while support vector regression uses $\epsilon$-insensitive loss, both combined with l2 regularization. In contrast to SVR, fitting KernelRidge can be done in closed-form and is typically faster for medium-sized datasets. On the other hand, the learned model is non-sparse and thus slower than SVR, which learns a sparse model for $\epsilon > 0$, at prediction-time.

The following figure compares KernelRidge and SVR on an artificial dataset, which consists of a sinusoidal target function and strong noise added to every fifth datapoint. The learned model of KernelRidge and SVR is plotted, where both complexity/regularization and bandwidth of the RBF kernel have been optimized using grid-search. The learned functions are very similar; however, fitting KernelRidge is approximately seven times faster than fitting SVR (both with grid-search). However, prediction of 100000 target values is more than three times faster with SVR since it has learned a sparse model using only approximately 1/3 of the 100 training datapoints as support vectors.

The next figure compares the time for fitting and prediction of KernelRidge and SVR for different sizes of the training set. Fitting KernelRidge is faster than SVR for medium-sized training sets (less than 1000 samples); however, for larger training sets SVR scales better. With regard to prediction time, SVR is faster than KernelRidge for all sizes of the training set because of the learned sparse solution. Note that the degree of sparsity and thus the prediction time depends on the parameters $\epsilon$ and $C$ of the SVR; $\epsilon = 0$ would correspond to a dense model.

References:

4.1.4 Support Vector Machines

Support vector machines (SVMs) are a set of supervised learning methods used for classification, regression and outliers detection.

The advantages of support vector machines are:

- Effective in high dimensional spaces.
- Still effective in cases where number of dimensions is greater than the number of samples.
- Uses a subset of training points in the decision function (called support vectors), so it is also memory efficient.
• Versatile: different *Kernel functions* can be specified for the decision function. Common kernels are provided, but it is also possible to specify custom kernels.

The disadvantages of support vector machines include:

• If the number of features is much greater than the number of samples, avoid over-fitting in choosing *Kernel functions* and regularization term is crucial.

• SVMs do not directly provide probability estimates, these are calculated using an expensive five-fold cross-validation (see *Scores and probabilities*, below).

The support vector machines in scikit-learn support both dense (*numpy.ndarray* and convertible to that by *numpy.asarray*) and sparse (any *scipy.sparse*) sample vectors as input. However, to use an SVM to make predictions for sparse data, it must have been fit on such data. For optimal performance, use C-ordered *numpy.ndarray* (dense) or *scipy.sparse.csr_matrix* (sparse) with *dtype=float64*.

**Classification**

*SVC, NuSVC* and *LinearSVC* are classes capable of performing binary and multi-class classification on a dataset.

*SVC* and *NuSVC* are similar methods, but accept slightly different sets of parameters and have different mathematical formulations (see section *Mathematical formulation*). On the other hand, *LinearSVC* is another (faster) implementation of Support Vector Classification for the case of a linear kernel. Note that *LinearSVC* does not accept parameter *kernel*, as this is assumed to be linear. It also lacks some of the attributes of *SVC* and *NuSVC*, like *support_*.
As other classifiers, `SVC`, `NuSVC` and `LinearSVC` take as input two arrays: an array `X` of shape `(n_samples, n_features)` holding the training samples, and an array `y` of class labels (strings or integers), of shape `(n_samples)`:

```python
>>> from sklearn import svm
>>> X = [[0, 0], [1, 1]]
>>> y = [0, 1]
>>> clf = svm.SVC()
>>> clf.fit(X, y)
SVC()
```

After being fitted, the model can then be used to predict new values:

```python
>>> clf.predict([[2., 2.]])
array([1])
```

SVMs decision function (detailed in the `Mathematical formulation`) depends on some subset of the training data, called the support vectors. Some properties of these support vectors can be found in attributes `support_vectors_`, `support_` and `n_support_`:

```python
>>> # get support vectors
>>> clf.support_vectors_
array([[0., 0.],
       [1., 1.]])
>>> # get indices of support vectors
>>> clf.support_
array([0, 1]...)
>>> # get number of support vectors for each class
>>> clf.n_support_
array([1, 1]...)
```

Examples:

- SVM: Maximum margin separating hyperplane,
- Non-linear SVM
- SVM-Anova: SVM with univariate feature selection,

Multi-class classification

`SVC` and `NuSVC` implement the “one-versus-one” approach for multi-class classification. In total, `n_classes * (n_classes - 1) / 2` classifiers are constructed and each one trains data from two classes. To provide a consistent interface with other classifiers, the `decision_function_shape` option allows to monotonically transform the results of the “one-versus-one” classifiers to a “one-vs-rest” decision function of shape `(n_samples, n_classes)`.

```python
>>> X = [[0], [1], [2], [3]]
>>> Y = [0, 1, 2, 3]
>>> clf = svm.SVC(decision_function_shape='ovo')
>>> clf.fit(X, Y)
SVC(decision_function_shape='ovo')
>>> dec = clf.decision_function([[1]])
>>> dec.shape[1] # 4 classes: 4*3/2 = 6
```
On the other hand, `LinearSVC` implements “one-vs-the-rest” multi-class strategy, thus training `n_classes` models.

```python
>>> lin_clf = svm.LinearSVC()
>>> lin_clf.fit(X, Y)
LinearSVC()
>>> dec = lin_clf.decision_function([[1]])
>>> dec.shape[1]
# 4 classes
4
```

See [Mathematical formulation](#) for a complete description of the decision function.

Note that the `LinearSVC` also implements an alternative multi-class strategy, the so-called multi-class SVM formulated by Crammer and Singer\(^\text{16}\), by using the option `multi_class='crammer_singer'`. In practice, one-vs-rest classification is usually preferred, since the results are mostly similar, but the runtime is significantly less.

For “one-vs-rest” `LinearSVC` the attributes `coef_` and `intercept_` have the shape `(n_classes, n_features)` and `(n_classes,)` respectively. Each row of the coefficients corresponds to one of the `n_classes` “one-vs-rest” classifiers and similar for the intercepts, in the order of the “one” class.

In the case of “one-vs-one” `SVC` and `NuSVC`, the layout of the attributes is a little more involved. In the case of a linear kernel, the attributes `coef_` and `intercept_` have the shape `(n_classes * (n_classes - 1) / 2, n_features)` and `(n_classes * (n_classes - 1) / 2)` respectively. This is similar to the layout for `LinearSVC` described above, with each row now corresponding to a binary classifier. The order for classes 0 to `n` is “0 vs 1”, “0 vs 2”, … “0 vs `n`”, “1 vs 2”, “1 vs 3”, “1 vs `n`”, … “`n-1` vs `n`”.

The shape of `dual_coef_` is `(n_classes-1, n_SV)` with a somewhat hard to grasp layout. The columns correspond to the support vectors involved in any of the `n_classes * (n_classes - 1) / 2` “one-vs-one” classifiers. Each of the support vectors is used in `n_classes - 1` classifiers. The `n_classes - 1` entries in each row correspond to the dual coefficients for these classifiers.

This might be clearer with an example: consider a three class problem with class 0 having three support vectors \(v_0^0, v_0^1, v_0^2\) and class 1 and 2 having two support vectors \(v_1^0, v_1^1\) and \(v_2^0, v_2^1\) respectively. For each support vector \(v_i^j\), there are two dual coefficients. Let’s call the coefficient of support vector \(v_i^j\) in the classifier between classes \(i\) and \(k\) \(\alpha_{i,k}^j\). Then `dual_coef_` looks like this:

<table>
<thead>
<tr>
<th>(\alpha_{0,1}^0)</th>
<th>(\alpha_{0,2}^0)</th>
<th>Coefficients for SVs of class 0</th>
</tr>
</thead>
<tbody>
<tr>
<td>(\alpha_{0,1}^1)</td>
<td>(\alpha_{0,2}^1)</td>
<td>(\alpha_{0,1}^2)</td>
</tr>
<tr>
<td>(\alpha_{1,0}^0)</td>
<td>(\alpha_{1,2}^0)</td>
<td>Coefficients for SVs of class 1</td>
</tr>
<tr>
<td>(\alpha_{1,0}^1)</td>
<td>(\alpha_{1,2}^1)</td>
<td></td>
</tr>
<tr>
<td>(\alpha_{2,0}^0)</td>
<td>(\alpha_{2,1}^0)</td>
<td>Coefficients for SVs of class 2</td>
</tr>
<tr>
<td>(\alpha_{2,0}^1)</td>
<td>(\alpha_{2,1}^1)</td>
<td></td>
</tr>
</tbody>
</table>

**Examples:**

- *Plot different SVM classifiers in the iris dataset*,

Scores and probabilities

The `decision_function` method of `SVC` and `NuSVC` gives per-class scores for each sample (or a single score per sample in the binary case). When the constructor option `probability` is set to `True`, class membership probability estimates (from the methods `predict_proba` and `predict_log_proba`) are enabled. In the binary case, the probabilities are calibrated using Platt scaling\(^9\): logistic regression on the SVM’s scores, fit by an additional cross-validation on the training data. In the multiclass case, this is extended as per\(^10\).

Note: The same probability calibration procedure is available for all estimators via the `CalibratedClassifierCV` (see Probability calibration). In the case of `SVC` and `NuSVC`, this procedure is built-in in `libsvm` which is used under the hood, so it does not rely on scikit-learn’s `CalibratedClassifierCV`.

The cross-validation involved in Platt scaling is an expensive operation for large datasets. In addition, the probability estimates may be inconsistent with the scores:

- the “argmax” of the scores may not be the argmax of the probabilities
- in binary classification, a sample may be labeled by `predict` as belonging to the positive class even if the output of `predict_proba` is less than 0.5; and similarly, it could be labeled as negative even if the output of `predict_proba` is more than 0.5.

Platt’s method is also known to have theoretical issues. If confidence scores are required, but these do not have to be probabilities, then it is advisable to set `probability=False` and use `decision_function` instead of `predict_proba`.

Please note that when `decision_function_shape='ovr'` and `n_classes > 2`, unlike `decision_function`, the `predict` method does not try to break ties by default. You can set `break_ties=True` for the output of `predict` to be the same as `np.argmax(clf.decision_function(. . .), axis=1)`, otherwise the first class among the tied classes will always be returned; but have in mind that it comes with a computational cost. See SVM Tie Breaking Example for an example on tie breaking.

Unbalanced problems

In problems where it is desired to give more importance to certain classes or certain individual samples, the parameters `class_weight` and `sample_weight` can be used.

`SVC` (but not `NuSVC`) implements the parameter `class_weight` in the `fit` method. It’s a dictionary of the form `{class_label : value}`, where `value` is a floating point number > 0 that sets the parameter `C` of class `class_label` to `C \times value`. The figure below illustrates the decision boundary of an unbalanced problem, with and without weight correction.

`SVC`, `NuSVC`, `SVR`, `NuSVR`, `LinearSVC`, `LinearSVR` and `OneClassSVM` implement also weights for individual samples in the `fit` method through the `sample_weight` parameter. Similar to `class_weight`, this sets the parameter `C` for the i-th example to `C \times sample_weight[i]`, which will encourage the classifier to get these samples right. The figure below illustrates the effect of sample weighting on the decision boundary. The size of the circles is proportional to the sample weights:

Examples:

- SVM: Separating hyperplane for unbalanced classes
- SVM: Weighted samples

4.1. Supervised learning
Regression

The method of Support Vector Classification can be extended to solve regression problems. This method is called Support Vector Regression.

The model produced by support vector classification (as described above) depends only on a subset of the training data, because the cost function for building the model does not care about training points that lie beyond the margin. Analogously, the model produced by Support Vector Regression depends only on a subset of the training data, because the cost function ignores samples whose prediction is close to their target.

There are three different implementations of Support Vector Regression: SVR, NuSVR and LinearSVR. LinearSVR provides a faster implementation than SVR but only considers the linear kernel, while NuSVR implements a slightly different formulation than SVR and LinearSVR. See Implementation details for further details.

As with classification classes, the fit method will take as argument vectors X, y, only that in this case y is expected to have floating point values instead of integer values:

```python
>>> from sklearn import svm
>>> X = [[0, 0], [2, 2]]
>>> y = [0.5, 2.5]
>>> regr = svm.SVR()
>>> regr.fit(X, y)
SVR()
>>> regr.predict([[1, 1]])
array([1.5])
```

Examples:

- Support Vector Regression (SVR) using linear and non-linear kernels

Density estimation, novelty detection

The class OneClassSVM implements a One-Class SVM which is used in outlier detection.

See Novelty and Outlier Detection for the description and usage of OneClassSVM.

Complexity

Support Vector Machines are powerful tools, but their compute and storage requirements increase rapidly with the number of training vectors. The core of an SVM is a quadratic programming problem (QP), separating support vectors from the rest of the training data. The QP solver used by the libsvm-based implementation scales between $O(n_{\text{features}} \times n_{\text{samples}}^2)$ and $O(n_{\text{features}} \times n_{\text{samples}}^3)$ depending on how efficiently the libsvm cache is used in practice (dataset dependent). If the data is very sparse $n_{\text{features}}$ should be replaced by the average number of non-zero features in a sample vector.

For the linear case, the algorithm used in LinearSVC by the liblinear implementation is much more efficient than its libsvm-based SVC counterpart and can scale almost linearly to millions of samples and/or features.
Tips on Practical Use

• **Avoiding data copy**  For SVC, SVR, NuSVC and NuSVR, if the data passed to certain methods is not C-ordered contiguous and double precision, it will be copied before calling the underlying C implementation. You can check whether a given numpy array is C-contiguous by inspecting its flags attribute.

For LinearSVC (and LogisticRegression) any input passed as a numpy array will be copied and converted to the liblinear internal sparse data representation (double precision floats and int32 indices of non-zero components). If you want to fit a large-scale linear classifier without copying a dense numpy C-contiguous double precision array as input, we suggest to use the SGDClassifier class instead. The objective function can be configured to be almost the same as the LinearSVC model.

• **Kernel cache size**: For SVC, SVR, NuSVC and NuSVR, the size of the kernel cache has a strong impact on run times for larger problems. If you have enough RAM available, it is recommended to set cache_size to a higher value than the default of 200(MB), such as 500(MB) or 1000(MB).

• **Setting C**: C is 1 by default and it’s a reasonable default choice. If you have a lot of noisy observations you should decrease it: decreasing C corresponds to more regularization.

LinearSVC and LinearSVR are less sensitive to C when it becomes large, and prediction results stop improving after a certain threshold. Meanwhile, larger C values will take more time to train, sometimes up to 10 times longer, as shown in 11.

• Support Vector Machine algorithms are not scale invariant, so it is highly recommended to scale your data. For example, scale each attribute on the input vector X to [0,1] or [-1,+1], or standardize it to have mean 0 and variance 1. Note that the same scaling must be applied to the test vector to obtain meaningful results. This can be done easily by using a Pipeline:

```python
>>> from sklearn.pipeline import make_pipeline
>>> from sklearn.preprocessing import StandardScaler
>>> from sklearn.svm import SVC

>>> clf = make_pipeline(StandardScaler(), SVC())
```

See section Preprocessing data for more details on scaling and normalization.

• Regarding the shrinking parameter, quoting 12: We found that if the number of iterations is large, then shrinking can shorten the training time. However, if we loosely solve the optimization problem (e.g., by using a large stopping tolerance), the code without using shrinking may be much faster.

• Parameter nu in NuSVC/OneClassSVM/NuSVR approximates the fraction of training errors and support vectors.

• In SVC, if the data is unbalanced (e.g. many positive and few negative), set class_weight='balanced' and/or try different penalty parameters C.

• **Randomness of the underlying implementations**: The underlying implementations of SVC and NuSVC use a random number generator only to shuffle the data for probability estimation (when probability is set to True). This randomness can be controlled with the random_state parameter. If probability is set to False these estimators are not random and random_state has no effect on the results. The underlying OneClassSVM implementation is similar to the ones of SVC and NuSVC. As no probability estimation is provided for OneClassSVM, it is not random.

The underlying LinearSVC implementation uses a random number generator to select features when fitting the model with a dual coordinate descent (i.e when dual is set to True). It is thus

---

12 Chang and Lin, LIBSVM: A Library for Support Vector Machines.
not uncommon to have slightly different results for the same input data. If that happens, try with a smaller \texttt{tol} parameter. This randomness can also be controlled with the \texttt{random_state} parameter. When \texttt{dual} is set to \texttt{False} the underlying implementation of \texttt{LinearSVC} is not random and \texttt{random_state} has no effect on the results.

- Using L1 penalization as provided by \texttt{LinearSVC(penalty='l1', dual=False)} yields a sparse solution, i.e. only a subset of feature weights is different from zero and contribute to the decision function. Increasing \texttt{C} yields a more complex model (more features are selected). The \texttt{C} value that yields a “null” model (all weights equal to zero) can be calculated using \texttt{l1_min_c}.

### Kernel functions

The \textit{kernel function} can be any of the following:

- linear: $\langle x, x' \rangle$.
- polynomial: $(\gamma \langle x, x' \rangle + r)^d$, where $d$ is specified by parameter \texttt{degree}, $r$ by \texttt{coef0}.
- rbf: $\exp(-\gamma \|x - x'\|^2)$, where $\gamma$ is specified by parameter \texttt{gamma}, must be greater than 0.
- sigmoid $\tanh(\gamma \langle x, x' \rangle + r)$, where $r$ is specified by \texttt{coef0}.

Different kernels are specified by the \texttt{kernel} parameter:

```python
>>> linear_svc = svm.SVC(kernel='linear')
>>> linear_svc.kernel
'linear'
>>> rbf_svc = svm.SVC(kernel='rbf')
>>> rbf_svc.kernel
'rbf'
```

### Parameters of the RBF Kernel

When training an SVM with the \textit{Radial Basis Function} (RBF) kernel, two parameters must be considered: \texttt{C} and \texttt{gamma}. The parameter \texttt{C}, common to all SVM kernels, trades off misclassification of training examples against simplicity of the decision surface. A low \texttt{C} makes the decision surface smooth, while a high \texttt{C} aims at classifying all training examples correctly. \texttt{gamma} defines how much influence a single training example has. The larger \texttt{gamma} is, the closer other examples must be to be affected.

Proper choice of \texttt{C} and \texttt{gamma} is critical to the SVM’s performance. One is advised to use \texttt{GridSearchCV} with \texttt{C} and \texttt{gamma} spaced exponentially far apart to choose good values.

### Examples:

- \textit{RBF SVM parameters}
- \textit{Non-linear SVM}
Custom Kernels

You can define your own kernels by either giving the kernel as a python function or by precomputing the Gram matrix. Classifiers with custom kernels behave the same way as any other classifiers, except that:

- Field `support_vectors_` is now empty, only indices of support vectors are stored in `support_`
- A reference (and not a copy) of the first argument in the `fit()` method is stored for future reference. If that array changes between the use of `fit()` and `predict()` you will have unexpected results.

Using Python functions as kernels

You can use your own defined kernels by passing a function to the `kernel` parameter.

Your kernel must take as arguments two matrices of shape `(n_samples_1, n_features), (n_samples_2, n_features)` and return a kernel matrix of shape `(n_samples_1, n_samples_2)`.

The following code defines a linear kernel and creates a classifier instance that will use that kernel:

```python
>>> import numpy as np
>>> from sklearn import svm
>>> def my_kernel(X, Y):
...     return np.dot(X, Y.T)
...
>>> clf = svm.SVC(kernel=my_kernel)
```

Examples:

- SVM with custom kernel.

Using the Gram matrix

You can pass pre-computed kernels by using the `kernel='precomputed'` option. You should then pass Gram matrix instead of `X` to the `fit` and `predict` methods. The kernel values between all training vectors and the test vectors must be provided:

```python
>>> import numpy as np
>>> from sklearn.datasets import make_classification
>>> from sklearn.model_selection import train_test_split
>>> from sklearn import svm

>>> X, y = make_classification(n_samples=10, random_state=0)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)

>>> clf = svm.SVC(kernel='precomputed')

>>> # linear kernel computation
>>> gram_train = np.dot(X_train, X_train.T)
>>> clf.fit(gram_train, y_train)
SVC(kernel='precomputed')

>>> # predict on training examples
>>> gram_test = np.dot(X_test, X_train.T)
>>> clf.predict(gram_test)
array([0, 1, 0])
```
Mathematical formulation

A support vector machine constructs a hyper-plane or set of hyper-planes in a high or infinite dimensional space, which can be used for classification, regression or other tasks. Intuitively, a good separation is achieved by the hyper-plane that has the largest distance to the nearest training data points of any class (so-called functional margin), since in general the larger the margin the lower the generalization error of the classifier. The figure below shows the decision function for a linearly separable problem, with three samples on the margin boundaries, called “support vectors”:

In general, when the problem isn’t linearly separable, the support vectors are the samples within the margin boundaries. We recommend\textsuperscript{13} and\textsuperscript{14} as good references for the theory and practicalities of SVMs.

SVC

Given training vectors \( x_i \in \mathbb{R}^p, i=1,\ldots, n \), in two classes, and a vector \( y \in \{1, -1\}^n \), our goal is to find \( w \in \mathbb{R}^p \) and \( b \in \mathbb{R} \) such that the prediction given by \( \text{sign}(w^T \phi(x) + b) \) is correct for most samples.

SVC solves the following primal problem:

\[
\begin{align*}
\min_{w,b,\zeta} & \quad \frac{1}{2} w^T w + C \sum_{i=1}^{n} \zeta_i \\
\text{subject to} & \quad y_i (w^T \phi(x_i) + b) \geq 1 - \zeta_i, \\
& \quad \zeta_i \geq 0, \quad i = 1, \ldots, n
\end{align*}
\]

Intuitively, we’re trying to maximize the margin (by minimizing \( \|w\|^2 = w^T w \)), while incurring a penalty when a sample is misclassified or within the margin boundary. Ideally, the value \( y_i (w^T \phi(x_i) + b) \) would be \( \geq 1 \) for all samples, which indicates a perfect prediction. But problems are usually not always perfectly separable with a hyperplane, so we

\textsuperscript{13} Bishop, Pattern recognition and machine learning, chapter 7 Sparse Kernel Machines
allow some samples to be at a distance $\zeta_i$ from their correct margin boundary. The penalty term $C$ controls the strength of this penalty, and as a result, acts as an inverse regularization parameter (see note below).

The dual problem to the primal is

$$
\min_{\alpha} \frac{1}{2} \alpha^T Q \alpha - e^T \alpha
$$

subject to $y_i^T \alpha = 0$

$$
0 \leq \alpha_i \leq C, i = 1, ..., n
$$

where $e$ is the vector of all ones, and $Q$ is an $n$ by $n$ positive semidefinite matrix, $Q_{ij} = y_i y_j K(x_i, x_j)$, where $K(x_i, x_j) = \phi(x_i)^T \phi(x_j)$ is the kernel. The terms $\alpha_i$ are called the dual coefficients, and they are upper-bounded by $C$. This dual representation highlights the fact that training vectors are implicitly mapped into a higher (maybe infinite) dimensional space by the function $\phi$: see kernel trick.

Once the optimization problem is solved, the output of `decision_function` for a given sample $x$ becomes:

$$
\sum_{i \in SV} y_i \alpha_i K(x_i, x) + b,
$$

and the predicted class correspond to its sign. We only need to sum over the support vectors (i.e. the samples that lie within the margin) because the dual coefficients $\alpha_i$ are zero for the other samples.

These parameters can be accessed through the attributes `dual_coef_` which holds the product $y_i \alpha_i$, `support_vectors_` which holds the support vectors, and `intercept_` which holds the independent term $b$

Note: While SVM models derived from `libsvm` and `liblinear` use $C$ as regularization parameter, most other estimators use alpha. The exact equivalence between the amount of regularization of two models depends on the exact objective function optimized by the model. For example, when the estimator used is `Ridge` regression, the relation between them is given as $C = \frac{1}{\alpha \text{rho}}$.

---

**LinearSVC**

The primal problem can be equivalently formulated as

$$
\min_{w, b} \frac{1}{2} w^T w + C \sum_{i=1} \max(0, y_i (w^T \phi(x_i) + b)),
$$

where we make use of the hinge loss. This is the form that is directly optimized by `LinearSVC`, but unlike the dual form, this one does not involve inner products between samples, so the famous kernel trick cannot be applied. This is why only the linear kernel is supported by `LinearSVC` ($\phi$ is the identity function).

**NuSVC**

The $\nu$-SVC formulation is a reparameterization of the $C$-SVC and therefore mathematically equivalent.

We introduce a new parameter $\nu$ (instead of $C$) which controls the number of support vectors and margin errors: $\nu \in (0, 1]$ is an upper bound on the fraction of margin errors and a lower bound of the fraction of support vectors. A margin error corresponds to a sample that lies on the wrong side of its margin boundary: it is either misclassified, or it is correctly classified but does not lie beyond the margin.

---

15 Schölkopf et. al New Support Vector Algorithms
SVR

Given training vectors \( x_i \in \mathbb{R}^p \), \( i = 1, \ldots, n \), and a vector \( y \in \mathbb{R}^n \), \( \varepsilon \)-SVR solves the following primal problem:

\[
\begin{align*}
\min_{w,b,\zeta,\zeta^*} & \quad \frac{1}{2} w^T w + C \sum_{i=1}^{n} (\zeta_i + \zeta_i^*) \\
\text{subject to} & \quad y_i - w^T \phi(x_i) - b \leq \varepsilon + \zeta_i, \\
& \quad w^T \phi(x_i) + b - y_i \leq \varepsilon + \zeta_i^*, \\
& \quad \zeta_i, \zeta_i^* \geq 0, \quad i = 1, \ldots, n
\end{align*}
\]

Here, we are penalizing samples whose prediction is at least \( \varepsilon \) away from their true target. These samples penalize the objective by \( \zeta_i \) or \( \zeta_i^* \), depending on whether their predictions lie above or below the \( \varepsilon \) tube.

The dual problem is

\[
\begin{align*}
\min_{\alpha,\alpha^*} & \quad \frac{1}{2} (\alpha - \alpha^*)^T Q (\alpha - \alpha^*) + \varepsilon e^T (\alpha + \alpha^*) - y^T (\alpha - \alpha^*) \\
\text{subject to} & \quad e^T (\alpha - \alpha^*) = 0 \\
& \quad 0 \leq \alpha_i, \alpha_i^* \leq C, \quad i = 1, \ldots, n
\end{align*}
\]

where \( e \) is the vector of all ones, \( Q \) is an \( n \) by \( n \) positive semidefinite matrix, \( Q_{ij} = K(x_i, x_j) = \phi(x_i)^T \phi(x_j) \) is the kernel. Here training vectors are implicitly mapped into a higher (maybe infinite) dimensional space by the function \( \phi \).

The prediction is:

\[
\sum_{i \in SV} (\alpha_i - \alpha_i^*) K(x_i, x) + b
\]

These parameters can be accessed through the attributes dual_coef_ which holds the difference \( \alpha_i - \alpha_i^* \), support_vectors_ which holds the support vectors, and intercept_ which holds the independent term \( b \).

LinearSVR

The primal problem can be equivalently formulated as

\[
\begin{align*}
\min_{w,b} & \quad \frac{1}{2} w^T w + C \sum_{i=1}^{n} \max(0, \ |y_i - (w^T \phi(x_i) + b)| - \varepsilon),
\end{align*}
\]

where we make use of the epsilon-insensitive loss, i.e. errors of less than \( \varepsilon \) are ignored. This is the form that is directly optimized by LinearSVR.

Implementation details

Internally, we use libsvm\(^{12}\) and liblinear\(^{11}\) to handle all computations. These libraries are wrapped using C and Cython. For a description of the implementation and details of the algorithms used, please refer to their respective papers.

References:
4.1.5 Stochastic Gradient Descent

Stochastic Gradient Descent (SGD) is a simple yet very efficient approach to fitting linear classifiers and regressors under convex loss functions such as (linear) Support Vector Machines and Logistic Regression. Even though SGD has been around in the machine learning community for a long time, it has received a considerable amount of attention just recently in the context of large-scale learning.

SGD has been successfully applied to large-scale and sparse machine learning problems often encountered in text classification and natural language processing. Given that the data is sparse, the classifiers in this module easily scale to problems with more than $10^5$ training examples and more than $10^5$ features.

Strictly speaking, SGD is merely an optimization technique and does not correspond to a specific family of machine learning models. It is only a way to train a model. Often, an instance of `SGDClassifier` or `SGDRegressor` will have an equivalent estimator in the scikit-learn API, potentially using a different optimization technique. For example, using `SGDClassifier(loss='log')` results in logistic regression, i.e. a model equivalent to `LogisticRegression` which is fitted via SGD instead of being fitted by one of the other solvers in `LogisticRegression`. Similarly, `SGDRegressor(loss='squared_loss', penalty='l2')` and `Ridge` solve the same optimization problem, via different means.

The advantages of Stochastic Gradient Descent are:

- Efficiency.
- Ease of implementation (lots of opportunities for code tuning).

The disadvantages of Stochastic Gradient Descent include:

- SGD requires a number of hyperparameters such as the regularization parameter and the number of iterations.
- SGD is sensitive to feature scaling.

**Warning:** Make sure you permute (shuffle) your training data before fitting the model or use `shuffle=True` to shuffle after each iteration (used by default). Also, ideally, features should be standardized using e.g. `make_pipeline(StandardScaler(), SGDClassifier())` (see Pipelines).

### Classification

The class `SGDClassifier` implements a plain stochastic gradient descent learning routine which supports different loss functions and penalties for classification. Below is the decision boundary of a `SGDClassifier` trained with the hinge loss, equivalent to a linear SVM.

As other classifiers, SGD has to be fitted with two arrays: an array $X$ of shape $(n_{\text{samples}}, n_{\text{features}})$ holding the training samples, and an array $y$ of shape $(n_{\text{samples}})$ holding the target values (class labels) for the training samples:

```python
>>> from sklearn.linear_model import SGDClassifier
>>> X = [[0., 0.], [1., 1.]]
>>> y = [0, 1]
>>> clf = SGDClassifier(loss="hinge", penalty="l2", max_iter=5)
>>> clf.fit(X, y)
SGDClassifier(max_iter=5)

After being fitted, the model can then be used to predict new values:

```python
>>> clf.predict([[2., 2.]])
array([1])
```

SGD fits a linear model to the training data. The `coef_` attribute holds the model parameters:
The `clf.coef_` attribute holds the intercept (aka offset or bias):

```python
>>> clf.coef_
array([[9.9..., 9.9...]])
```

Whether or not the model should use an intercept, i.e., a biased hyperplane, is controlled by the parameter `fit_intercept`.

The signed distance to the hyperplane (computed as the dot product between the coefficients and the input sample, plus the intercept) is given by `SGDClassifier.decision_function`:

```python
>>> clf.intercept_
array([-9.9...])
```

```python
>>> clf.decision_function([[2., 2.]])
array([29.6...])
```

The concrete loss function can be set via the `loss` parameter. `SGDClassifier` supports the following loss functions:

- `loss="hinge"`: (soft-margin) linear Support Vector Machine,
- `loss="modified_huber"`: smoothed hinge loss,
- `loss="log"`: logistic regression,
- and all regression losses below. In this case the target is encoded as -1 or 1, and the problem is treated as a regression problem. The predicted class then correspond to the sign of the predicted target.

Please refer to the mathematical section below for formulas. The first two loss functions are lazy, they only update the model parameters if an example violates the margin constraint, which makes training very efficient and may result in sparser models (i.e., with more zero coefficients), even when L2 penalty is used.
Using `loss="log"` or `loss="modified_huber"` enables the `predict_proba` method, which gives a vector of probability estimates $P(y|x)$ per sample $x$:

```python
>>> clf = SGDClassifier(loss="log", max_iter=5).fit(X, y)
>>> clf.predict_proba([[1., 1.]])
array([[0.00..., 0.99...]])
```

The concrete penalty can be set via the `penalty` parameter. SGD supports the following penalties:

- `penalty="l2"`: L2 norm penalty on `coef_`.
- `penalty="l1"`: L1 norm penalty on `coef_`.
- `penalty="elasticnet"`: Convex combination of L2 and L1; $(1 - l1_ratio) * L2 + l1_ratio * L1$.

The default setting is `penalty="l2"`. The L1 penalty leads to sparse solutions, driving most coefficients to zero. The Elastic Net\[11\] solves some deficiencies of the L1 penalty in the presence of highly correlated attributes. The parameter `l1_ratio` controls the convex combination of L1 and L2 penalty.

`SGDClassifier` supports multi-class classification by combining multiple binary classifiers in a “one versus all” (OVA) scheme. For each of the $K$ classes, a binary classifier is learned that discriminates between that and all other $K - 1$ classes. At testing time, we compute the confidence score (i.e. the signed distances to the hyperplane) for each classifier and choose the class with the highest confidence. The Figure below illustrates the OVA approach on the iris dataset. The dashed lines represent the three OVA classifiers; the background colors show the decision surface induced by the three classifiers.

![Decision surface of multi-class SGD](image)

In the case of multi-class classification `coef_` is a two-dimensional array of shape `(n_classes, n_features)` and `intercept_` is a one-dimensional array of shape `(n_classes,)`. The i-th row of `coef_` holds the weight vector of the OVA classifier for the i-th class; classes are indexed in ascending order (see attribute `classes_`). Note that, in principle, since they allow to create a probability model, `loss="log"` and `loss="modified_huber"` are more suitable for one-vs-all classification.

---

SGDClassifier supports both weighted classes and weighted instances via the fit parameters class_weight and sample_weight. See the examples below and the docstring of SGDClassifier.fit for further information.

SGDClassifier supports averaged SGD (ASGD)\(^\text{10}\). Averaging can be enabled by setting average=True. ASGD performs the same updates as the regular SGD (see Mathematical formulation), but instead of using the last value of the coefficients as the coef_ attribute (i.e. the values of the last update), coef_ is set instead to the average value of the coefficients across all updates. The same is done for the intercept_ attribute. When using ASGD the learning rate can be larger and even constant, leading on some datasets to a speed up in training time.

For classification with a logistic loss, another variant of SGD with an averaging strategy is available with Stochastic Average Gradient (SAG) algorithm, available as a solver in LogisticRegression.

Examples:

- SGD: Maximum margin separating hyperplane,
- Plot multi-class SGD on the iris dataset
- SGD: Weighted samples
- Comparing various online solvers
- SVM: Separating hyperplane for unbalanced classes (See the Note in the example)

Regression

The class SGDRegressor implements a plain stochastic gradient descent learning routine which supports different loss functions and penalties to fit linear regression models. SGDRegressor is well suited for regression problems with a large number of training samples (> 10,000), for other problems we recommend Ridge, Lasso, or ElasticNet.

The concrete loss function can be set via the loss parameter. SGDRegressor supports the following loss functions:

- loss="squared_loss": Ordinary least squares,
- loss="huber": Huber loss for robust regression,
- loss="epsilon_insensitive": linear Support Vector Regression.

Please refer to the mathematical section below for formulas. The Huber and epsilon-insensitive loss functions can be used for robust regression. The width of the insensitive region has to be specified via the parameter epsilon. This parameter depends on the scale of the target variables.

The penalty parameter determines the regularization to be used (see description above in the classification section). SGDRegressor also supports averaged SGD\(^\text{10}\) (here again, see description above in the classification section).

For regression with a squared loss and a l2 penalty, another variant of SGD with an averaging strategy is available with Stochastic Average Gradient (SAG) algorithm, available as a solver in Ridge.

\(^{10}\)“Towards Optimal One Pass Large Scale Learning with Averaged Stochastic Gradient Descent” Xu, Wei
Stochastic Gradient Descent for sparse data

Note: The sparse implementation produces slightly different results from the dense implementation, due to a shrunk learning rate for the intercept. See Implementation details.

There is built-in support for sparse data given in any matrix in a format supported by scipy.sparse. For maximum efficiency, however, use the CSR matrix format as defined in scipy.sparse.csr_matrix.

Complexity

The major advantage of SGD is its efficiency, which is basically linear in the number of training examples. If X is a matrix of size (n, p) training has a cost of \( O(kn\bar{p}) \), where \( k \) is the number of iterations (epochs) and \( \bar{p} \) is the average number of non-zero attributes per sample.

Recent theoretical results, however, show that the runtime to get some desired optimization accuracy does not increase as the training set size increases.

Stopping criterion

The classes SGDClassifier and SGDRegressor provide two criteria to stop the algorithm when a given level of convergence is reached:

- With early_stopping=True, the input data is split into a training set and a validation set. The model is then fitted on the training set, and the stopping criterion is based on the prediction score (using the score method) computed on the validation set. The size of the validation set can be changed with the parameter validation_fraction.

- With early_stopping=False, the model is fitted on the entire input data and the stopping criterion is based on the objective function computed on the training data.

In both cases, the criterion is evaluated once by epoch, and the algorithm stops when the criterion does not improve \( n\_iter\_no\_change \) times in a row. The improvement is evaluated with absolute tolerance \( tol \), and the algorithm stops in any case after a maximum number of iteration \( max\_iter \).

Tips on Practical Use

- Stochastic Gradient Descent is sensitive to feature scaling, so it is highly recommended to scale your data. For example, scale each attribute on the input vector X to \([0,1]\) or \([-1,+1]\), or standardize it to have mean 0 and variance 1. Note that the same scaling must be applied to the test vector to obtain meaningful results. This can be easily done using StandardScaler:

```python
from sklearn.preprocessing import StandardScaler
scaler = StandardScaler()
scaler.fit(X_train) # Don't cheat - fit only on training data
X_train = scaler.transform(X_train)
X_test = scaler.transform(X_test) # apply same transformation to test data
```

(continues on next page)
# Or better yet: use a pipeline!

```python
from sklearn.pipeline import make_pipeline
est = make_pipeline(StandardScaler(), SGDClassifier())
est.fit(X_train)
est.predict(X_test)
```

If your attributes have an intrinsic scale (e.g. word frequencies or indicator features) scaling is not needed.

- Finding a reasonable regularization term \( \alpha \) is best done using automatic hyper-parameter search, e.g. `GridSearchCV` or `RandomizedSearchCV`, usually in the range \( 10.0^{+\text{-np.arange(1,7)}} \).
- Empirically, we found that SGD converges after observing approximately \( 10^6 \) training samples. Thus, a reasonable first guess for the number of iterations is \( \text{max\_iter} = \text{np.ceil}(10^6 / n) \), where \( n \) is the size of the training set.
- If you apply SGD to features extracted using PCA we found that it is often wise to scale the feature values by some constant \( c \) such that the average L2 norm of the training data equals one.
- We found that Averaged SGD works best with a larger number of features and a higher \( \eta_0 \)

### References:

#### Mathematical formulation

We describe here the mathematical details of the SGD procedure. A good overview with convergence rates can be found in\(^\text{12}\). Given a set of training examples \((x_1, y_1), \ldots, (x_n, y_n)\) where \( x_i \in \mathbb{R}^m \) and \( y_i \in \mathbb{R} \) (\( y_i \in \{-1, 1\} \) for classification), our goal is to learn a linear scoring function \( f(x) = w^T x + b \) with model parameters \( w \in \mathbb{R}^m \) and intercept \( b \in \mathbb{R} \). In order to make predictions for binary classification, we simply look at the sign of \( f(x) \). To find the model parameters, we minimize the regularized training error given by

\[
E(w, b) = \frac{1}{n} \sum_{i=1}^n L(y_i, f(x_i)) + \alpha R(w)
\]

where \( L \) is a loss function that measures model (mis)fit and \( R \) is a regularization term (aka penalty) that penalizes model complexity; \( \alpha > 0 \) is a non-negative hyperparameter that controls the regularization strength.

Different choices for \( L \) entail different classifiers or regressors:

- **Hinge (soft-margin):** equivalent to Support Vector Classification. \( L(y_i, f(x_i)) = \max(0, 1 - y_i f(x_i)) \).
- **Perceptron:** \( L(y_i, f(x_i)) = \max(0, -y_i f(x_i)) \).
- **Modified Huber:** \( L(y_i, f(x_i)) = \max(0, 1 - y_i f(x_i))^2 \) if \( y_i f(x_i) > 1 \), and \( L(y_i, f(x_i)) = -4 y_i f(x_i) \) otherwise.
- **Log:** equivalent to Logistic Regression. \( L(y_i, f(x_i)) = \log(1 + \exp(-y_i f(x_i))) \).
- **Least-Squares:** Linear regression (Ridge or Lasso depending on \( R \)). \( L(y_i, f(x_i)) = \frac{1}{2} (y_i - f(x_i))^2 \).
- **Huber:** less sensitive to outliers than least-squares. It is equivalent to least squares when \( |y_i - f(x_i)| \leq \varepsilon \), and \( L(y_i, f(x_i)) = \varepsilon |y_i - f(x_i)| - \frac{1}{2} \varepsilon^2 \) otherwise.

---

\(^{12}\) “Solving large scale linear prediction problems using stochastic gradient descent algorithms” T. Zhang - In Proceedings of ICML ‘04.
• Epsilon-Insensitive: (soft-margin) equivalent to Support Vector Regression. \( L(y_i, f(x_i)) = \max(0, |y_i - f(x_i)| - \varepsilon) \).

All of the above loss functions can be regarded as an upper bound on the misclassification error (Zero-one loss) as shown in the Figure below.

![Loss Functions Contours](image)

Popular choices for the regularization term \( R \) (the penalty parameter) include:

• L2 norm: \( R(w) := \frac{1}{2} \sum_{j=1}^{m} w_j^2 = ||w||^2 \).

• L1 norm: \( R(w) := \sum_{j=1}^{m} |w_j| \), which leads to sparse solutions.

• Elastic Net: \( R(w) := \frac{\rho}{2} \sum_{j=1}^{m} w_j^2 + (1 - \rho) \sum_{j=1}^{m} |w_j| \), a convex combination of L2 and L1, where \( \rho \) is given by \( 1 - \text{l1_ratio} \).

The Figure below shows the contours of the different regularization terms in a 2-dimensional parameter space \( (m = 2) \) when \( R(w) = 1 \).

**SGD**

Stochastic gradient descent is an optimization method for unconstrained optimization problems. In contrast to (batch) gradient descent, SGD approximates the true gradient of \( E(w, b) \) by considering a single training example at a time.

The class `SGDClassifier` implements a first-order SGD learning routine. The algorithm iterates over the training examples and for each example updates the model parameters according to the update rule given by

\[
w \leftarrow w - \eta \left[ \frac{\partial R(w)}{\partial w} + \frac{\partial L(w^T x_i + b, y_i)}{\partial w} \right]
\]

where \( \eta \) is the learning rate which controls the step-size in the parameter space. The intercept \( b \) is updated similarly but without regularization (and with additional decay for sparse matrices, as detailed in Implementation details).
The learning rate $\eta$ can be either constant or gradually decaying. For classification, the default learning rate schedule (learning_rate='optimal') is given by

$$\eta(t) = \frac{1}{\alpha(t_0 + t)}$$

where $t$ is the time step (there are a total of $n_{samples} \times n_{iter}$ time steps), $t_0$ is determined based on a heuristic proposed by Léon Bottou such that the expected initial updates are comparable with the expected size of the weights (this assuming that the norm of the training samples is approx. 1). The exact definition can be found in _init_t in BaseSGD.

For regression the default learning rate schedule is inverse scaling (learning_rate='invscaling'), given by

$$\eta(t) = \frac{\text{eta}_0}{t^{\text{power}_t}}$$

where $\text{eta}_0$ and $\text{power}_t$ are hyperparameters chosen by the user via eta0 and power_t, resp.

For a constant learning rate use learning_rate='constant' and use eta0 to specify the learning rate.

For an adaptively decreasing learning rate, use learning_rate='adaptive' and use eta0 to specify the starting learning rate. When the stopping criterion is reached, the learning rate is divided by 5, and the algorithm does not stop. The algorithm stops when the learning rate goes below 1e-6.

The model parameters can be accessed through the coef_ and intercept_ attributes: coef_ holds the weights $w$ and intercept_ holds $b$.

When using Averaged SGD (with the average parameter), coef_ is set to the average weight across all updates: $\text{coef}_- = \frac{1}{T} \sum_{t=0}^{T-1} w(t)$, where $T$ is the total number of updates, found in the t_ attribute.

**Implementation details**

The implementation of SGD is influenced by the Stochastic Gradient SVM of\(^7\). Similar to SvmSGD, the weight vector is represented as the product of a scalar and a vector which allows an efficient weight update in the case of L2 regularization. In the case of sparse input $X$, the intercept is updated with a smaller learning rate (multiplied by 0.01) to account for the fact that it is updated more frequently. Training examples are picked up sequentially and the learning rate is lowered after each observed example. We adopted the learning rate schedule from\(^8\). For multi-class classification, a “one versus all” approach is used. We use the truncated gradient algorithm proposed in\(^9\) for L1 regularization (and the Elastic Net). The code is written in Cython.

4.1.6 Nearest Neighbors

`sklearn.neighbors` provides functionality for unsupervised and supervised neighbors-based learning methods. Unsupervised nearest neighbors is the foundation of many other learning methods, notably manifold learning and spectral clustering. Supervised neighbors-based learning comes in two flavors: classification for data with discrete labels, and regression for data with continuous labels.

The principle behind nearest neighbor methods is to find a predefined number of training samples closest in distance to the new point, and predict the label from these. The number of samples can be a user-defined constant (k-nearest

\(^7\) "Stochastic Gradient Descent" L. Bottou - Website, 2010.

\(^8\) "Pegasos: Primal estimated sub-gradient solver for svm" S. Shalev-Shwartz, Y. Singer, N. Srebro - In Proceedings of ICML '07.

neighbor learning), or vary based on the local density of points (radius-based neighbor learning). The distance can, in general, be any metric measure: standard Euclidean distance is the most common choice. Neighbors-based methods are known as non-generalizing machine learning methods, since they simply “remember” all of its training data (possibly transformed into a fast indexing structure such as a Ball Tree or KD Tree).

Despite its simplicity, nearest neighbors has been successful in a large number of classification and regression problems, including handwritten digits and satellite image scenes. Being a non-parametric method, it is often successful in classification situations where the decision boundary is very irregular.

The classes in sklearn.neighbors can handle either NumPy arrays or scipy.sparse matrices as input. For dense matrices, a large number of possible distance metrics are supported. For sparse matrices, arbitrary Minkowski metrics are supported for searches.

There are many learning routines which rely on nearest neighbors at their core. One example is kernel density estimation, discussed in the density estimation section.

Unsupervised Nearest Neighbors

NearestNeighbors implements unsupervised nearest neighbors learning. It acts as a uniform interface to three different nearest neighbors algorithms: BallTree, KDTree, and a brute-force algorithm based on routines in sklearn.metrics.pairwise. The choice of neighbors search algorithm is controlled through the keyword 'algorithm', which must be one of ['auto', 'ball_tree', 'kd_tree', 'brute']. When the default value 'auto' is passed, the algorithm attempts to determine the best approach from the training data. For a discussion of the strengths and weaknesses of each option, see Nearest Neighbor Algorithms.

Warning: Regarding the Nearest Neighbors algorithms, if two neighbors \( k + 1 \) and \( k \) have identical distances but different labels, the result will depend on the ordering of the training data.

Finding the Nearest Neighbors

For the simple task of finding the nearest neighbors between two sets of data, the unsupervised algorithms within sklearn.neighbors can be used:

```python
>>> from sklearn.neighbors import NearestNeighbors
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
>>> nbrs = NearestNeighbors(n_neighbors=2, algorithm='ball_tree').fit(X)
>>> distances, indices = nbrs.kneighbors(X)
>>> indices
array([[0, 1],
       [1, 0],
       [2, 1],
       [3, 4],
       [4, 3],
       [5, 4]])...
>>> distances
array([[0. , 1. ],
       [0. , 1. ],
       [0. , 1.41421356],
       [0. , 1. ],
       [0. , 1. ],
       [0. , 1.41421356]])
```
Because the query set matches the training set, the nearest neighbor of each point is the point itself, at a distance of zero.

It is also possible to efficiently produce a sparse graph showing the connections between neighboring points:

```python
gnbrs.kneighbors_graph(X).toarray()
array([[1., 1., 0., 0., 0., 0.],
       [1., 1., 0., 0., 0., 0.],
       [0., 1., 1., 0., 0., 0.],
       [0., 0., 0., 1., 1., 0.],
       [0., 0., 0., 1., 1., 0.],
       [0., 0., 0., 0., 1., 1.]])
```

The dataset is structured such that points nearby in index order are nearby in parameter space, leading to an approximately block-diagonal matrix of K-nearest neighbors. Such a sparse graph is useful in a variety of circumstances which make use of spatial relationships between points for unsupervised learning: in particular, see Isomap, LocallyLinearEmbedding, and SpectralClustering.

**KDTree and BallTree Classes**

Alternatively, one can use the KDTree or BallTree classes directly to find nearest neighbors. This is the functionality wrapped by the NearestNeighbors class used above. The Ball Tree and KD Tree have the same interface; we’ll show an example of using the KD Tree here:

```python
from sklearn.neighbors import KDTree
import numpy as np

X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])

kdt = KDTree(X, leaf_size=30, metric='euclidean')

kdt.query(X, k=2, return_distance=False)
array([[0, 1],
       [1, 0],
       [2, 1],
       [3, 4],
       [4, 3],
       [5, 4]])
```

Refer to the KDTree and BallTree class documentation for more information on the options available for nearest neighbors searches, including specification of query strategies, distance metrics, etc. For a list of available metrics, see the documentation of the DistanceMetric class.

**Nearest Neighbors Classification**

Neighbors-based classification is a type of instance-based learning or non-generalizing learning: it does not attempt to construct a general internal model, but simply stores instances of the training data. Classification is computed from a simple majority vote of the nearest neighbors of each point: a query point is assigned the data class which has the most representatives within the nearest neighbors of the point.

scikit-learn implements two different nearest neighbors classifiers: KNeighborsClassifier implements learning based on the $k$ nearest neighbors of each query point, where $k$ is an integer value specified by the user. RadiusNeighborsClassifier implements learning based on the number of neighbors within a fixed radius $r$ of each training point, where $r$ is a floating-point value specified by the user.

The $k$-neighbors classification in KNeighborsClassifier is the most commonly used technique. The optimal choice of the value $k$ is highly data-dependent: in general a larger $k$ suppresses the effects of noise, but makes the classification boundaries less distinct.
In cases where the data is not uniformly sampled, radius-based neighbors classification in `RadiusNeighborsClassifier` can be a better choice. The user specifies a fixed radius $r$, such that points in sparser neighborhoods use fewer nearest neighbors for the classification. For high-dimensional parameter spaces, this method becomes less effective due to the so-called “curse of dimensionality”.

The basic nearest neighbors classification uses uniform weights: that is, the value assigned to a query point is computed from a simple majority vote of the nearest neighbors. Under some circumstances, it is better to weight the neighbors such that nearer neighbors contribute more to the fit. This can be accomplished through the `weights` keyword. The default value, `weights = 'uniform'`, assigns uniform weights to each neighbor. `weights = 'distance'` assigns weights proportional to the inverse of the distance from the query point. Alternatively, a user-defined function of the distance can be supplied to compute the weights.

Examples:

- **Nearest Neighbors Classification**: an example of classification using nearest neighbors.
Nearest Neighbors Regression

Neighbors-based regression can be used in cases where the data labels are continuous rather than discrete variables. The label assigned to a query point is computed based on the mean of the labels of its nearest neighbors.

scikit-learn implements two different neighbors regressors: `KNeighborsRegressor` implements learning based on the $k$ nearest neighbors of each query point, where $k$ is an integer value specified by the user. `RadiusNeighborsRegressor` implements learning based on the neighbors within a fixed radius $r$ of the query point, where $r$ is a floating-point value specified by the user.

The basic nearest neighbors regression uses uniform weights: that is, each point in the local neighborhood contributes uniformly to the classification of a query point. Under some circumstances, it can be advantageous to weight points such that nearby points contribute more to the regression than faraway points. This can be accomplished through the `weights` keyword. The default value, `weights = 'uniform'`, assigns equal weights to all points. `weights = 'distance'` assigns weights proportional to the inverse of the distance from the query point. Alternatively, a user-defined function of the distance can be supplied, which will be used to compute the weights.

The use of multi-output nearest neighbors for regression is demonstrated in `Face completion with a multi-output estimators`. In this example, the inputs $X$ are the pixels of the upper half of faces and the outputs $Y$ are the pixels of the lower half of those faces.

Examples:

- *Nearest Neighbors regression*: an example of regression using nearest neighbors.
- *Face completion with a multi-output estimators*: an example of multi-output regression using nearest neighbors.
Face completion with multi-output estimators

Nearest Neighbor Algorithms

Brute Force

Fast computation of nearest neighbors is an active area of research in machine learning. The most naive neighbor search implementation involves the brute-force computation of distances between all pairs of points in the dataset: for \( N \) samples in \( D \) dimensions, this approach scales as \( O(DN^2) \). Efficient brute-force neighbors searches can be very competitive for small data samples. However, as the number of samples \( N \) grows, the brute-force approach quickly becomes infeasible. In the classes within `sklearn.neighbors`, brute-force neighbors searches are specified using the keyword `algorithm = 'brute'`, and are computed using the routines available in `sklearn.metrics.pairwise`.

K-D Tree

To address the computational inefficiencies of the brute-force approach, a variety of tree-based data structures have been invented. In general, these structures attempt to reduce the required number of distance calculations by efficiently encoding aggregate distance information for the sample. The basic idea is that if point \( A \) is very distant from point \( B \), and point \( B \) is very close to point \( C \), then we know that points \( A \) and \( C \) are very distant, without having to explicitly calculate their distance. In this way, the computational cost of a nearest neighbors search can be reduced to \( O(DN \log(N)) \) or better. This is a significant improvement over brute-force for large \( N \).

An early approach to taking advantage of this aggregate information was the KD tree data structure (short for K-dimensional tree), which generalizes two-dimensional Quad-trees and 3-dimensional Oct-trees to an arbitrary number of dimensions. The KD tree is a binary tree structure which recursively partitions the parameter space along the data axes, dividing it into nested orthotropic regions into which data points are filed. The construction of a KD tree is very fast: because partitioning is performed only along the data axes, no \( D \)-dimensional distances need to be computed. Once constructed, the nearest neighbor of a query point can be determined with only \( O(\log(N)) \) distance computations. Though the KD tree approach is very fast for low-dimensional (\( D < 20 \)) neighbors searches, it becomes inefficient as \( D \) grows very large: this is one manifestation of the so-called “curse of dimensionality”. In scikit-learn, KD tree neighbors searches are specified using the keyword `algorithm = 'kd_tree'`, and are computed using the class `KDTree`.

References:
- “Multidimensional binary search trees used for associative searching”, Bentley, J.L., Communications of the ACM (1975)

Ball Tree

To address the inefficiencies of KD Trees in higher dimensions, the ball tree data structure was developed. Where KD trees partition data along Cartesian axes, ball trees partition data in a series of nesting hyper-spheres. This makes tree construction more costly than that of the KD tree, but results in a data structure which can be very efficient on highly structured data, even in very high dimensions.

A ball tree recursively divides the data into nodes defined by a centroid \( C \) and radius \( r \), such that each point in the node lies within the hyper-sphere defined by \( r \) and \( C \). The number of candidate points for a neighbor search is reduced through use of the triangle inequality:

\[
|x + y| \leq |x| + |y|
\]

With this setup, a single distance calculation between a test point and the centroid is sufficient to determine a lower and upper bound on the distance to all points within the node. Because of the spherical geometry of the ball tree nodes, it
can out-perform a *KD-tree* in high dimensions, though the actual performance is highly dependent on the structure of the training data. In scikit-learn, ball-tree-based neighbors searches are specified using the keyword \texttt{algorithm = 'ball\_tree'}, and are computed using the class \texttt{BallTree}. Alternatively, the user can work with the \texttt{BallTree} class directly.

References:

### Choice of Nearest Neighbors Algorithm

The optimal algorithm for a given dataset is a complicated choice, and depends on a number of factors:

- number of samples \( N \) (i.e. \texttt{n\_samples}) and dimensionality \( D \) (i.e. \texttt{n\_features}).
  - \textit{Brute force} query time grows as \( O[D N] \)
  - \textit{Ball tree} query time grows as approximately \( O[D \log(N)] \)
  - \textit{KD tree} query time changes with \( D \) in a way that is difficult to precisely characterise. For small \( D \) (less than 20 or so) the cost is approximately \( O[D \log(N)] \), and the KD tree query can be very efficient. For larger \( D \), the cost increases to nearly \( O[D N] \), and the overhead due to the tree structure can lead to queries which are slower than brute force.

For small data sets (\( N \) less than 30 or so), \( \log(N) \) is comparable to \( N \), and brute force algorithms can be more efficient than a tree-based approach. Both \texttt{KDTree} and \texttt{BallTree} address this through providing a leaf size parameter: this controls the number of samples at which a query switches to brute-force. This allows both algorithms to approach the efficiency of a brute-force computation for small \( N \).

- data structure: intrinsic dimensionality of the data and/or sparsity of the data. Intrinsic dimensionality refers to the dimension \( d \leq D \) of a manifold on which the data lies, which can be linearly or non-linearly embedded in the parameter space. Sparsity refers to the degree to which the data fills the parameter space (this is to be distinguished from the concept as used in “sparse” matrices. The data matrix may have no zero entries, but the structure can still be “sparse” in this sense).
  - \textit{Brute force} query time is unchanged by data structure.
  - \textit{Ball tree} and \textit{KD tree} query times can be greatly influenced by data structure. In general, sparser data with a smaller intrinsic dimensionality leads to faster query times. Because the KD tree internal representation is aligned with the parameter axes, it will not generally show as much improvement as ball tree for arbitrarily structured data.

Datasets used in machine learning tend to be very structured, and are very well-suited for tree-based queries.

- number of neighbors \( k \) requested for a query point.
  - \textit{Brute force} query time is largely unaffected by the value of \( k \)
  - \textit{Ball tree} and \textit{KD tree} query time will become slower as \( k \) increases. This is due to two effects: first, a larger \( k \) leads to the necessity to search a larger portion of the parameter space. Second, using \( k > 1 \) requires internal queueing of results as the tree is traversed.

As \( k \) becomes large compared to \( N \), the ability to prune branches in a tree-based query is reduced. In this situation, Brute force queries can be more efficient.

- number of query points. Both the ball tree and the KD Tree require a construction phase. The cost of this construction becomes negligible when amortized over many queries. If only a small number of queries will
be performed, however, the construction can make up a significant fraction of the total cost. If very few query points will be required, brute force is better than a tree-based method.

Currently, algorithm = 'auto' selects 'brute' if any of the following conditions are verified:

- input data is sparse
- metric = 'precomputed'
- \( D > 15 \)
- \( k > N/2 \)
- effective_metric_ isn’t in the VALID_METRICS list for either 'kd_tree' or 'ball_tree'

Otherwise, it selects the first out of 'kd_tree' and 'ball_tree' that has effective_metric_ in its VALID_METRICS list. This heuristic is based on the following assumptions:

- the number of query points is at least the same order as the number of training points
- leaf_size is close to its default value of 30
- when \( D > 15 \), the intrinsic dimensionality of the data is generally too high for tree-based methods

**Effect of leaf_size**

As noted above, for small sample sizes a brute force search can be more efficient than a tree-based query. This fact is accounted for in the ball tree and KD tree by internally switching to brute force searches within leaf nodes. The level of this switch can be specified with the parameter leaf_size. This parameter choice has many effects:

**construction time** A larger leaf_size leads to a faster tree construction time, because fewer nodes need to be created

**query time** Both a large or small leaf_size can lead to suboptimal query cost. For leaf_size approaching 1, the overhead involved in traversing nodes can significantly slow query times. For leaf_size approaching the size of the training set, queries become essentially brute force. A good compromise between these is leaf_size = 30, the default value of the parameter.

**memory** As leaf_size increases, the memory required to store a tree structure decreases. This is especially important in the case of ball tree, which stores a \( D \)-dimensional centroid for each node. The required storage space for BallTree is approximately \( 1 / \text{leaf\_size} \) times the size of the training set.

leaf_size is not referenced for brute force queries.

**Nearest Centroid Classifier**

The NearestCentroid classifier is a simple algorithm that represents each class by the centroid of its members. In effect, this makes it similar to the label updating phase of the KMeans algorithm. It also has no parameters to choose, making it a good baseline classifier. It does, however, suffer on non-convex classes, as well as when classes have drastically different variances, as equal variance in all dimensions is assumed. See Linear Discriminant Analysis (LinearDiscriminantAnalysis) and Quadratic Discriminant Analysis (QuadraticDiscriminantAnalysis) for more complex methods that do not make this assumption. Usage of the default NearestCentroid is simple:

```python
>>> from sklearn.neighbors import NearestCentroid
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
>>> y = np.array([1, 1, 1, 2, 2, 2])
>>> clf = NearestCentroid()
```
```python
>>> clf.fit(X, y)
NearestCentroid()
>>> print(clf.predict([[-0.8, -1]]))
[1]
```

## Nearest Shrunken Centroid

The `NearestCentroid` classifier has a `shrink_threshold` parameter, which implements the nearest shrunken centroid classifier. In effect, the value of each feature for each centroid is divided by the within-class variance of that feature. The feature values are then reduced by `shrink_threshold`. Most notably, if a particular feature value crosses zero, it is set to zero. In effect, this removes the feature from affecting the classification. This is useful, for example, for removing noisy features.

In the example below, using a small shrink threshold increases the accuracy of the model from 0.81 to 0.82.

Examples:

- **Nearest Centroid Classification**: an example of classification using nearest centroid with different shrink thresholds.

## Nearest Neighbors Transformer

Many scikit-learn estimators rely on nearest neighbors: Several classifiers and regressors such as `KNeighborsClassifier` and `KNeighborsRegressor`, but also some clustering methods such as `DBSCAN` and `SpectralClustering`, and some manifold embeddings such as `TSNE` and `Isomap`.

All these estimators can compute internally the nearest neighbors, but most of them also accept precomputed nearest neighbors `sparse graph`, as given by `kneighbors_graph` and `radius_neighbors_graph`. With mode `mode='connectivity'`, these functions return a binary adjacency sparse graph as required, for instance, in `SpectralClustering`. Whereas with `mode='distance'`, they return a distance sparse graph as required, for instance, in `DBSCAN`. To include these functions in a scikit-learn pipeline, one can also use the corresponding classes `KNeighborsTransformer` and `RadiusNeighborsTransformer`. The benefits of this sparse graph API are multiple.

First, the precomputed graph can be re-used multiple times, for instance while varying a parameter of the estimator. This can be done manually by the user, or using the caching properties of the scikit-learn pipeline:
Second, precomputing the graph can give finer control on the nearest neighbors estimation, for instance enabling multiprocessing through the parameter `n_jobs`, which might not be available in all estimators.

Finally, the precomputation can be performed by custom estimators to use different implementations, such as approximate nearest neighbors methods, or implementation with special data types. The precomputed neighbors sparse graph needs to be formatted as in `radius_neighbors_graph` output:

- a CSR matrix (although COO, CSC or LIL will be accepted).
- only explicitly store nearest neighborhoods of each sample with respect to the training data. This should include those at 0 distance from a query point, including the matrix diagonal when computing the nearest neighborhoods between the training data and itself.
- each row's `data` should store the distance in increasing order (optional. Unsorted data will be stable-sorted, adding a computational overhead).
- all values in data should be non-negative.
- there should be no duplicate `indices` in any row (see https://github.com/scipy/scipy/issues/5807).
- if the algorithm being passed the precomputed matrix uses k nearest neighbors (as opposed to radius neighborhood), at least k neighbors must be stored in each row (or k+1, as explained in the following note).

**Note:** When a specific number of neighbors is queried (using `KNeighborsTransformer`), the definition of `n_neighbors` is ambiguous since it can either include each training point as its own neighbor, or exclude them. Neither choice is perfect, since including them leads to a different number of non-self neighbors during training and testing, while excluding them leads to a difference between `fit(X).transform(X)` and `fit_transform(X)`, which is against scikit-learn API. In `KNeighborsTransformer` we use the definition which includes each training point as its own neighbor in the count of `n_neighbors`. However, for compatibility reasons with other estimators which use the other definition, one extra neighbor will be computed when `mode == 'distance'`. To maximise compatibility with all estimators, a safe choice is to always include one extra neighbor in a custom nearest neighbors estimator, since unnecessary neighbors will be filtered by following estimators.

**Examples:**

- **Approximate nearest neighbors in TSNE**: an example of pipelining `KNeighborsTransformer` and `TSNE`. Also proposes two custom nearest neighbors estimators based on external packages.
- **Caching nearest neighbors**: an example of pipelining `KNeighborsTransformer` and `KNeighborsClassifier` to enable caching of the neighbors graph during a hyper-parameter grid-search.
Neighborhood Components Analysis

Neighborhood Components Analysis (NCA, \texttt{NeighborhoodComponentsAnalysis}) is a distance metric learning algorithm which aims to improve the accuracy of nearest neighbors classification compared to the standard Euclidean distance. The algorithm directly maximizes a stochastic variant of the leave-one-out k-nearest neighbors (KNN) score on the training set. It can also learn a low-dimensional linear projection of data that can be used for data visualization and fast classification.

In the above illustrating figure, we consider some points from a randomly generated dataset. We focus on the stochastic KNN classification of point no. 3. The thickness of a link between sample 3 and another point is proportional to their distance, and can be seen as the relative weight (or probability) that a stochastic nearest neighbor prediction rule would assign to this point. In the original space, sample 3 has many stochastic neighbors from various classes, so the right class is not very likely. However, in the projected space learned by NCA, the only stochastic neighbors with non-negligible weight are from the same class as sample 3, guaranteeing that the latter will be well classified. See the mathematical formulation for more details.

Classification

Combined with a nearest neighbors classifier (\texttt{KNeighborsClassifier}), NCA is attractive for classification because it can naturally handle multi-class problems without any increase in the model size, and does not introduce additional parameters that require fine-tuning by the user.

NCA classification has been shown to work well in practice for data sets of varying size and difficulty. In contrast to related methods such as Linear Discriminant Analysis, NCA does not make any assumptions about the class distributions. The nearest neighbor classification can naturally produce highly irregular decision boundaries.

To use this model for classification, one needs to combine a \texttt{NeighborhoodComponentsAnalysis} instance that learns the optimal transformation with a \texttt{KNeighborsClassifier} instance that performs the classification in the projected space. Here is an example using the two classes:

```python
>>> from sklearn.neighbors import (NeighborhoodComponentsAnalysis,
... KNeighborsClassifier)
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.pipeline import Pipeline

>>> X, y = load_iris(return_X_y=True)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y,
... stratify=y, test_size=0.7, random_state=42)
>>> nca = NeighborhoodComponentsAnalysis(random_state=42)
>>> knn = KNeighborsClassifier(n_neighbors=3)
```
nca_pipe = Pipeline([('nca', nca), ('knn', knn)])
nca_pipe.fit(X_train, y_train)
Pipeline(...)
print(nca_pipe.score(X_test, y_test))
0.96190476...

The plot shows decision boundaries for Nearest Neighbor Classification and Neighborhood Components Analysis classification on the iris dataset, when training and scoring on only two features, for visualisation purposes.

Dimensionality reduction

NCA can be used to perform supervised dimensionality reduction. The input data are projected onto a linear subspace consisting of the directions which minimize the NCA objective. The desired dimensionality can be set using the parameter n_components. For instance, the following figure shows a comparison of dimensionality reduction with Principal Component Analysis (PCA), Linear Discriminant Analysis (LinearDiscriminantAnalysis) and Neighborhood Component Analysis (NeighborhoodComponentsAnalysis) on the Digits dataset, a dataset with size n_samples = 1797 and n_features = 64. The data set is split into a training and a test set of equal size, then standardized. For evaluation the 3-nearest neighbor classification accuracy is computed on the 2-dimensional projected points found by each method. Each data sample belongs to one of 10 classes.

Examples:

- Comparing Nearest Neighbors with and without Neighborhood Components Analysis
- Dimensionality Reduction with Neighborhood Components Analysis
- Manifold learning on handwritten digits: Locally Linear Embedding, Isomap...
Mathematical formulation

The goal of NCA is to learn an optimal linear transformation matrix of size \( (n\_components, n\_features) \), which maximises the sum over all samples \( i \) of the probability \( p_i \) that \( i \) is correctly classified, i.e.:

\[
\arg \max_L \sum_{i=0}^{N-1} p_i
\]

with \( N = n\_samples \) and \( p_i \) the probability of sample \( i \) being correctly classified according to a stochastic nearest neighbors rule in the learned embedded space:

\[
p_i = \sum_{j \in C_i} p_{ij}
\]

where \( C_i \) is the set of points in the same class as sample \( i \), and \( p_{ij} \) is the softmax over Euclidean distances in the embedded space:

\[
p_{ij} = \frac{\exp(-||Lx_i - Lx_j||^2)}{\sum_{k \neq i} \exp(-||Lx_i - Lx_k||^2)}, \quad p_{ii} = 0
\]

Mahalanobis distance

NCA can be seen as learning a (squared) Mahalanobis distance metric:

\[
||L(x_i - x_j)||^2 = (x_i - x_j)^T M (x_i - x_j),
\]

where \( M = L^T L \) is a symmetric positive semi-definite matrix of size \( (n\_features, n\_features) \).

Implementation

This implementation follows what is explained in the original paper\(^1\). For the optimisation method, it currently uses scipy’s L-BFGS-B with a full gradient computation at each iteration, to avoid to tune the learning rate and provide stable learning.

See the examples below and the docstring of \texttt{NeighborhoodComponentsAnalysis.fit} for further information.

Complexity

Training

NCA stores a matrix of pairwise distances, taking \( n\_samples ** 2 \) memory. Time complexity depends on the number of iterations done by the optimisation algorithm. However, one can set the maximum number of iterations with the argument \texttt{max\_iter}. For each iteration, time complexity is \( O(n\_components \times n\_samples \times \min(n\_samples, n\_features)) \).

Transform

Here the transform operation returns $LX^T$, therefore its time complexity equals $n_{\text{components}} \times n_{\text{features}} \times n_{\text{samples\_test}}$. There is no added space complexity in the operation.

4.1.7 Gaussian Processes

Gaussian Processes (GP) are a generic supervised learning method designed to solve regression and probabilistic classification problems.

The advantages of Gaussian processes are:

- The prediction interpolates the observations (at least for regular kernels).
- The prediction is probabilistic (Gaussian) so that one can compute empirical confidence intervals and decide based on those if one should refit (online fitting, adaptive fitting) the prediction in some region of interest.
- Versatile: different kernels can be specified. Common kernels are provided, but it is also possible to specify custom kernels.

The disadvantages of Gaussian processes include:

- They are not sparse, i.e., they use the whole samples/features information to perform the prediction.
- They lose efficiency in high dimensional spaces – namely when the number of features exceeds a few dozens.

Gaussian Process Regression (GPR)

The GaussianProcessRegressor implements Gaussian processes (GP) for regression purposes. For this, the prior of the GP needs to be specified. The prior mean is assumed to be constant and zero (for normalize_y=False) or the training data’s mean (for normalize_y=True). The prior’s covariance is specified by passing a kernel object. The hyperparameters of the kernel are optimized during fitting of GaussianProcessRegressor by maximizing the log-marginal-likelihood (LML) based on the passed optimizer. As the LML may have multiple local optima, the optimizer can be started repeatedly by specifying n_restarts_optimizer. The first run is always conducted starting from the initial hyperparameter values of the kernel; subsequent runs are conducted from hyperparameter values that have been chosen randomly from the range of allowed values. If the initial hyperparameters should be kept fixed, None can be passed as optimizer.

The noise level in the targets can be specified by passing it via the parameter alpha, either globally as a scalar or per datapoint. Note that a moderate noise level can also be helpful for dealing with numeric issues during fitting as it is effectively implemented as Tikhonov regularization, i.e., by adding it to the diagonal of the kernel matrix. An alternative to specifying the noise level explicitly is to include a WhiteKernel component into the kernel, which can estimate the global noise level from the data (see example below).

The implementation is based on Algorithm 2.1 of [RW2006]. In addition to the API of standard scikit-learn estimators, GaussianProcessRegressor:

- allows prediction without prior fitting (based on the GP prior)
- provides an additional method sample_y(X), which evaluates samples drawn from the GPR (prior or posterior) at given inputs
• exposes a method `log_marginal_likelihood(theta)`, which can be used externally for other ways of selecting hyperparameters, e.g., via Markov chain Monte Carlo.

GPR examples

GPR with noise-level estimation

This example illustrates that GPR with a sum-kernel including a WhiteKernel can estimate the noise level of data. An illustration of the log-marginal-likelihood (LML) landscape shows that there exist two local maxima of LML.

```
Initial: 1**2 * RBF(length_scale=100) + WhiteKernel(noise_level=1)
Optimum: 0.00316**2 * RBF(length_scale=109) + WhiteKernel(noise_level=1)
Log-Marginal-Likelihood: -23.87233736198489
```

The first corresponds to a model with a high noise level and a large length scale, which explains all variations in the data by noise.

The second one has a smaller noise level and shorter length scale, which explains most of the variation by the noise-free functional relationship. The second model has a higher likelihood; however, depending on the initial value for the hyperparameters, the gradient-based optimization might also converge to the high-noise solution. It is thus important to repeat the optimization several times for different initializations.
Initial: \(1^{**2} * \text{RBF}(\text{length\_scale}=1) + \text{WhiteKernel}(\text{noise\_level}=1e-05)\)
Optimum: \(0.64^{**2} * \text{RBF}(\text{length\_scale}=0.365) + \text{WhiteKernel}(\text{noise\_level}=0)\).
Log-Marginal-Likelihood: -21.805090890162035
Comparison of GPR and Kernel Ridge Regression

Both kernel ridge regression (KRR) and GPR learn a target function by employing internally the “kernel trick”. KRR learns a linear function in the space induced by the respective kernel which corresponds to a non-linear function in the original space. The linear function in the kernel space is chosen based on the mean-squared error loss with ridge regularization. GPR uses the kernel to define the covariance of a prior distribution over the target functions and uses the observed training data to define a likelihood function. Based on Bayes theorem, a (Gaussian) posterior distribution over target functions is defined, whose mean is used for prediction.

A major difference is that GPR can choose the kernel’s hyperparameters based on gradient-ascent on the marginal likelihood function while KRR needs to perform a grid search on a cross-validated loss function (mean-squared error loss). A further difference is that GPR learns a generative, probabilistic model of the target function and can thus provide meaningful confidence intervals and posterior samples along with the predictions while KRR only provides predictions.

The following figure illustrates both methods on an artificial dataset, which consists of a sinusoidal target function and strong noise. The figure compares the learned model of KRR and GPR based on a ExpSineSquared kernel, which is suited for learning periodic functions. The kernel’s hyperparameters control the smoothness (length scale) and periodicity of the kernel (periodicity). Moreover, the noise level of the data is learned explicitly by GPR by an additional WhiteKernel component in the kernel and by the regularization parameter alpha of KRR.

The figure shows that both methods learn reasonable models of the target function. GPR correctly identifies the periodicity of the function to be roughly $2 \pi$ (6.28), while KRR chooses the doubled periodicity $4 \pi$. Besides that, GPR provides reasonable confidence bounds on the prediction which are not available for KRR. A major difference between the two methods is the time required for fitting and predicting: while fitting KRR is fast in principle, the grid-search for hyperparameter optimization scales exponentially with the number of hyperparameters (“curse of dimensionality”). The gradient-based optimization of the parameters in GPR does not suffer from this exponential scaling and is thus considerably faster on this example with 3-dimensional hyperparameter space. The time for predicting is similar; however, generating the variance of the predictive distribution of GPR takes considerable longer than just predicting the mean.
GPR on Mauna Loa CO2 data

This example is based on Section 5.4.3 of [RW2006]. It illustrates an example of complex kernel engineering and hyperparameter optimization using gradient ascent on the log-marginal-likelihood. The data consists of the monthly average atmospheric CO2 concentrations (in parts per million by volume (ppmv)) collected at the Mauna Loa Observatory in Hawaii, between 1958 and 1997. The objective is to model the CO2 concentration as a function of the time $t$.

The kernel is composed of several terms that are responsible for explaining different properties of the signal:

- a long term, smooth rising trend is to be explained by an RBF kernel. The RBF kernel with a large length-scale enforces this component to be smooth; it is not enforced that the trend is rising which leaves this choice to the GP. The specific length-scale and the amplitude are free hyperparameters.
- a seasonal component, which is to be explained by the periodic ExpSineSquared kernel with a fixed periodicity of 1 year. The length-scale of this periodic component, controlling its smoothness, is a free parameter. In order to allow decaying away from exact periodicity, the product with an RBF kernel is taken. The length-scale of this RBF component controls the decay time and is a further free parameter.
- smaller, medium term irregularities are to be explained by a RationalQuadratic kernel component, whose length-scale and alpha parameter, which determines the diffuseness of the length-scales, are to be determined. According to [RW2006], these irregularities can better be explained by a RationalQuadratic than an RBF kernel component, probably because it can accommodate several length-scales.
- a “noise” term, consisting of an RBF kernel contribution, which shall explain the correlated noise components such as local weather phenomena, and a WhiteKernel contribution for the white noise. The relative amplitudes and the RBF’s length scale are further free parameters.

Maximizing the log-marginal-likelihood after subtracting the target’s mean yields the following kernel with an LML of -83.214:

$$34.4^{\times}2 \times \text{RBF}(\text{length\_scale}=41.8)$$
$$+ 3.27^{\times}2 \times \text{RBF}(\text{length\_scale}=180) \times \text{ExpSineSquared}(\text{length\_scale}=1.44, \text{periodicity}=1)$$
$$+ 0.446^{\times}2 \times \text{RationalQuadratic}(\text{alpha}=17.7, \text{length\_scale}=0.957)$$
$$+ 0.197^{\times}2 \times \text{RBF}(\text{length\_scale}=0.138) + \text{WhiteKernel}(\text{noise\_level}=0.0336)$$

Thus, most of the target signal (34.4 ppm) is explained by a long-term rising trend (length-scale 41.8 years). The periodic component has an amplitude of 3.27 ppm, a decay time of 180 years and a length-scale of 1.44. The long decay time indicates that we have a locally very close to periodic seasonal component. The correlated noise has an amplitude of 0.197 ppm with a length scale of 0.138 years and a white-noise contribution of 0.0336 ppm. Thus, the overall noise level is very small, indicating that the data can be very well explained by the model. The figure shows also that the model makes very confident predictions until around 2015.

Gaussian Process Classification (GPC)

The GaussianProcessClassifier implements Gaussian processes (GP) for classification purposes, more specifically for probabilistic classification, where test predictions take the form of class probabilities. GaussianProcessClassifier places a GP prior on a latent function $f$, which is then squashed through a link function to obtain the probabilistic classification. The latent function $f$ is a so-called nuisance function, whose values are not observed and are not relevant by themselves. Its purpose is to allow a convenient formulation of the model, and $f$ is removed (integrated out) during prediction. GaussianProcessClassifier implements the logistic link function, for which the integral cannot be computed analytically but is easily approximated in the binary case.

In contrast to the regression setting, the posterior of the latent function $f$ is not Gaussian even for a GP prior since a Gaussian likelihood is inappropriate for discrete class labels. Rather, a non-Gaussian likelihood corresponding to
Atmospheric CO₂ concentration at Mauna Loa
the logistic link function (logit) is used. GaussianProcessClassifier approximates the non-Gaussian posterior with a
Gaussian based on the Laplace approximation. More details can be found in Chapter 3 of [RW2006].

The GP prior mean is assumed to be zero. The prior’s covariance is specified by passing a kernel object. The hyper-
parameters of the kernel are optimized during fitting of GaussianProcessRegressor by maximizing the log-marginal-
likelihood (LML) based on the passed optimizer. As the LML may have multiple local optima, the optimizer can
be started repeatedly by specifying n_restarts_optimizer. The first run is always conducted starting from the
initial hyperparameter values of the kernel; subsequent runs are conducted from hyperparameter values that have been
chosen randomly from the range of allowed values. If the initial hyperparameters should be kept fixed, None can be
passed as optimizer.

GaussianProcessClassifier supports multi-class classification by performing either one-versus-rest or one-
versus-one based training and prediction. In one-versus-rest, one binary Gaussian process classifier is fitted for each
class, which is trained to separate this class from the rest. In “one_vs_one”, one binary Gaussian process classifier is
fitted for each pair of classes, which is trained to separate these two classes. The predictions of these binary predictors
are combined into multi-class predictions. See the section on multi-class classification for more details.

In the case of Gaussian process classification, “one_vs_one” might be computationally cheaper since it has to solve
many problems involving only a subset of the whole training set rather than fewer problems on the whole dataset. Since
Gaussian process classification scales cubically with the size of the dataset, this might be considerably faster. How-
ever, note that “one_vs_one” does not support predicting probability estimates but only plain predictions. Moreover,
note that GaussianProcessClassifier does not (yet) implement a true multi-class Laplace approximation in-
ternally, but as discussed above is based on solving several binary classification tasks internally, which are combined
using one-versus-rest or one-versus-one.

**GPC examples**

**Probabilistic predictions with GPC**

This example illustrates the predicted probability of GPC for an RBF kernel with different choices of the hyperparam-
eters. The first figure shows the predicted probability of GPC with arbitrarily chosen hyperparameters and with the
hyperparameters corresponding to the maximum log-marginal-likelihood (LML).

While the hyperparameters chosen by optimizing LML have a considerable larger LML, they perform slightly worse
according to the log-loss on test data. The figure shows that this is because they exhibit a steep change of the class
probabilities at the class boundaries (which is good) but have predicted probabilities close to 0.5 far away from the
class boundaries (which is bad). This undesirable effect is caused by the Laplace approximation used internally by
GPC.

The second figure shows the log-marginal-likelihood for different choices of the kernel’s hyperparameters, highlighting
the two choices of the hyperparameters used in the first figure by black dots.

**Illustration of GPC on the XOR dataset**

This example illustrates GPC on XOR data. Compared are a stationary, isotropic kernel (RBF) and a non-stationary
kernel (DotProduct). On this particular dataset, the DotProduct kernel obtains considerably better results be-
cause the class-boundaries are linear and coincide with the coordinate axes. In practice, however, stationary kernels
such as RBF often obtain better results.
4.1. Supervised learning
Gaussian process classification (GPC) on iris dataset

This example illustrates the predicted probability of GPC for an isotropic and anisotropic RBF kernel on a two-dimensional version for the iris-dataset. This illustrates the applicability of GPC to non-binary classification. The anisotropic RBF kernel obtains slightly higher log-marginal-likelihood by assigning different length-scales to the two feature dimensions.

Kernels for Gaussian Processes

Kernels (also called “covariance functions” in the context of GPs) are a crucial ingredient of GPs which determine the shape of prior and posterior of the GP. They encode the assumptions on the function being learned by defining the “similarity” of two datapoints combined with the assumption that similar datapoints should have similar target values. Two categories of kernels can be distinguished: stationary kernels depend only on the distance of two datapoints and not on their absolute values \( k(x_i, x_j) = k(d(x_i, x_j)) \) and are thus invariant to translations in the input space, while non-stationary kernels depend also on the specific values of the datapoints. Stationary kernels can further be subdivided into isotropic and anisotropic kernels, where isotropic kernels are also invariant to rotations in the input space. For more details, we refer to Chapter 4 of [RW2006]. For guidance on how to best combine different kernels, we refer to [Duv2014].

Gaussian Process Kernel API

The main usage of a Kernel is to compute the GP’s covariance between datapoints. For this, the method __call__ of the kernel can be called. This method can either be used to compute the “auto-covariance” of all pairs of datapoints in a 2d array X, or the “cross-covariance” of all combinations of datapoints of a 2d array X with datapoints in a 2d array Y. The following identity holds true for all kernels k (except for the WhiteKernel): \( k(X) = K(X, Y=X) \)

If only the diagonal of the auto-covariance is being used, the method diag() of a kernel can be called, which is more computationally efficient than the equivalent call to __call__: \( \text{np.diag}(k(X, X)) = k\text{.diag}(X) \)

Kernels are parameterized by a vector \( \theta \) of hyperparameters. These hyperparameters can for instance control length-scales or periodicity of a kernel (see below). All kernels support computing analytic gradients of the kernel’s auto-covariance with respect to \( \log(\theta) \) via setting eval_gradient=True in the __call__ method. That is,
a \((\text{len}(X), \text{len}(X), \text{len}(\theta))\) array is returned where the entry \([i, j, l]\) contains \(\frac{\partial^2 \mathcal{L}}{\partial \theta_i \partial \theta_j}\). This gradient is used by the Gaussian process (both regressor and classifier) in computing the gradient of the log-marginal-likelihood, which in turn is used to determine the value of \(\theta\), which maximizes the log-marginal-likelihood, via gradient ascent. For each hyperparameter, the initial value and the bounds need to be specified when creating an instance of the kernel. The current value of \(\theta\) can be get and set via the property \(\text{theta}\) of the kernel object. Moreover, the bounds of the hyperparameters can be accessed by the property \(\text{bounds}\) of the kernel. Note that both properties (theta and bounds) return log-transformed values of the internally used values since those are typically more amenable to gradient-based optimization. The specification of each hyperparameter is stored in the form of an instance of \(\text{Hyperparameter}\) in the respective kernel. Note that a kernel using a hyperparameter with name “x” must have the attributes \(\text{self.x}\) and \(\text{self.x.bounds}\).

The abstract base class for all kernels is \(\text{Kernel}\). Kernel implements a similar interface as \(\text{Estimator}\), providing the methods \(\text{get_params()}\), \(\text{set_params()}\), and \(\text{clone()}\). This allows setting kernel values also via meta-estimators such as \(\text{Pipeline}\) or \(\text{GridSearch}\). Note that due to the nested structure of kernels (by applying kernel operators, see below), the names of kernel parameters might become relatively complicated. In general, for a binary kernel operator, parameters of the left operand are prefixed with \(\text{k1__}\) and parameters of the right operand with \(\text{k2__}\). An additional convenience method is \(\text{clone_with_theta(\theta)}\), which returns a cloned version of the kernel but with the hyperparameters set to \(\theta\). An illustrative example:

```python
>>> from sklearn.gaussian_process.kernels import ConstantKernel, RBF
>>> kernel = ConstantKernel(constant_value=1.0, constant_value_bounds=(0.0, 10.0)) * RBF(length_scale=0.5, length_scale_bounds=(0.0, 10.0)) + RBF(length_scale=2.0, length_scale_bounds=(0.0, 10.0))
>>> for hyperparameter in kernel.hyperparameters: print(hyperparameter)
Hyperparameter(name='k1__k1__constant_value', value_type='numeric', bounds=array([[ 0., 10.]]), n_elements=1, fixed=False)
Hyperparameter(name='k1__k2__length_scale', value_type='numeric', bounds=array([[ 0., 10.]]), n_elements=1, fixed=False)
Hyperparameter(name='k2__length_scale', value_type='numeric', bounds=array([[ 0., 10.]]), n_elements=1, fixed=False)
>>> params = kernel.get_params()
>>> for key in sorted(params): print("%s : %s \%(key, params[key])")
  k1 : 1**2 * RBF(length_scale=0.5)
  k1__k1 : 1**2
  k1__k1__constant_value : 1.0
  k1__k1__constant_value_bounds : (0.0, 10.0)
  k1__k2 : RBF(length_scale=0.5)
  k1__k2__length_scale : 0.5
  k1__k2__length_scale_bounds : (0.0, 10.0)
  k2 : RBF(length_scale=2)
  k2__length_scale : 2.0
  k2__length_scale_bounds : (0.0, 10.0)
>>> print(kernel.theta)  # Note: log-transformed
[ 0. -0.69314718  0.69314718]
>>> print(kernel.bounds)  # Note: log-transformed
[[ -inf 2.30258509]
 [ -inf 2.30258509]
 [ -inf 2.30258509]]
```

All Gaussian process kernels are interoperable with \(\text{sklearn.metrics.pairwise}\) and vice versa: instances of subclasses of \(\text{Kernel}\) can be passed as metric to \(\text{pairwise_kernels}\) from \(\text{sklearn.metrics.pairwise}\). Moreover, kernel functions from pairwise can be used as GP kernels by using the wrapper class \(\text{PairwiseKernel}\). The only caveat is that the gradient of the hyperparameters is not analytic but numeric and all those kernels support only isotropic distances. The parameter \(\gamma\) is considered to be a hyperparameter and may be optimized. The other kernel parameters are set directly at initialization and are kept fixed.
Basic kernels

The `ConstantKernel` kernel can be used as part of a `Product` kernel where it scales the magnitude of the other factor (kernel) or as part of a `Sum` kernel, where it modifies the mean of the Gaussian process. It depends on a parameter `constant_value`. It is defined as:

\[ k(x_i, x_j) = constant_value \forall x_1, x_2 \]

The main use-case of the `WhiteKernel` kernel is as part of a sum-kernel where it explains the noise-component of the signal. Tuning its parameter `noise_level` corresponds to estimating the noise-level. It is defined as:

\[ k(x_i, x_j) = noise_level \text{ if } x_i == x_j \text{ else } 0 \]

Kernel operators

Kernel operators take one or two base kernels and combine them into a new kernel. The `Sum` kernel takes two kernels \( k_1 \) and \( k_2 \) and combines them via \( k_{\text{sum}}(X, Y) = k_1(X, Y) + k_2(X, Y) \). The `Product` kernel takes two kernels \( k_1 \) and \( k_2 \) and combines them via \( k_{\text{product}}(X, Y) = k_1(X, Y) \ast k_2(X, Y) \). The `Exponentiation` kernel takes one base kernel and a scalar parameter \( p \) and combines them via \( k_{\text{exp}}(X, Y) = k(X, Y)^p \). Note that magic methods `__add__`, `__mul__` and `__pow__` are overridden on the Kernel objects, so one can use e.g. `RBF() + RBF()` as a shortcut for `Sum(RBF(), RBF())`.

Radial-basis function (RBF) kernel

The `RBF` kernel is a stationary kernel. It is also known as the “squared exponential” kernel. It is parameterized by a length-scale parameter \( l > 0 \), which can either be a scalar (isotropic variant of the kernel) or a vector with the same number of dimensions as the inputs \( x \) (anisotropic variant of the kernel). The kernel is given by:

\[ k(x_i, x_j) = \exp\left(-\frac{d(x_i, x_j)^2}{2l^2}\right) \]

where \( d(\cdot, \cdot) \) is the Euclidean distance. This kernel is infinitely differentiable, which implies that GPs with this kernel as covariance function have mean square derivatives of all orders, and are thus very smooth. The prior and posterior of a GP resulting from an RBF kernel are shown in the following figure:

Matérn kernel

The `Matern` kernel is a stationary kernel and a generalization of the RBF kernel. It has an additional parameter \( \nu \) which controls the smoothness of the resulting function. It is parameterized by a length-scale parameter \( l > 0 \), which can either be a scalar (isotropic variant of the kernel) or a vector with the same number of dimensions as the inputs \( x \) (anisotropic variant of the kernel). The kernel is given by:

\[ k(x_i, x_j) = \frac{1}{\Gamma(\nu)2^{\nu-1}} \left(\frac{\sqrt{2\nu}}{l} d(x_i, x_j)\right)^\nu K_{\nu} \left(\frac{\sqrt{2\nu}}{l} d(x_i, x_j)\right) \]

where \( d(\cdot, \cdot) \) is the Euclidean distance, \( K_{\nu}(\cdot) \) is a modified Bessel function and \( \Gamma(\cdot) \) is the gamma function. As \( \nu \to \infty \), the Matérn kernel converges to the RBF kernel. When \( \nu = 1/2 \), the Matérn kernel becomes identical to the absolute exponential kernel, i.e.,

\[ k(x_i, x_j) = \exp\left(-\frac{1}{l} d(x_i, x_j)\right) \quad \nu = \frac{1}{2} \]
In particular, \( \nu = 3/2 \):

\[
k(x_i, x_j) = \left( 1 + \frac{\sqrt{3}}{l}d(x_i, x_j) \right) \exp \left( -\frac{\sqrt{3}}{l}d(x_i, x_j) \right) \quad \nu = \frac{3}{2}
\]

and \( \nu = 5/2 \):

\[
k(x_i, x_j) = \left( 1 + \frac{\sqrt{5}}{l}d(x_i, x_j) + \frac{5}{3l^3}d(x_i, x_j)^2 \right) \exp \left( -\frac{\sqrt{5}}{l}d(x_i, x_j) \right) \quad \nu = \frac{5}{2}
\]

are popular choices for learning functions that are not infinitely differentiable (as assumed by the RBF kernel) but at
least once (\( \nu = 3/2 \)) or twice differentiable (\( \nu = 5/2 \)).

The flexibility of controlling the smoothness of the learned function via \( \nu \) allows adapting to the properties of the
true underlying functional relation. The prior and posterior of a GP resulting from a Matérn kernel are shown in the
following figure:

See [RW2006], pp84 for further details regarding the different variants of the Matérn kernel.

**Rational quadratic kernel**

The `RationalQuadratic` kernel can be seen as a scale mixture (an infinite sum) of `RBF` kernels with different
characteristic length-scales. It is parameterized by a length-scale parameter \( l > 0 \) and a scale mixture parameter \( \alpha > 0 \)
Only the isotropic variant where \( l \) is a scalar is supported at the moment. The kernel is given by:

\[
k(x_i, x_j) = \left( 1 + \frac{d(x_i, x_j)^2}{2\alpha l^2} \right)^{-\alpha}
\]

The prior and posterior of a GP resulting from a `RationalQuadratic` kernel are shown in the following figure:

**Exp-Sine-Squared kernel**

The `ExpSineSquared` kernel allows modeling periodic functions. It is parameterized by a length-scale parameter \( l > 0 \) and a periodicity parameter \( p > 0 \). Only the isotropic variant where \( l \) is a scalar is supported at the moment. The kernel is given by:

\[
k(x_i, x_j) = \exp \left( -\frac{2\sin^2(\pi d(x_i, x_j)/p)}{l^2} \right)
\]

The prior and posterior of a GP resulting from an `ExpSineSquared` kernel are shown in the following figure:

**Dot-Product kernel**

The `DotProduct` kernel is non-stationary and can be obtained from linear regression by putting \( N(0, 1) \) priors on
the coefficients of \( x_d(d = 1, \ldots, D) \) and a prior of \( N(0, \sigma_0^2) \) on the bias. The `DotProduct` kernel is invariant to a
rotation of the coordinates about the origin, but not translations. It is parameterized by a parameter \( \sigma_0^2 \). For \( \sigma_0^2 = 0 \),
the kernel is called the homogeneous linear kernel, otherwise it is inhomogeneous. The kernel is given by

\[
k(x_i, x_j) = \sigma_0^2 + x_i \cdot x_j
\]

The `DotProduct` kernel is commonly combined with exponentiation. An example with exponent 2 is shown in the
following figure:

4.1. Supervised learning
4.1. Supervised learning
4.1.8 Cross decomposition

The cross decomposition module contains supervised estimators for dimensionality reduction and regression, belonging to the “Partial Least Squares” family.

Cross decomposition algorithms find the fundamental relations between two matrices (X and Y). They are latent variable approaches to modeling the covariance structures in these two spaces. They will try to find the multidimensional direction in the X space that explains the maximum multidimensional variance direction in the Y space. In other words, PLS projects both X and Y into a lower-dimensional subspace such that the covariance between transformed(X) and transformed(Y) is maximal.

PLS draws similarities with Principal Component Regression (PCR), where the samples are first projected into a lower-dimensional subspace, and the targets y are predicted using transformed(X). One issue with PCR is that the dimensionality reduction is unsupervised, and may lose some important variables: PCR would keep the features with the most variance, but it’s possible that features with a small variances are relevant from predicting the target. In a way, PLS allows for the same kind of dimensionality reduction, but by taking into account the targets y. An illustration of this fact is given in the following example: *Principal Component Regression vs Partial Least Squares Regression.*

Apart from CCA, the PLS estimators are particularly suited when the matrix of predictors has more variables than observations, and when there is multicollinearity among the features. By contrast, standard linear regression would fail in these cases unless it is regularized.

Classes included in this module are PLSRegression, PLSCanonical, CCA and PLSSVD.
**PLSCanonical**

We here describe the algorithm used in *PLSCanonical*. The other estimators use variants of this algorithm, and are detailed below. We recommend section 1 for more details and comparisons between these algorithms. In 1, *PLSCanonical* corresponds to “PLSW2A”.

Given two centered matrices $X \in \mathbb{R}^{n \times d}$ and $Y \in \mathbb{R}^{n \times t}$, and a number of components $K$, *PLSCanonical* proceeds as follows:

Set $X_1$ to $X$ and $Y_1$ to $Y$. Then, for each $k \in [1, K]$:

- a) compute $u_k \in \mathbb{R}^d$ and $v_k \in \mathbb{R}^t$, the first left and right singular vectors of the cross-covariance matrix $C = X_k^T Y_k$. $u_k$ and $v_k$ are called the weights. By definition, $u_k$ and $v_k$ are chosen so that they maximize the covariance between the projected $X_k$ and the projected target, that is $\text{Cov}(X_k u_k, Y_k v_k)$.

- b) Project $X_k$ and $Y_k$ on the singular vectors to obtain scores: $\xi_k = X_k u_k$ and $\omega_k = Y_k v_k$.

- c) Regress $X_k$ on $\xi_k$, i.e. find a vector $\gamma_k \in \mathbb{R}^d$ such that the rank-1 matrix $\xi_k \gamma_k^T$ is as close as possible to $X_k$.

Do the same on $Y_k$ with $\omega_k$ to obtain $\delta_k$. The vectors $\gamma_k$ and $\delta_k$ are called the loadings.

- d) Deflate $X_k$ and $Y_k$, i.e. subtract the rank-1 approximations: $X_{k+1} = X_k - \xi_k \gamma_k^T$, and $Y_{k+1} = Y_k - \omega_k \delta_k^T$.

At the end, we have approximated $X$ as a sum of rank-1 matrices: $X = \Xi \Gamma^T$ where $\Xi \in \mathbb{R}^{n \times K}$ contains the scores in its columns, and $\Gamma^T \in \mathbb{R}^{K \times d}$ contains the loadings in its rows. Similarly for $Y$, we have $Y = \Omega \Delta^T$.

Note that the scores matrices $\Xi$ and $\Omega$ correspond to the projections of the training data $X$ and $Y$, respectively.

Step a) may be performed in two ways: either by computing the whole SVD of $C$ and only retain the singular vectors with the biggest singular values, or by directly computing the singular vectors using the power method (cf section 11.3 in 1), which corresponds to the ‘nipals’ option of the algorithm parameter.

**Transforming data**

To transform $X$ into $\hat{X}$, we need to find a projection matrix $P$ such that $\hat{X} = XP$. We know that for the training data, $\Xi = XP$, and $X = \Xi \Gamma^T$. Setting $P = U(\Gamma^T U)^{-1}$ where $U$ is the matrix with the $u_k$ in the columns, we have $XP = XU(\Gamma^T U)^{-1} = \Xi(\Gamma^T U)(\Gamma^T U)^{-1} = \Xi$ as desired. The rotation matrix $P$ can be accessed from the attribute.

Similarly, $Y$ can be transformed using the rotation matrix $V(\Delta^T V)^{-1}$, accessed via the attribute.

**Predicting the targets $Y$**

To predict the targets of some data $X$, we are looking for a coefficient matrix $\beta \in \mathbb{R}^{d \times t}$ such that $Y = X \beta$.

The idea is to try to predict the transformed targets $\Omega$ as a function of the transformed samples $\Xi$, by computing $\alpha \in \mathbb{R}$ such that $\Omega = \alpha \Xi$.

Then, we have $Y = \Omega \Delta^T = \alpha \Xi \Delta^T$, and since $\Xi$ is the transformed training data we have that $Y = X \alpha P \Delta^T$, and as a result the coefficient matrix $\beta = \alpha P \Delta^T$.

$\beta$ can be accessed through the attribute.

---

1 A survey of Partial Least Squares (PLS) methods, with emphasis on the two-block case JA Wegelin
PLSSVD

PLSSVD is a simplified version of PLSCanonical described earlier: instead of iteratively deflating the matrices $X_k$ and $Y_k$, PLSSVD computes the SVD of $C = X^TY$ only once, and stores the n_components singular vectors corresponding to the biggest singular values in the matrices $U$ and $V$, corresponding to the x_weights_ and y_weights_ attributes. Here, the transformed data is simply $\text{transformed}(X) = XU$ and $\text{transformed}(Y) = YV$.

If n_components == 1, PLSSVD and PLSCanonical are strictly equivalent.

PLSRegression

The PLSRegression estimator is similar to PLSCanonical with algorithm='nipals', with 2 significant differences:

- at step a) in the power method to compute $u_k$ and $v_k$, $v_k$ is never normalized.
- at step c), the targets $Y_k$ are approximated using the projection of $X_k$ (i.e. $\xi_k$) instead of the projection of $Y_k$ (i.e. $\omega_k$). In other words, the loadings computation is different. As a result, the deflation in step d) will also be affected.

These two modifications affect the output of predict and transform, which are not the same as for PLSCanonical. Also, while the number of components is limited by min(n_samples, n_features, n_targets) in PLSCanonical, here the limit is the rank of $X^TX$, i.e. min(n_samples, n_features).

PLSRegression is also known as PLS1 (single targets) and PLS2 (multiple targets). Much like Lasso, PLSRegression is a form of regularized linear regression where the number of components controls the strength of the regularization.

Canonical Correlation Analysis

Canonical Correlation Analysis was developed prior and independently to PLS. But it turns out that CCA is a special case of PLS, and corresponds to PLS in “Mode B” in the literature.

CCA differs from PLSCanonical in the way the weights $u_k$ and $v_k$ are computed in the power method of step a). Details can be found in section 10 of¹.

Since CCA involves the inversion of $X_k^TX_k$ and $Y_k^TY_k$, this estimator can be unstable if the number of features or targets is greater than the number of samples.

Naive Bayes

Naive Bayes methods are a set of supervised learning algorithms based on applying Bayes’ theorem with the “naive” assumption of conditional independence between every pair of features given the value of the class variable. Bayes’ theorem states the following relationship, given class variable \( y \) and dependent feature vector \( x_1 \) through \( x_n \):

\[
P(y \mid x_1, \ldots, x_n) = \frac{P(y)P(x_1, \ldots, x_n \mid y)}{P(x_1, \ldots, x_n)}
\]

Using the naive conditional independence assumption that

\[
P(x_i \mid y, x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n) = P(x_i \mid y),
\]

for all \( i \), this relationship is simplified to

\[
P(y \mid x_1, \ldots, x_n) = \frac{P(y) \prod_{i=1}^{n} P(x_i \mid y) }{P(x_1, \ldots, x_n)}
\]

Since \( P(x_1, \ldots, x_n) \) is constant given the input, we can use the following classification rule:

\[
P(y \mid x_1, \ldots, x_n) \propto P(y) \prod_{i=1}^{n} P(x_i \mid y) \\
\downarrow
\]

\[
\hat{y} = \arg \max_{y} P(y) \prod_{i=1}^{n} P(x_i \mid y),
\]

and we can use Maximum A Posteriori (MAP) estimation to estimate \( P(y) \) and \( P(x_i \mid y) \); the former is then the relative frequency of class \( y \) in the training set.

The different naive Bayes classifiers differ mainly by the assumptions they make regarding the distribution of \( P(x_i \mid y) \).

In spite of their apparently over-simplified assumptions, naive Bayes classifiers have worked quite well in many real-world situations, famously document classification and spam filtering. They require a small amount of training data to estimate the necessary parameters. (For theoretical reasons why naive Bayes works well, and on which types of data it does, see the references below.)

Naive Bayes learners and classifiers can be extremely fast compared to more sophisticated methods. The decoupling of the class conditional feature distributions means that each distribution can be independently estimated as a one dimensional distribution. This in turn helps to alleviate problems stemming from the curse of dimensionality.

On the flip side, although naive Bayes is known as a decent classifier, it is known to be a bad estimator, so the probability outputs from `predict_proba` are not to be taken too seriously.

References:

Gaussian Naive Bayes

`GaussianNB` implements the Gaussian Naive Bayes algorithm for classification. The likelihood of the features is assumed to be Gaussian:

\[
P(x_i \mid y) = \frac{1}{\sqrt{2\pi \sigma_y^2}} \exp\left(-\frac{(x_i - \mu_y)^2}{2\sigma_y^2}\right)
\]

The parameters \( \sigma_y \) and \( \mu_y \) are estimated using maximum likelihood.

```python
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.naive_bayes import GaussianNB

X, y = load_iris(return_X_y=True)
X_train, X_test, y_train, y_test = train_test_split(X, y, test_size=0.5, random_state=0)

gnb = GaussianNB()
y_pred = gnb.fit(X_train, y_train).predict(X_test)

print("Number of mislabeled points out of a total %d points : %d"
... % (X_test.shape[0], (y_test != y_pred).sum()))
```

Multinomial Naive Bayes

`MultinomialNB` implements the naive Bayes algorithm for multinomially distributed data, and is one of the two classic naive Bayes variants used in text classification (where the data are typically represented as word vector counts, although tf-idf vectors are also known to work well in practice). The distribution is parametrized by vectors \( \theta_y = (\theta_{y1}, \ldots, \theta_{yn}) \) for each class \( y \), where \( n \) is the number of features (in text classification, the size of the vocabulary) and \( \theta_{yi} \) is the probability \( P(x_i \mid y) \) of feature \( i \) appearing in a sample belonging to class \( y \).

The parameters \( \theta_y \) is estimated by a smoothed version of maximum likelihood, i.e. relative frequency counting:

\[
\hat{\theta}_{yi} = \frac{N_{yi} + \alpha}{N_y + \alpha n}
\]

where \( N_{yi} = \sum_{x \in T} x_i \) is the number of times feature \( i \) appears in a sample of class \( y \) in the training set \( T \), and \( N_y = \sum_{i=1}^{n} N_{yi} \) is the total count of all features for class \( y \).

The smoothing priors \( \alpha \geq 0 \) accounts for features not present in the learning samples and prevents zero probabilities in further computations. Setting \( \alpha = 1 \) is called Laplace smoothing, while \( \alpha < 1 \) is called Lidstone smoothing.

Complement Naive Bayes

`ComplementNB` implements the complement naive Bayes (CNB) algorithm. CNB is an adaptation of the standard multinomial naive Bayes (MNB) algorithm that is particularly suited for imbalanced data sets. Specifically, CNB uses statistics from the complement of each class to compute the model’s weights. The inventors of CNB show empirically that the parameter estimates for CNB are more stable than those for MNB. Further, CNB regularly outperforms MNB (often by a considerable margin) on text classification tasks. The procedure for calculating the weights is as follows:

\[
\hat{\theta}_{ci} = \frac{\alpha + \sum_{j:y_j \neq c} d_{ij}}{\alpha + \sum_{j:y_j \neq c} \sum_k d_{kj}}
\]

\[
w_{ci} = \log \hat{\theta}_{ci}
\]

\[
w_{ci} = \frac{w_{ci}}{\sum_j |w_{cj}|}
\]
where the summations are over all documents $j$ not in class $c$, $d_{ij}$ is either the count or tf-idf value of term $i$ in document $j$, $\alpha_i$ is a smoothing hyperparameter like that found in MNB, and $\alpha = \sum_i \alpha_i$. The second normalization addresses the tendency for longer documents to dominate parameter estimates in MNB. The classification rule is:

$$
\hat{c} = \arg\min_c \sum_i t_i w_{ci}
$$

i.e., a document is assigned to the class that is the poorest complement match.

### Bernoulli Naive Bayes

$\text{BernoulliNB}$ implements the naive Bayes training and classification algorithms for data that is distributed according to multivariate Bernoulli distributions; i.e., there may be multiple features but each one is assumed to be a binary-valued (Bernoulli, boolean) variable. Therefore, this class requires samples to be represented as binary-valued feature vectors; if handed any other kind of data, a $\text{BernoulliNB}$ instance may binarize its input (depending on the $\text{binarize}$ parameter).

The decision rule for Bernoulli naive Bayes is based on

$$
P(x_i \mid y) = P(i \mid y)x_i + (1 - P(i \mid y))(1 - x_i)
$$

which differs from multinomial NB’s rule in that it explicitly penalizes the non-occurrence of a feature $i$ that is an indicator for class $y$, where the multinomial variant would simply ignore a non-occurring feature.

In the case of text classification, word occurrence vectors (rather than word count vectors) may be used to train and use this classifier. $\text{BernoulliNB}$ might perform better on some datasets, especially those with shorter documents. It is advisable to evaluate both models, if time permits.

### References:

### Categorical Naive Bayes

$\text{CategoricalNB}$ implements the categorical naive Bayes algorithm for categorically distributed data. It assumes that each feature, which is described by the index $i$, has its own categorical distribution.

For each feature $i$ in the training set $X$, $\text{CategoricalNB}$ estimates a categorical distribution for each feature $i$ of $X$ conditioned on the class $y$. The index set of the samples is defined as $J = \{1, \ldots, m\}$, with $m$ as the number of samples.
The probability of category $t$ in feature $i$ given class $c$ is estimated as:

$$P(x_i = t \mid y = c; \alpha) = \frac{N_{tic} + \alpha}{N_c + \alpha n_i}$$

where $N_{tic} = \{j \in J \mid x_{ij} = t, y_j = c\}$ is the number of times category $t$ appears in the samples $x_i$, which belong to class $c$, $N_c = \{j \in J \mid y_j = c\}$ is the number of samples with class $c$, $\alpha$ is a smoothing parameter and $n_i$ is the number of available categories of feature $i$.

**CategoricalNB** assumes that the sample matrix $X$ is encoded (for instance with the help of *OrdinalEncoder*) such that all categories for each feature $i$ are represented with numbers $0, ..., n_i - 1$ where $n_i$ is the number of available categories of feature $i$.

**Out-of-core naive Bayes model fitting**

Naive Bayes models can be used to tackle large scale classification problems for which the full training set might not fit in memory. To handle this case, *MultinomialNB*, *BernoulliNB*, and *GaussianNB* expose a *partial_fit* method that can be used incrementally as done with other classifiers as demonstrated in *Out-of-core classification of text documents*. All naive Bayes classifiers support sample weighting.

Contrary to the *fit* method, the first call to *partial_fit* needs to be passed the list of all the expected class labels.

For an overview of available strategies in scikit-learn, see also the *out-of-core learning* documentation.

**Note:** The *partial_fit* method call of naive Bayes models introduces some computational overhead. It is recommended to use data chunk sizes that are as large as possible, that is as the available RAM allows.

### 4.1.10 Decision Trees

**Decision Trees (DTs)** are a non-parametric supervised learning method used for *classification* and *regression*. The goal is to create a model that predicts the value of a target variable by learning simple decision rules inferred from the data features.

For instance, in the example below, decision trees learn from data to approximate a sine curve with a set of if-then-else decision rules. The deeper the tree, the more complex the decision rules and the fitter the model.

Some advantages of decision trees are:

- Simple to understand and to interpret. Trees can be visualised.
- Requires little data preparation. Other techniques often require data normalisation, dummy variables need to be created and blank values to be removed. Note however that this module does not support missing values.
- The cost of using the tree (i.e., predicting data) is logarithmic in the number of data points used to train the tree.
- Able to handle both numerical and categorical data. However scikit-learn implementation does not support categorical variables for now. Other techniques are usually specialised in analysing datasets that have only one type of variable. See *algorithms* for more information.
- Able to handle multi-output problems.
- Uses a white box model. If a given situation is observable in a model, the explanation for the condition is easily explained by boolean logic. By contrast, in a black box model (e.g., in an artificial neural network), results may be more difficult to interpret.
- Possible to validate a model using statistical tests. That makes it possible to account for the reliability of the model.
Perform well even if its assumptions are somewhat violated by the true model from which the data were generated.

The disadvantages of decision trees include:

- Decision-tree learners can create over-complex trees that do not generalise the data well. This is called overfitting. Mechanisms such as pruning, setting the minimum number of samples required at a leaf node or setting the maximum depth of the tree are necessary to avoid this problem.
- Decision trees can be unstable because small variations in the data might result in a completely different tree being generated. This problem is mitigated by using decision trees within an ensemble.
- The problem of learning an optimal decision tree is known to be NP-complete under several aspects of optimality and even for simple concepts. Consequently, practical decision-tree learning algorithms are based on heuristic algorithms such as the greedy algorithm where locally optimal decisions are made at each node. Such algorithms cannot guarantee to return the globally optimal decision tree. This can be mitigated by training multiple trees in an ensemble learner, where the features and samples are randomly sampled with replacement.
- There are concepts that are hard to learn because decision trees do not express them easily, such as XOR, parity or multiplexer problems.
- Decision tree learners create biased trees if some classes dominate. It is therefore recommended to balance the dataset prior to fitting with the decision tree.
Classification

**DecisionTreeClassifier** is a class capable of performing multi-class classification on a dataset.

As with other classifiers, **DecisionTreeClassifier** takes as input two arrays: an array X, sparse or dense, of shape (n_samples, n_features) holding the training samples, and an array Y of integer values, shape (n_samples,), holding the class labels for the training samples:

```python
>>> from sklearn import tree
>>> X = [[0, 0], [1, 1]]
>>> Y = [0, 1]
>>> clf = tree.DecisionTreeClassifier()
>>> clf = clf.fit(X, Y)
```

After being fitted, the model can then be used to predict the class of samples:

```python
>>> clf.predict([[2., 2.]])
array([1])
```

In case that there are multiple classes with the same and highest probability, the classifier will predict the class with the lowest index amongst those classes.

As an alternative to outputting a specific class, the probability of each class can be predicted, which is the fraction of training samples of the class in a leaf:

```python
>>> clf.predict_proba([[2., 2.]])
array([[0., 1.]])
```

**DecisionTreeClassifier** is capable of both binary (where the labels are [-1, 1]) classification and multiclass (where the labels are [0, ..., K-1]) classification.

Using the Iris dataset, we can construct a tree as follows:

```python
>>> from sklearn.datasets import load_iris
>>> from sklearn import tree
>>> X, y = load_iris(return_X_y=True)
>>> clf = tree.DecisionTreeClassifier()
>>> clf = clf.fit(X, y)
```

Once trained, you can plot the tree with the `plot_tree` function:

```python
>>> tree.plot_tree(clf)
```

We can also export the tree in Graphviz format using the `export_graphviz` exporter. If you use the conda package manager, the graphviz binaries and the python package can be installed with conda install python-graphviz.

Alternatively binaries for graphviz can be downloaded from the graphviz project homepage, and the Python wrapper installed from pypi with pip install graphviz.

Below is an example graphviz export of the above tree trained on the entire iris dataset; the results are saved in an output file iris.pdf:

```python
>>> import graphviz
>>> dot_data = tree.export_graphviz(clf, out_file=None)
>>> graph = graphviz.Source(dot_data)
>>> graph.render("iris")
```
The `export_graphviz` exporter also supports a variety of aesthetic options, including coloring nodes by their class (or value for regression) and using explicit variable and class names if desired. Jupyter notebooks also render these plots inline automatically:

```python
>>> dot_data = tree.export_graphviz(clf, out_file=None,
...                                 feature_names=iris.feature_names,
...                                 class_names=iris.target_names,
...                                 filled=True, rounded=True,
...                                 special_characters=True)
>>> graph = graphviz.Source(dot_data)
>>> graph
```

Alternatively, the tree can also be exported in textual format with the function `export_text`. This method doesn’t require the installation of external libraries and is more compact:

```python
>>> from sklearn.datasets import load_iris
>>> from sklearn.tree import DecisionTreeClassifier
>>> from sklearn.tree import export_text

>>> iris = load_iris()

>>> decision_tree = DecisionTreeClassifier(random_state=0, max_depth=2)

>>> decision_tree = decision_tree.fit(iris.data, iris.target)

>>> r = export_text(decision_tree, feature_names=iris['feature_names'])

>>> print(r)
|--- petal width (cm) <= 0.80
 |   |--- class: 0
 |   |--- petal width (cm) > 0.80
 |   |   |--- petal width (cm) <= 1.75
 |   |   |   |--- class: 1
 |   |   |--- petal width (cm) > 1.75
 |   |   |   |--- class: 2
```

4.1. Supervised learning
Decision surface of a decision tree using paired features
Regression

Decision trees can also be applied to regression problems, using the `DecisionTreeRegressor` class.

As in the classification setting, the fit method will take as argument arrays X and y, only that in this case y is expected to have floating point values instead of integer values:

```python
>>> from sklearn import tree
>>> X = [[0, 0], [2, 2]]
>>> y = [0.5, 2.5]
>>> clf = tree.DecisionTreeRegressor()
>>> clf = clf.fit(X, y)
>>> clf.predict([[1, 1]])
array([0.5])
```

Examples:

- Decision Tree Regression
Multi-output problems

A multi-output problem is a supervised learning problem with several outputs to predict, that is when \( Y \) is a 2d array of shape \((n_{\text{samples}}, n_{\text{outputs}})\).

When there is no correlation between the outputs, a very simple way to solve this kind of problem is to build \( n \) independent models, i.e. one for each output, and then to use those models to independently predict each one of the \( n \) outputs. However, because it is likely that the output values related to the same input are themselves correlated, an often better way is to build a single model capable of predicting simultaneously all \( n \) outputs. First, it requires lower training time since only a single estimator is built. Second, the generalization accuracy of the resulting estimator may often be increased.

With regard to decision trees, this strategy can readily be used to support multi-output problems. This requires the following changes:

- Store \( n \) output values in leaves, instead of 1;
- Use splitting criteria that compute the average reduction across all \( n \) outputs.

This module offers support for multi-output problems by implementing this strategy in both `DecisionTreeClassifier` and `DecisionTreeRegressor`. If a decision tree is fit on an output array \( Y \) of shape \((n_{\text{samples}}, n_{\text{outputs}})\) then the resulting estimator will:

- Output \( n_{\text{output}} \) values upon `predict`;
- Output a list of \( n_{\text{output}} \) arrays of class probabilities upon `predict_proba`.

The use of multi-output trees for regression is demonstrated in `Multi-output Decision Tree Regression`. In this example, the input \( X \) is a single real value and the outputs \( Y \) are the sine and cosine of \( X \).

The use of multi-output trees for classification is demonstrated in `Face completion with a multi-output estimators`. In this example, the inputs \( X \) are the pixels of the upper half of faces and the outputs \( Y \) are the pixels of the lower half of those faces.
Face completion with multi-output estimators

Complexity

In general, the run time cost to construct a balanced binary tree is $O(n_{samples} n_{features} \log(n_{samples}))$ and query time $O(\log(n_{samples}))$. Although the tree construction algorithm attempts to generate balanced trees, they will not always be balanced. Assuming that the subtrees remain approximately balanced, the cost at each node consists of searching through $O(n_{features})$ to find the feature that offers the largest reduction in entropy. This has a cost of $O(n_{features} n_{samples} \log(n_{samples}))$ at each node, leading to a total cost over the entire trees (by summing the cost at each node) of $O(n_{features} n_{samples}^2 \log(n_{samples}))$.

Tips on practical use

- Decision trees tend to overfit on data with a large number of features. Getting the right ratio of samples to number of features is important, since a tree with few samples in high dimensional space is very likely to overfit.
- Consider performing dimensionality reduction (PCA, ICA, or Feature selection) beforehand to give your tree a better chance of finding features that are discriminative.
- Understanding the decision tree structure will help in gaining more insights about how the decision tree makes predictions, which is important for understanding the important features in the data.
- Visualise your tree as you are training by using the export function. Use max_depth=3 as an initial tree depth to get a feel for how the tree is fitting to your data, and then increase the depth.
- Remember that the number of samples required to populate the tree doubles for each additional level the tree grows to. Use max_depth to control the size of the tree to prevent overfitting.
- Use min_samples_split or min_samples_leaf to ensure that multiple samples inform every decision in the tree, by controlling which splits will be considered. A very small number will usually mean the tree will overfit, whereas a large number will prevent the tree from learning the data. Try min_samples_leaf=5 as an initial value. If the sample size varies greatly, a float number can be used as percentage in these two parameters. While min_samples_split can create arbitrarily small leaves, min_samples_leaf guarantees that each leaf has a minimum size, avoiding low-variance, over-fit leaf nodes in regression problems. For classification with few classes, min_samples_leaf=1 is often the best choice.
- Balance your dataset before training to prevent the tree from being biased toward the classes that are dominant. Class balancing can be done by sampling an equal number of samples from each class, or preferably by normalizing the sum of the sample weights (sample_weight) for each class to the same value. Also note that weight-based pre-pruning criteria, such as min_weight_fraction_leaf, will then be less biased toward dominant classes than criteria that are not aware of the sample weights, like min_samples_leaf.
• If the samples are weighted, it will be easier to optimize the tree structure using weight-based pre-pruning criterion such as `min_weight_fraction_leaf`, which ensure that leaf nodes contain at least a fraction of the overall sum of the sample weights.

• All decision trees use `np.float32` arrays internally. If training data is not in this format, a copy of the dataset will be made.

• If the input matrix X is very sparse, it is recommended to convert to sparse `csc_matrix` before calling fit and sparse `csr_matrix` before calling predict. Training time can be orders of magnitude faster for a sparse matrix input compared to a dense matrix when features have zero values in most of the samples.

**Tree algorithms: ID3, C4.5, C5.0 and CART**

What are all the various decision tree algorithms and how do they differ from each other? Which one is implemented in scikit-learn?

ID3 (Iterative Dichotomiser 3) was developed in 1986 by Ross Quinlan. The algorithm creates a multiway tree, finding for each node (i.e. in a greedy manner) the categorical feature that will yield the largest information gain for categorical targets. Trees are grown to their maximum size and then a pruning step is usually applied to improve the ability of the tree to generalise to unseen data.

C4.5 is the successor to ID3 and removed the restriction that features must be categorical by dynamically defining a discrete attribute (based on numerical variables) that partitions the continuous attribute value into a discrete set of intervals. C4.5 converts the trained trees (i.e. the output of the ID3 algorithm) into sets of if-then rules. These accuracy of each rule is then evaluated to determine the order in which they should be applied. Pruning is done by removing a rule’s precondition if the accuracy of the rule improves without it.

C5.0 is Quinlan’s latest version release under a proprietary license. It uses less memory and builds smaller rulesets than C4.5 while being more accurate.

CART (Classification and Regression Trees) is very similar to C4.5, but it differs in that it supports numerical target variables (regression) and does not compute rule sets. CART constructs binary trees using the feature and threshold that yield the largest information gain at each node.

scikit-learn uses an optimised version of the CART algorithm; however, scikit-learn implementation does not support categorical variables for now.

**Mathematical formulation**

Given training vectors $x_i \in \mathbb{R}^n$, $i=1, \ldots, l$ and a label vector $y \in \mathbb{R}^l$, a decision tree recursively partitions the space such that the samples with the same labels are grouped together.

Let the data at node $m$ be represented by $Q$. For each candidate split $\theta = (j, t_m)$ consisting of a feature $j$ and threshold $t_m$, partition the data into $Q_{left}(\theta)$ and $Q_{right}(\theta)$ subsets

$$Q_{left}(\theta) = (x, y) | x_j \leq t_m$$

$$Q_{right}(\theta) = Q \setminus Q_{left}(\theta)$$

The impurity at $m$ is computed using an impurity function $H(\cdot)$, the choice of which depends on the task being solved (classification or regression)

$$G(Q, \theta) = \frac{n_{left}}{N_m} H(Q_{left}(\theta)) + \frac{n_{right}}{N_m} H(Q_{right}(\theta))$$

Select the parameters that minimise the impurity

$$\theta^* = \arg\min_\theta G(Q, \theta)$$

Recurse for subsets $Q_{left}(\theta^*)$ and $Q_{right}(\theta^*)$ until the maximum allowable depth is reached, $N_m < \min_{samples}$ or $N_m = 1$. 

4.1. Supervised learning
Classification criteria

If a target is a classification outcome taking on values 0, 1, . . . , K-1, for node \( m \), representing a region \( R_m \) with \( N_m \) observations, let

\[ p_{mk} = \frac{1}{N_m} \sum_{x_i \in R_m} I(y_i = k) \]

be the proportion of class \( k \) observations in node \( m \)

Common measures of impurity are Gini

\[ H(X_m) = \sum_k p_{mk} (1 - p_{mk}) \]

Entropy

\[ H(X_m) = -\sum_k p_{mk} \log(p_{mk}) \]

and Misclassification

\[ H(X_m) = 1 - \max(p_{mk}) \]

where \( X_m \) is the training data in node \( m \)

Regression criteria

If the target is a continuous value, then for node \( m \), representing a region \( R_m \) with \( N_m \) observations, common criteria to minimise as for determining locations for future splits are Mean Squared Error, which minimizes the L2 error using mean values at terminal nodes, and Mean Absolute Error, which minimizes the L1 error using median values at terminal nodes.

Mean Squared Error:

\[ \bar{y}_m = \frac{1}{N_m} \sum_{i \in N_m} y_i \]

\[ H(X_m) = \frac{1}{N_m} \sum_{i \in N_m} (y_i - \bar{y}_m)^2 \]

Mean Absolute Error:

\[ \text{median}(y)_m = \text{median}(y_i) \]

\[ H(X_m) = \frac{1}{N_m} \sum_{i \in N_m} |y_i - \text{median}(y)_m| \]

where \( X_m \) is the training data in node \( m \)

Minimal Cost-Complexity Pruning

Minimal cost-complexity pruning is an algorithm used to prune a tree to avoid over-fitting, described in Chapter 3 of [BRE]. This algorithm is parameterized by \( \alpha \geq 0 \) known as the complexity parameter. The complexity parameter is used to define the cost-complexity measure, \( R_\alpha(T) \) of a given tree \( T \):

\[ R_\alpha(T) = R(T) + \alpha |\tilde{T}| \]
where $|T|$ is the number of terminal nodes in $T$ and $R(T)$ is traditionally defined as the total misclassification rate of the terminal nodes. Alternatively, scikit-learn uses the total sample weighted impurity of the terminal nodes for $R(T)$. As shown above, the impurity of a node depends on the criterion. Minimal cost-complexity pruning finds the subtree of $T$ that minimizes $R_\alpha(T)$.

The cost complexity measure of a single node is $R_\alpha(t) = R(t) + \alpha t$. The branch, $T_t$, is defined to be a tree where node $t$ is its root. In general, the impurity of a node is greater than the sum of impurities of its terminal nodes, $R(T_t) < R(t)$. However, the cost complexity measure of a node, $t$, and its branch, $T_t$, can be equal depending on $\alpha$. We define the effective $\alpha$ of a node to be the value where they are equal, $R_\alpha(T_t) = R_\alpha(t)$ or $\alpha_{eff}(t) = \frac{R(t) - R(T_t)}{|T| - 1}$. A non-terminal node with the smallest value of $\alpha_{eff}$ is the weakest link and will be pruned. This process stops when the pruned tree's minimal $\alpha_{eff}$ is greater than the $ccp\_alpha$ parameter.

Examples:

- Post pruning decision trees with cost complexity pruning

4.1.11 Ensemble methods

The goal of ensemble methods is to combine the predictions of several base estimators built with a given learning algorithm in order to improve generalizability / robustness over a single estimator.

Two families of ensemble methods are usually distinguished:

- In averaging methods, the driving principle is to build several estimators independently and then to average their predictions. On average, the combined estimator is usually better than any of the single base estimator because its variance is reduced.

  Examples: Bagging methods, Forests of randomized trees, . . .

- By contrast, in boosting methods, base estimators are built sequentially and one tries to reduce the bias of the combined estimator. The motivation is to combine several weak models to produce a powerful ensemble.

  Examples: AdaBoost, Gradient Tree Boosting, . . .
Bagging meta-estimator

In ensemble algorithms, bagging methods form a class of algorithms which build several instances of a black-box estimator on random subsets of the original training set and then aggregate their individual predictions to form a final prediction. These methods are used as a way to reduce the variance of a base estimator (e.g., a decision tree), by introducing randomization into its construction procedure and then making an ensemble out of it. In many cases, bagging methods constitute a very simple way to improve with respect to a single model, without making it necessary to adapt the underlying base algorithm. As they provide a way to reduce overfitting, bagging methods work best with strong and complex models (e.g., fully developed decision trees), in contrast with boosting methods which usually work best with weak models (e.g., shallow decision trees).

Bagging methods come in many flavours but mostly differ from each other by the way they draw random subsets of the training set:

- When random subsets of the dataset are drawn as random subsets of the samples, then this algorithm is known as Pasting [B1999].
- When samples are drawn with replacement, then the method is known as Bagging [B1996].
- When random subsets of the dataset are drawn as random subsets of the features, then the method is known as Random Subspaces [H1998].
- Finally, when base estimators are built on subsets of both samples and features, then the method is known as Random Patches [LG2012].

In scikit-learn, bagging methods are offered as a unified `BaggingClassifier` meta-estimator (resp. `BaggingRegressor`), taking as input a user-specified base estimator along with parameters specifying the strategy to draw random subsets. In particular, `max_samples` and `max_features` control the size of the subsets (in terms of samples and features), while `bootstrap` and `bootstrap_features` control whether samples and features are drawn with or without replacement. When using a subset of the available samples the generalization accuracy can be estimated with the out-of-bag samples by setting `oob_score=True`. As an example, the snippet below illustrates how to instantiate a bagging ensemble of `KNeighborsClassifier` base estimators, each built on random subsets of 50% of the samples and 50% of the features.

```python
>>> from sklearn.ensemble import BaggingClassifier
>>> from sklearn.neighbors import KNeighborsClassifier

>>> bagging = BaggingClassifier(KNeighborsClassifier(),
                           ... max_samples=0.5, max_features=0.5)
```

Examples:

- Single estimator versus bagging: bias-variance decomposition

References
Forests of randomized trees

The `sklearn.ensemble` module includes two averaging algorithms based on randomized decision trees: the RandomForest algorithm and the Extra-Trees method. Both algorithms are perturb-and-combine techniques [B1998] specifically designed for trees. This means a diverse set of classifiers is created by introducing randomness in the classifier construction. The prediction of the ensemble is given as the averaged prediction of the individual classifiers.

As other classifiers, forest classifiers have to be fitted with two arrays: a sparse or dense array `X` of shape `(n_samples, n_features)` holding the training samples, and an array `Y` of shape `(n_samples,)` holding the target values (class labels) for the training samples:

```python
>>> from sklearn.ensemble import RandomForestClassifier
>>> X = [[0, 0], [1, 1]]
>>> Y = [0, 1]
>>> clf = RandomForestClassifier(n_estimators=10)
>>> clf = clf.fit(X, Y)
```

Like decision trees, forests of trees also extend to multi-output problems (if `Y` is an array of shape `(n_samples, n_outputs)`).

Random Forests

In random forests (see `RandomForestClassifier` and `RandomForestRegressor` classes), each tree in the ensemble is built from a sample drawn with replacement (i.e., a bootstrap sample) from the training set.

Furthermore, when splitting each node during the construction of a tree, the best split is found either from all input features or a random subset of size `max_features`. (See the parameter tuning guidelines for more details).

The purpose of these two sources of randomness is to decrease the variance of the forest estimator. Indeed, individual decision trees typically exhibit high variance and tend to overfit. The injected randomness in forests yield decision trees with somewhat decoupled prediction errors. By taking an average of those predictions, some errors can cancel out. Random forests achieve a reduced variance by combining diverse trees, sometimes at the cost of a slight increase in bias. In practice the variance reduction is often significant hence yielding an overall better model.

In contrast to the original publication [B2001], the scikit-learn implementation combines classifiers by averaging their probabilistic prediction, instead of letting each classifier vote for a single class.

Extremely Randomized Trees

In extremely randomized trees (see `ExtraTreesClassifier` and `ExtraTreesRegressor` classes), randomness goes one step further in the way splits are computed. As in random forests, a random subset of candidate features is used, but instead of looking for the most discriminative thresholds, thresholds are drawn at random for each candidate feature and the best of these randomly-generated thresholds is picked as the splitting rule. This usually allows to reduce the variance of the model a bit more, at the expense of a slightly greater increase in bias:

```python
>>> from sklearn.model_selection import cross_val_score
>>> from sklearn.datasets import make_blobs
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.ensemble import ExtraTreesClassifier
>>> from sklearn.tree import DecisionTreeClassifier

>>> X, y = make_blobs(n_samples=10000, n_features=10, centers=100,
...                   random_state=0)

>>> clf = DecisionTreeClassifier(max_depth=None, min_samples_split=2,
...                               random_state=0)
```
... random_state=0)
>>> scores = cross_val_score(clf, X, y, cv=5)
>>> scores.mean()
0.98...

>>> clf = RandomForestClassifier(n_estimators=10, max_depth=None,
... min_samples_split=2, random_state=0)
>>> scores = cross_val_score(clf, X, y, cv=5)
>>> scores.mean()
0.999...

>>> clf = ExtraTreesClassifier(n_estimators=10, max_depth=None,
... min_samples_split=2, random_state=0)
>>> scores = cross_val_score(clf, X, y, cv=5)
>>> scores.mean() > 0.999
True

Classifiers on feature subsets of the Iris dataset

Parameters

The main parameters to adjust when using these methods is `n_estimators` and `max_features`. The former is the number of trees in the forest. The larger the better, but also the longer it will take to compute. In addition, note that results will stop getting significantly better beyond a critical number of trees. The latter is the size of the random subsets of features to consider when splitting a node. The lower the greater the reduction of variance, but also the greater the increase in bias. Empirical good default values are `max_features=None` (always considering all features instead of a random subset) for regression problems, and `max_features="sqrt"` (using a random subset of size $\sqrt{n_{\text{features}}}$) for classification tasks (where `n_features` is the number of features in the data). Good results are often achieved when setting `max_depth=None` in combination with `min_samples_split=2` (i.e., when fully developing the trees). Bear in mind though that these values are usually not optimal, and might result in models that consume a lot of RAM. The best parameter values should always be cross-validated. In addition, note that in random forests, bootstrap samples are used by default (`bootstrap=True`) while the default strategy for
extra-trees is to use the whole dataset (bootstrap=False). When using bootstrap sampling the generalization accuracy can be estimated on the left out or out-of-bag samples. This can be enabled by setting oob_score=True.

Note: The size of the model with the default parameters is $O(M \times N \times \log(N))$, where $M$ is the number of trees and $N$ is the number of samples. In order to reduce the size of the model, you can change these parameters: min_samples_split, max_leaf_nodes, max_depth and min_samples_leaf.

Parallelization

Finally, this module also features the parallel construction of the trees and the parallel computation of the predictions through the n_jobs parameter. If n_jobs=k then computations are partitioned into k jobs, and run on k cores of the machine. If n_jobs=-1 then all cores available on the machine are used. Note that because of inter-process communication overhead, the speedup might not be linear (i.e., using k jobs will unfortunately not be k times as fast). Significant speedup can still be achieved though when building a large number of trees, or when building a single tree requires a fair amount of time (e.g., on large datasets).

Examples:

• Plot the decision surfaces of ensembles of trees on the iris dataset
• Pixel importances with a parallel forest of trees
• Face completion with a multi-output estimators

References

Feature importance evaluation

The relative rank (i.e. depth) of a feature used as a decision node in a tree can be used to assess the relative importance of that feature with respect to the predictability of the target variable. Features used at the top of the tree contribute to the final prediction decision of a larger fraction of the input samples. The expected fraction of the samples they contribute to can thus be used as an estimate of the relative importance of the features. In scikit-learn, the fraction of samples a feature contributes to is combined with the decrease in impurity from splitting them to create a normalized estimate of the predictive power of that feature.

By averaging the estimates of predictive ability over several randomized trees one can reduce the variance of such an estimate and use it for feature selection. This is known as the mean decrease in impurity, or MDI. Refer to [L2014] for more information on MDI and feature importance evaluation with Random Forests.

Warning: The impurity-based feature importances computed on tree-based models suffer from two flaws that can lead to misleading conclusions. First they are computed on statistics derived from the training dataset and therefore do not necessarily inform us on which features are most important to make good predictions on held-out dataset. Secondly, they favor high cardinality features, that is features with many unique values. Permutation feature importance is an alternative to impurity-based feature importance that does not suffer from these flaws. These two methods of obtaining feature importance are explored in: Permutation Importance vs Random Forest Feature Importance (MDI).
The following example shows a color-coded representation of the relative importances of each individual pixel for a face recognition task using an `ExtraTreesClassifier` model.

In practice those estimates are stored as an attribute named `feature_importances_` on the fitted model. This is an array with shape `(n_features,)` whose values are positive and sum to 1.0. The higher the value, the more important is the contribution of the matching feature to the prediction function.

**Examples:**

- Pixel importances with a parallel forest of trees
- Feature importances with forests of trees

**Totally Random Trees Embedding**

`RandomTreesEmbedding` implements an unsupervised transformation of the data. Using a forest of completely random trees, `RandomTreesEmbedding` encodes the data by the indices of the leaves a data point ends up in. This index is then encoded in a one-of-K manner, leading to a high dimensional, sparse binary coding. This coding can be computed very efficiently and can then be used as a basis for other learning tasks. The size and sparsity of the code can be influenced by choosing the number of trees and the maximum depth per tree. For each tree in the ensemble, the coding contains one entry of one. The size of the coding is at most `n_estimators * 2 ** max_depth`, the maximum number of leaves in the forest.

As neighboring data points are more likely to lie within the same leaf of a tree, the transformation performs an implicit, non-parametric density estimation.
Examples:

- **Hashing feature transformation using Totally Random Trees**
- **Manifold learning on handwritten digits: Locally Linear Embedding, Isomap...** compares non-linear dimensionality reduction techniques on handwritten digits.
- **Feature transformations with ensembles of trees** compares supervised and unsupervised tree based feature transformations.

See also:

*Manifold learning* techniques can also be useful to derive non-linear representations of feature space, also these approaches focus also on dimensionality reduction.

**AdaBoost**

The module `sklearn.ensemble` includes the popular boosting algorithm AdaBoost, introduced in 1995 by Freund and Schapire [FS1995].

The core principle of AdaBoost is to fit a sequence of weak learners (i.e., models that are only slightly better than random guessing, such as small decision trees) on repeatedly modified versions of the data. The predictions from all of them are then combined through a weighted majority vote (or sum) to produce the final prediction. The data modifications at each so-called boosting iteration consist of applying weights $w_1, w_2, \ldots, w_N$ to each of the training samples. Initially, those weights are all set to $w_i = 1/N$, so that the first step simply trains a weak learner on the original data. For each successive iteration, the sample weights are individually modified and the learning algorithm is reapplied to the reweighted data. At a given step, those training examples that were incorrectly predicted by the boosted model induced at the previous step have their weights increased, whereas the weights are decreased for those that were predicted correctly. As iterations proceed, examples that are difficult to predict receive ever-increasing influence. Each subsequent weak learner is thereby forced to concentrate on the examples that are missed by the previous ones in the sequence [HTF].
AdaBoost can be used both for classification and regression problems:

- For multi-class classification, `AdaBoostClassifier` implements AdaBoost-SAMME and AdaBoost-SAMME.R [ZZRH2009].
- For regression, `AdaBoostRegressor` implements AdaBoost.R2 [D1997].

### Usage

The following example shows how to fit an AdaBoost classifier with 100 weak learners:

```python
>>> from sklearn.model_selection import cross_val_score
>>> from sklearn.datasets import load_iris
>>> from sklearn.ensemble import AdaBoostClassifier

>>> X, y = load_iris(return_X_y=True)
>>> clf = AdaBoostClassifier(n_estimators=100)
>>> scores = cross_val_score(clf, X, y, cv=5)
>>> scores.mean()
0.9...
```

The number of weak learners is controlled by the parameter `n_estimators`. The `learning_rate` parameter controls the contribution of the weak learners in the final combination. By default, weak learners are decision stumps. Different weak learners can be specified through the `base_estimator` parameter. The main parameters to tune to obtain good results are `n_estimators` and the complexity of the base estimators (e.g., its depth `max_depth` or minimum required number of samples to consider a split `min_samples_split`).

### Examples:

- **Discrete versus Real AdaBoost** compares the classification error of a decision stump, decision tree, and a boosted decision stump using AdaBoost-SAMME and AdaBoost-SAMME.R.
- **Two-class AdaBoost** shows the decision boundary and decision function values for a non-linearly separable two-class problem using AdaBoost-SAMME.
- **Decision Tree Regression with AdaBoost** demonstrates regression with the AdaBoost.R2 algorithm.

### References

**Gradient Tree Boosting**

Gradient Tree Boosting or Gradient Boosted Decision Trees (GBDT) is a generalization of boosting to arbitrary differentiable loss functions. GBDT is an accurate and effective off-the-shelf procedure that can be used for both regression and classification problems in a variety of areas including Web search ranking and ecology.

The module `sklearn.ensemble` provides methods for both classification and regression via gradient boosted decision trees.

**Note:** Scikit-learn 0.21 introduces two new experimental implementations of gradient boosting trees, namely
HistGradientBoostingClassifier and HistGradientBoostingRegressor, inspired by LightGBM (See [LightGBM]).

These histogram-based estimators can be orders of magnitude faster than GradientBoostingClassifier and GradientBoostingRegressor when the number of samples is larger than tens of thousands of samples.

They also have built-in support for missing values, which avoids the need for an imputer.

These estimators are described in more detail below in Histogram-Based Gradient Boosting.

The following guide focuses on GradientBoostingClassifier and GradientBoostingRegressor, which might be preferred for small sample sizes since binning may lead to split points that are too approximate in this setting.

The usage and the parameters of GradientBoostingClassifier and GradientBoostingRegressor are described below. The 2 most important parameters of these estimators are n_estimators and learning_rate.

Classification

GradientBoostingClassifier supports both binary and multi-class classification. The following example shows how to fit a gradient boosting classifier with 100 decision stumps as weak learners:

```python
>>> from sklearn.datasets import make_hastie_10_2
>>> from sklearn.ensemble import GradientBoostingClassifier

>>> X, y = make_hastie_10_2(random_state=0)
>>> X_train, X_test = X[:2000], X[2000:]
>>> y_train, y_test = y[:2000], y[2000:]

>>> clf = GradientBoostingClassifier(n_estimators=100, learning_rate=1.0, ...
...                                       max_depth=1, random_state=0).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.913...
```

The number of weak learners (i.e. regression trees) is controlled by the parameter n_estimators; The size of each tree can be controlled either by setting the tree depth via max_depth or by setting the number of leaf nodes via max_leaf_nodes. The learning_rate is a hyper-parameter in the range (0.0, 1.0] that controls overfitting via shrinkage.

Note: Classification with more than 2 classes requires the induction of n_classes regression trees at each iteration, thus, the total number of induced trees equals n_classes * n_estimators. For datasets with a large number of classes we strongly recommend to use HistGradientBoostingClassifier as an alternative to GradientBoostingClassifier.
Regression

**GradientBoostingRegressor** supports a number of *different loss functions* for regression which can be specified via the argument *loss*; the default loss function for regression is least squares (`'ls'`).

```python
>>> import numpy as np
>>> from sklearn.metrics import mean_squared_error
>>> from sklearn.datasets import make_friedman1
>>> from sklearn.ensemble import GradientBoostingRegressor

>>> X, y = make_friedman1(n_samples=1200, random_state=0, noise=1.0)
>>> X_train, X_test = X[:200], X[200:]
>>> y_train, y_test = y[:200], y[200:]
>>> est = GradientBoostingRegressor(n_estimators=100, learning_rate=0.1,
... max_depth=1, random_state=0, loss='ls').fit(X_train, y_train)
>>> mean_squared_error(y_test, est.predict(X_test))
5.00...
```

The figure below shows the results of applying **GradientBoostingRegressor** with least squares loss and 500 base learners to the diabetes dataset (*sklearn.datasets.load_diabetes*). The plot on the left shows the train and test error at each iteration. The train error at each iteration is stored in the `train_score_` attribute of the gradient boosting model. The test error at each iterations can be obtained via the `staged_predict` method which returns a generator that yields the predictions at each stage. Plots like these can be used to determine the optimal number of trees (i.e. `n_estimators`) by early stopping.

![Deviance](image)
Examples:

- Gradient Boosting regression
- Gradient Boosting Out-of-Bag estimates

Fitting additional weak-learners

Both `GradientBoostingRegressor` and `GradientBoostingClassifier` support `warm_start=True` which allows you to add more estimators to an already fitted model.

```python
>>> _ = est.set_params(n_estimators=200, warm_start=True)  # set warm_start and new nr of trees
>>> _ = est.fit(X_train, y_train)  # fit additional 100 trees to est
>>> mean_squared_error(y_test, est.predict(X_test))
3.84...
```

Controlling the tree size

The size of the regression tree base learners defines the level of variable interactions that can be captured by the gradient boosting model. In general, a tree of depth $h$ can capture interactions of order $h$. There are two ways in which the size of the individual regression trees can be controlled.

If you specify `max_depth=h` then complete binary trees of depth $h$ will be grown. Such trees will have (at most) $2^h$ leaf nodes and $2^h - 1$ split nodes.

Alternatively, you can control the tree size by specifying the number of leaf nodes via the parameter `max_leaf_nodes`. In this case, trees will be grown using best-first search where nodes with the highest improvement in impurity will be expanded first. A tree with `max_leaf_nodes=k` has $k - 1$ split nodes and thus can model interactions of up to order $\text{max_leaf_nodes} - 1$.

We found that `max_leaf_nodes=k` gives comparable results to `max_depth=k-1` but is significantly faster to train at the expense of a slightly higher training error. The parameter `max_leaf_nodes` corresponds to the variable $J$ in the chapter on gradient boosting in [F2001] and is related to the parameter `interaction.depth` in R’s gbm package where `max_leaf_nodes == interaction.depth + 1`.

Mathematical formulation

We first present GBRT for regression, and then detail the classification case.

Regression

GBRT regressors are additive models whose prediction $\hat{y}_i$ for a given input $x_i$ is of the following form:

$$\hat{y}_i = F_M(x_i) = \sum_{m=1}^{M} h_m(x_i)$$

where the $h_m$ are estimators called weak learners in the context of boosting. Gradient Tree Boosting uses decision tree regressors of fixed size as weak learners. The constant $M$ corresponds to the `n_estimators` parameter.
Similar to other boosting algorithms, a GBRT is built in a greedy fashion:

\[
F_m(x) = F_{m-1}(x) + h_m(x),
\]

where the newly added tree \(h_m\) is fitted in order to minimize a sum of losses \(L_m\), given the previous ensemble \(F_{m-1}\):

\[
h_m = \arg \min \ h \sum_{i=1}^{n} l(y_i, F_{m-1}(x_i) + h(x_i)),
\]

where \(l(y_i, F(x_i))\) is defined by the \texttt{loss} parameter, detailed in the next section.

By default, the initial model \(F_0\) is chosen as the constant that minimizes the loss: for a least-squares loss, this is the empirical mean of the target values. The initial model can also be specified via the \texttt{init} argument.

Using a first-order Taylor approximation, the value of \(l\) can be approximated as follows:

\[
l(y_i, F_{m-1}(x_i) + h_m(x_i)) \approx l(y_i, F_{m-1}(x_i)) + h_m(x_i) \left[ \frac{\partial l(y_i, F(x_i))}{\partial F(x_i)} \right]_{F=F_{m-1}}.
\]

**Note:** Briefly, a first-order Taylor approximation says that \(l(z) \approx l(a) + (z - a) \frac{\partial l(a)}{\partial a}\). Here, \(z\) corresponds to \(F_{m-1}(x_i) + h_m(x_i)\), and \(a\) corresponds to \(F_{m-1}(x_i)\).

The quantity \( \left[ \frac{\partial l(y_i, F(x_i))}{\partial F(x_i)} \right]_{F=F_{m-1}} \) is the derivative of the loss with respect to its second parameter, evaluated at \(F_{m-1}(x)\). It is easy to compute for any given \(F_{m-1}(x_i)\) in a closed form since the loss is differentiable. We will denote it by \(g_i\).

Removing the constant terms, we have:

\[
h_m \approx \arg \min \ h \sum_{i=1}^{n} h(x_i) g_i
\]

This is minimized if \(h(x_i)\) is fitted to predict a value that is proportional to the negative gradient \(-g_i\). Therefore, at each iteration, the estimator \(h_m\) is fitted to predict the negative gradients of the samples. The gradients are updated at each iteration. This can be considered as some kind of gradient descent in a functional space.

**Note:** For some losses, e.g. the least absolute deviation (LAD) where the gradients are \(\pm 1\), the values predicted by a fitted \(h_m\) are not accurate enough: the tree can only output integer values. As a result, the leaves values of the tree \(h_m\) are modified once the tree is fitted, such that the leaves values minimize the loss \(L_m\). The update is loss-dependent: for the LAD loss, the value of a leaf is updated to the median of the samples in that leaf.
Classification

Gradient boosting for classification is very similar to the regression case. However, the sum of the trees $F_M(x_i) = \sum_m h_m(x_i)$ is not homogeneous to a prediction: it cannot be a class, since the trees predict continuous values.

The mapping from the value $F_M(x_i)$ to a class or a probability is loss-dependent. For the deviance (or log-loss), the probability that $x_i$ belongs to the positive class is modeled as $p(y_i = 1|x_i) = \sigma(F_M(x_i))$ where $\sigma$ is the sigmoid function.

For multiclass classification, K trees (for K classes) are built at each of the $M$ iterations. The probability that $x_i$ belongs to class k is modeled as a softmax of the $F_{M,k}(x_i)$ values.

Note that even for a classification task, the $h_m$ sub-estimator is still a regressor, not a classifier. This is because the sub-estimators are trained to predict (negative) gradients, which are always continuous quantities.

Loss Functions

The following loss functions are supported and can be specified using the parameter `loss`:

- **Regression**
  - Least squares ('ls'): The natural choice for regression due to its superior computational properties. The initial model is given by the mean of the target values.
  - Least absolute deviation ('lad'): A robust loss function for regression. The initial model is given by the median of the target values.
  - Huber ('huber'): Another robust loss function that combines least squares and least absolute deviation; use `alpha` to control the sensitivity with regards to outliers (see [F2001] for more details).
  - Quantile ('quantile'): A loss function for quantile regression. Use $0 < \alpha < 1$ to specify the quantile. This loss function can be used to create prediction intervals (see Prediction Intervals for Gradient Boosting Regression).

- **Classification**
  - Binomial deviance ('deviance'): The negative binomial log-likelihood loss function for binary classification (provides probability estimates). The initial model is given by the log odds-ratio.
  - Multinomial deviance ('deviance'): The negative multinomial log-likelihood loss function for multiclass classification with `n_classes` mutually exclusive classes. It provides probability estimates. The initial model is given by the prior probability of each class. At each iteration `n_classes` regression trees have to be constructed which makes GBRT rather inefficient for data sets with a large number of classes.
  - Exponential loss ('exponential'): The same loss function as AdaBoostClassifier. Less robust to mislabeled examples than 'deviance'; can only be used for binary classification.

Shrinkage via learning rate

[F2001] proposed a simple regularization strategy that scales the contribution of each weak learner by a constant factor $\nu$:

$$F_m(x) = F_{m-1}(x) + \nu h_m(x)$$

The parameter $\nu$ is also called the **learning rate** because it scales the step length the gradient descent procedure; it can be set via the `learning_rate` parameter.

The parameter `learning_rate` strongly interacts with the parameter `n_estimators`, the number of weak learners to fit. Smaller values of `learning_rate` require larger numbers of weak learners to maintain a constant training
error. Empirical evidence suggests that small values of `learning_rate` favor better test error. [HTF] recommend to set the learning rate to a small constant (e.g. `learning_rate <= 0.1`) and choose `n_estimators` by early stopping. For a more detailed discussion of the interaction between `learning_rate` and `n_estimators` see [R2007].

**Subsampling**

[F1999] proposed stochastic gradient boosting, which combines gradient boosting with bootstrap averaging (bagging). At each iteration the base classifier is trained on a fraction `subsample` of the available training data. The subsample is drawn without replacement. A typical value of `subsample` is 0.5.

The figure below illustrates the effect of shrinkage and subsampling on the goodness-of-fit of the model. We can clearly see that shrinkage outperforms no-shrinkage. Subsampling with shrinkage can further increase the accuracy of the model. Subsampling without shrinkage, on the other hand, does poorly.

![Graph showing the effect of shrinkage and subsampling on the goodness-of-fit of the model.](image)

Another strategy to reduce the variance is by subsampling the features analogous to the random splits in `RandomForestClassifier`. The number of subsampled features can be controlled via the `max_features` parameter.

**Note:** Using a small `max_features` value can significantly decrease the runtime.

Stochastic gradient boosting allows to compute out-of-bag estimates of the test deviance by computing the improvement in deviance on the examples that are not included in the bootstrap sample (i.e. the out-of-bag examples). The improvements are stored in the attribute `oob_improvement_`. `oob_improvement_[i]` holds the improvement in terms of the loss on the OOB samples if you add the i-th stage to the current predictions. Out-of-bag estimates can be used for model selection, for example to determine the optimal number of iterations. OOB estimates are usually very pessimistic thus we recommend to use cross-validation instead and only use OOB if cross-validation is too time consuming.
Interpretation with feature importance

Individual decision trees can be interpreted easily by simply visualizing the tree structure. Gradient boosting models, however, comprise hundreds of regression trees thus they cannot be easily interpreted by visual inspection of the individual trees. Fortunately, a number of techniques have been proposed to summarize and interpret gradient boosting models.

Often features do not contribute equally to predict the target response; in many situations the majority of the features are in fact irrelevant. When interpreting a model, the first question usually is: what are those important features and how do they contributing in predicting the target response?

Individual decision trees intrinsically perform feature selection by selecting appropriate split points. This information can be used to measure the importance of each feature; the basic idea is: the more often a feature is used in the split points of a tree the more important that feature is. This notion of importance can be extended to decision tree ensembles by simply averaging the impurity-based feature importance of each tree (see Feature importance evaluation for more details).

The feature importance scores of a fit gradient boosting model can be accessed via the `feature_importances_` property:

```python
>>> from sklearn.datasets import make_hastie_10_2
>>> from sklearn.ensemble import GradientBoostingClassifier

>>> X, y = make_hastie_10_2(random_state=0)
>>> clf = GradientBoostingClassifier(n_estimators=100, learning_rate=1.0,
... max_depth=1, random_state=0).fit(X, y)
>>> clf.feature_importances_
array([0.10..., 0.10..., 0.11..., ...
```

Note that this computation of feature importance is based on entropy, and it is distinct from `sklearn.inspection.permutation_importance` which is based on permutation of the features.

Examples:

- Gradient Boosting regression

```
Examples:

• Gradient Boosting regularization
• Gradient Boosting Out-of-Bag estimates
• OOB Errors for Random Forests
```
Histogram-Based Gradient Boosting

Scikit-learn 0.21 introduced two new experimental implementations of gradient boosting trees, namely `HistGradientBoostingClassifier` and `HistGradientBoostingRegressor`, inspired by LightGBM (See [LightGBM]).

These histogram-based estimators can be orders of magnitude faster than `GradientBoostingClassifier` and `GradientBoostingRegressor` when the number of samples is larger than tens of thousands of samples. They also have built-in support for missing values, which avoids the need for an imputer.

These fast estimators first bin the input samples \( X \) into integer-valued bins (typically 256 bins) which tremendously reduces the number of splitting points to consider, and allows the algorithm to leverage integer-based data structures (histograms) instead of relying on sorted continuous values when building the trees. The API of these estimators is slightly different, and some of the features from `GradientBoostingClassifier` and `GradientBoostingRegressor` are not yet supported, for instance some loss functions.

These estimators are still experimental: their predictions and their API might change without any deprecation cycle. To use them, you need to explicitly import `enable_hist_gradient_boosting`:

```python
>>> # explicitly require this experimental feature
>>> from sklearn.experimental import enable_hist_gradient_boosting
>>> # now you can import normally from ensemble
>>> from sklearn.ensemble import HistGradientBoostingClassifier
```

Examples:

- Partial Dependence and Individual Conditional Expectation Plots

Usage

Most of the parameters are unchanged from `GradientBoostingClassifier` and `GradientBoostingRegressor`. One exception is the `max_iter` parameter that replaces `n_estimators`, and controls the number of iterations of the boosting process:

```python
>>> from sklearn.experimental import enable_hist_gradient_boosting
>>> from sklearn.ensemble import HistGradientBoostingClassifier
>>> from sklearn.datasets import make_hastie_10_2

>>> X, y = make_hastie_10_2(random_state=0)
>>> X_train, X_test = X[:2000], X[2000:]
>>> y_train, y_test = y[:2000], y[2000:]

>>> clf = HistGradientBoostingClassifier(max_iter=100).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.8965
```

Available losses for regression are ‘least_squares’, ‘least_absolute_deviation’, which is less sensitive to outliers, and ‘poisson’, which is well suited to model counts and frequencies. For classification, ‘binary_crossentropy’ is used for binary classification and ‘categorical_crossentropy’ is used for multiclass classification. By default the loss is ‘auto’ and will select the appropriate loss depending on \( y \) passed to `fit`.

The size of the trees can be controlled through the `max_leaf_nodes`, `max_depth`, and `min_samples_leaf` parameters.
The number of bins used to bin the data is controlled with the `max_bins` parameter. Using less bins acts as a form of regularization. It is generally recommended to use as many bins as possible, which is the default.

The `l2_regularization` parameter is a regularizer on the loss function and corresponds to $\lambda$ in equation (2) of [XGBoost].

Note that early-stopping is enabled by default if the number of samples is larger than 10,000. The early-stopping behaviour is controlled via the `early-stopping`, `scoring`, `validation_fraction`, `n_iter_no_change`, and `tol` parameters. It is possible to early-stop using an arbitrary `scorer`, or just the training or validation loss. Note that for technical reasons, using a scorer is significantly slower than using the loss. By default, early-stopping is performed if there are at least 10,000 samples in the training set, using the validation loss.

**Missing values support**

`HistGradientBoostingClassifier` and `HistGradientBoostingRegressor` have built-in support for missing values (NaNs).

During training, the tree grower learns at each split point whether samples with missing values should go to the left or right child, based on the potential gain. When predicting, samples with missing values are assigned to the left or right child consequently:

```python
>>> from sklearn.experimental import enable_hist_gradient_boosting  # noqa
>>> from sklearn.ensemble import HistGradientBoostingClassifier
>>> import numpy as np

>>> X = np.array([0, 1, 2, np.nan]).reshape(-1, 1)
>>> y = [0, 0, 1, 1]

>>> gbdt = HistGradientBoostingClassifier(min_samples_leaf=1).fit(X, y)

>>> gbdt.predict(X)
array([0, 0, 1, 1])
```

When the missingness pattern is predictive, the splits can be done on whether the feature value is missing or not:

```python
>>> X = np.array([0, np.nan, 1, 2, np.nan]).reshape(-1, 1)
>>> y = [0, 1, 0, 0, 1]

>>> gbdt = HistGradientBoostingClassifier(min_samples_leaf=1,
...                                       max_depth=2,
...                                       learning_rate=1,
...                                       max_iter=1).fit(X, y)

>>> gbdt.predict(X)
array([0, 1, 0, 0, 1])
```

If no missing values were encountered for a given feature during training, then samples with missing values are mapped to whichever child has the most samples.
Sample weight support

`HistGradientBoostingClassifier` and `HistGradientBoostingRegressor` sample support weights during `fit`.

The following toy example demonstrates how the model ignores the samples with zero sample weights:

```python
>>> X = [[1, 0],
      ... [1, 0],
      ... [1, 0],
      ... [0, 1]]
>>> y = [0, 0, 1, 0]
>>> # ignore the first 2 training samples by setting their weight to 0
>>> sample_weight = [0, 0, 1, 1]
>>> gb = HistGradientBoostingClassifier(min_samples_leaf=1)
>>> gb.fit(X, y, sample_weight=sample_weight)
HistGradientBoostingClassifier(...)
>>> gb.predict([[1, 0]])
array([1])
>>> gb.predict_proba([[1, 0]])[0, 1]
0.99...
```

As you can see, the `[1, 0]` is comfortably classified as 1 since the first two samples are ignored due to their sample weights.

Implementation detail: taking sample weights into account amounts to multiplying the gradients (and the hessians) by the sample weights. Note that the binning stage (specifically the quantiles computation) does not take the weights into account.

Monotonic Constraints

Depending on the problem at hand, you may have prior knowledge indicating that a given feature should in general have a positive (or negative) effect on the target value. For example, all else being equal, a higher credit score should increase the probability of getting approved for a loan. Monotonic constraints allow you to incorporate such prior knowledge into the model.

A positive monotonic constraint is a constraint of the form:

\[ x_1 \leq x'_1 \implies F(x_1, x_2) \leq F(x'_1, x_2), \]

where \( F \) is the predictor with two features.

Similarly, a negative monotonic constraint is of the form:

\[ x_1 \leq x'_1 \implies F(x_1, x_2) \geq F(x'_1, x_2). \]

Note that monotonic constraints only constrain the output “all else being equal”. Indeed, the following relation is not enforced by a positive constraint: \( x_1 \leq x'_1 \implies F(x_1, x_2) \leq F(x'_1, x'_2) \).

You can specify a monotonic constraint on each feature using the `monotonic_cst` parameter. For each feature, a value of 0 indicates no constraint, while -1 and 1 indicate a negative and positive constraint, respectively:

```python
>>> from sklearn.experimental import enable_hist_gradient_boosting  # noqa
>>> from sklearn.ensemble import HistGradientBoostingRegressor
... # positive, negative, and no constraint on the 3 features
>>> gbdt = HistGradientBoostingRegressor(monotonic_cst=[1, -1, 0])
```

In a binary classification context, imposing a monotonic constraint means that the feature is supposed to have a positive / negative effect on the probability to belong to the positive class. Monotonic constraints are not supported for multiclass context.
Examples:

- Monotonic Constraints

Low-level parallelism

HistGradientBoostingClassifier and HistGradientBoostingRegressor have implementations that use OpenMP for parallelization through Cython. For more details on how to control the number of threads, please refer to our Parallelism notes.

The following parts are parallelized:

- mapping samples from real values to integer-valued bins (finding the bin thresholds is however sequential)
- building histograms is parallelized over features
- finding the best split point at a node is parallelized over features
- during fit, mapping samples into the left and right children is parallelized over samples
- gradient and hessians computations are parallelized over samples
- predicting is parallelized over samples

Why it's faster

The bottleneck of a gradient boosting procedure is building the decision trees. Building a traditional decision tree (as in the other GBDTs GradientBoostingClassifier and GradientBoostingRegressor) requires sorting the samples at each node (for each feature). Sorting is needed so that the potential gain of a split point can be computed efficiently. Splitting a single node has thus a complexity of $O(n_{\text{features}} \times n \log(n))$ where $n$ is the number of samples at the node.

HistGradientBoostingClassifier and HistGradientBoostingRegressor, in contrast, do not require sorting the feature values and instead use a data-structure called a histogram, where the samples are implicitly ordered. Building a histogram has a $O(n)$ complexity, so the node splitting procedure has a $O(n_{\text{features}} \times n)$ complexity, much smaller than the previous one. In addition, instead of considering $n$ split points, we here consider only max_bins split points, which is much smaller.

In order to build histograms, the input data $X$ needs to be binned into integer-valued bins. This binning procedure does require sorting the feature values, but it only happens once at the very beginning of the boosting process (not at each node, like in GradientBoostingClassifier and GradientBoostingRegressor).

Finally, many parts of the implementation of HistGradientBoostingClassifier and HistGradientBoostingRegressor are parallelized.

References
Voting Classifier

The idea behind the VotingClassifier is to combine conceptually different machine learning classifiers and use a majority vote or the average predicted probabilities (soft vote) to predict the class labels. Such a classifier can be useful for a set of equally well performing model in order to balance out their individual weaknesses.

Majority Class Labels (Majority/Hard Voting)

In majority voting, the predicted class label for a particular sample is the class label that represents the majority (mode) of the class labels predicted by each individual classifier.

E.g., if the prediction for a given sample is

- classifier 1 -> class 1
- classifier 2 -> class 1
- classifier 3 -> class 2

the VotingClassifier (with voting='hard') would classify the sample as “class 1” based on the majority class label.

In the cases of a tie, the VotingClassifier will select the class based on the ascending sort order. E.g., in the following scenario

- classifier 1 -> class 2
- classifier 2 -> class 1

the class label 1 will be assigned to the sample.

Usage

The following example shows how to fit the majority rule classifier:

```python
>>> from sklearn import datasets
>>> from sklearn.model_selection import cross_val_score
>>> from sklearn.linear_model import LogisticRegression
>>> from sklearn.naive_bayes import GaussianNB
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.ensemble import VotingClassifier

>>> iris = datasets.load_iris()
>>> X, y = iris.data[:, 1:3], iris.target

>>> clf1 = LogisticRegression(random_state=1)
>>> clf2 = RandomForestClassifier(n_estimators=50, random_state=1)
>>> clf3 = GaussianNB()

>>> eclf = VotingClassifier(...
...    estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)],
...    voting='hard')

>>> for clf, label in zip([clf1, clf2, clf3, eclf], ['Logistic Regression', 'Random Forest', 'naive Bayes', 'Ensemble']):
...    scores = cross_val_score(clf, X, y, scoring='accuracy', cv=5)
...    print("Accuracy: $0.2f (+/- $0.2f) \ [\%s]\)" % (scores.mean(), scores.std(), label))
Accuracy: 0.95 (+/- 0.04) [Logistic Regression]
```
(continues on next page)
Accuracy: 0.94 (+/- 0.04) [Random Forest]
Accuracy: 0.91 (+/- 0.04) [naive Bayes]
Accuracy: 0.95 (+/- 0.04) [Ensemble]

### Weighted Average Probabilities (Soft Voting)

In contrast to majority voting (hard voting), soft voting returns the class label as argmax of the sum of predicted probabilities.

Specific weights can be assigned to each classifier via the `weights` parameter. When weights are provided, the predicted class probabilities for each classifier are collected, multiplied by the classifier weight, and averaged. The final class label is then derived from the class label with the highest average probability.

To illustrate this with a simple example, let’s assume we have 3 classifiers and a 3-class classification problems where we assign equal weights to all classifiers: \(w_1=1\), \(w_2=1\), \(w_3=1\).

The weighted average probabilities for a sample would then be calculated as follows:

<table>
<thead>
<tr>
<th>classifier</th>
<th>class 1</th>
<th>class 2</th>
<th>class 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>classifier 1</td>
<td>(w_1 \times 0.2)</td>
<td>(w_1 \times 0.5)</td>
<td>(w_1 \times 0.3)</td>
</tr>
<tr>
<td>classifier 2</td>
<td>(w_2 \times 0.6)</td>
<td>(w_2 \times 0.3)</td>
<td>(w_2 \times 0.1)</td>
</tr>
<tr>
<td>classifier 3</td>
<td>(w_3 \times 0.3)</td>
<td>(w_3 \times 0.4)</td>
<td>(w_3 \times 0.3)</td>
</tr>
<tr>
<td>weighted average</td>
<td>0.37</td>
<td>0.4</td>
<td>0.23</td>
</tr>
</tbody>
</table>

Here, the predicted class label is 2, since it has the highest average probability.

The following example illustrates how the decision regions may change when a soft `VotingClassifier` is used based on an linear Support Vector Machine, a Decision Tree, and a K-nearest neighbor classifier:

```python
>>> from sklearn import datasets
>>> from sklearn.tree import DecisionTreeClassifier
>>> from sklearn.neighbors import KNeighborsClassifier
>>> from sklearn.svm import SVC
>>> from itertools import product
>>> from sklearn.ensemble import VotingClassifier

>>> # Loading some example data
>>> iris = datasets.load_iris()
>>> X = iris.data[:, [0, 2]]
>>> y = iris.target

>>> # Training classifiers
>>> clf1 = DecisionTreeClassifier(max_depth=4)
>>> clf2 = KNeighborsClassifier(n_neighbors=7)
>>> clf3 = SVC(kernel='rbf', probability=True)
>>> eclf = VotingClassifier(estimators=[('dt', clf1), ('knn', clf2), ('svc', clf3)],
... voting='soft', weights=[2, 1, 2])

>>> clf1 = clf1.fit(X, y)
>>> clf2 = clf2.fit(X, y)
>>> clf3 = clf3.fit(X, y)
>>> eclf = eclf.fit(X, y)
```
Using the VotingClassifier with GridSearchCV

The VotingClassifier can also be used together with GridSearchCV in order to tune the hyperparameters of the individual estimators:

```python
>>> from sklearn.model_selection import GridSearchCV
>>> clf1 = LogisticRegression(random_state=1)
>>> clf2 = RandomForestClassifier(random_state=1)
>>> clf3 = GaussianNB()
>>> eclf = VotingClassifier(
...    estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)],
...    voting='soft'
...)
>>> params = {'lr__C': [1.0, 100.0], 'rf__n_estimators': [20, 200]}
>>> grid = GridSearchCV(estimator=eclf, param_grid=params, cv=5)
>>> grid = grid.fit(iris.data, iris.target)
```

Usage

In order to predict the class labels based on the predicted class-probabilities (scikit-learn estimators in the VotingClassifier must support predict_proba method):

```python
>>> eclf = VotingClassifier(
...    estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)],
...    voting='soft'
...)
```

Optionally, weights can be provided for the individual classifiers:

```python
>>> eclf = VotingClassifier(
...    estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)],
...    voting='soft', weights=[2,5,1]
...)
```

Voting Regressor

The idea behind the VotingRegressor is to combine conceptually different machine learning regressors and return the average predicted values. Such a regressor can be useful for a set of equally well performing models in order to balance out their individual weaknesses.

Usage

The following example shows how to fit the VotingRegressor:

```python
>>> from sklearn.datasets import load_diabetes
>>> from sklearn.ensemble import GradientBoostingRegressor
>>> from sklearn.ensemble import RandomForestRegressor
>>> from sklearn.linear_model import LinearRegression
>>> from sklearn.ensemble import VotingRegressor
```

(continues on next page)
>>> # Loading some example data
>>> X, y = load_diabetes(return_X_y=True)

>>> # Training classifiers
>>> reg1 = GradientBoostingRegressor(random_state=1)
>>> reg2 = RandomForestRegressor(random_state=1)
>>> reg3 = LinearRegression()
>>> ereg = VotingRegressor(estimators=[('gb', reg1), ('rf', reg2), ('lr', reg3)])
>>> ereg = ereg.fit(X, y)

Examples:

- Plot individual and voting regression predictions

Stacked generalization

Stacked generalization is a method for combining estimators to reduce their biases [W1992] [HTF]. More precisely, the predictions of each individual estimator are stacked together and used as input to a final estimator to compute the prediction. This final estimator is trained through cross-validation.

The StackingClassifier and StackingRegressor provide such strategies which can be applied to classification and regression problems.

The estimators parameter corresponds to the list of the estimators which are stacked together in parallel on the input data. It should be given as a list of names and estimators:

```python
>>> from sklearn.linear_model import RidgeCV, LassoCV
>>> from sklearn.neighbors import KNeighborsRegressor
```

(continues on next page)
The `final_estimator` will use the predictions of the `estimators` as input. It needs to be a classifier or a regressor when using `StackingClassifier` or `StackingRegressor`, respectively:

```python
>>> from sklearn.ensemble import GradientBoostingRegressor
>>> from sklearn.ensemble import StackingRegressor

>>> final_estimator = GradientBoostingRegressor(
...     n_estimators=25, subsample=0.5, min_samples_leaf=25, max_features=1,
...     random_state=42)
>>> reg = StackingRegressor(
...     estimators=estimators,
...     final_estimator=final_estimator)
```

To train the `estimators` and `final_estimator`, the `fit` method needs to be called on the training data:

```python
>>> from sklearn.datasets import load_diabetes
>>> X, y = load_diabetes(return_X_y=True)
>>> from sklearn.model_selection import train_test_split

>>> X_train, X_test, y_train, y_test = train_test_split(X, y,
...     random_state=42)
>>> reg.fit(X_train, y_train)
```

During training, the `estimators` are fitted on the whole training data `X_train`. They will be used when calling `predict` or `predict_proba`. To generalize and avoid over-fitting, the `final_estimator` is trained on out-samples using `sklearn.model_selection.cross_val_predict` internally.

For `StackingClassifier`, note that the output of the `estimators` is controlled by the parameter `stack_method` and it is called by each estimator. This parameter is either a string, being estimator method names, or 'auto' which will automatically identify an available method depending on the availability, tested in the order of preference: `predict_proba`, `decision_function` and `predict`.

A `StackingRegressor` and `StackingClassifier` can be used as any other regressor or classifier, exposing a `predict`, `predict_proba`, and `decision_function` methods, e.g.:

```python
>>> y_pred = reg.predict(X_test)
>>> from sklearn.metrics import r2_score

>>> print('R2 score: {:.2f}'.format(r2_score(y_test, y_pred)))
R2 score: 0.53
```

Note that it is also possible to get the output of the stacked `estimators` using the `transform` method:

```python
>>> reg.transform(X_test[:5])
array([[142..., 138..., 146...],
[179..., 182..., 151...],
[139..., 132..., 158...],
[286..., 292..., 225...],
[126..., 124..., 164...]])
```

In practice, a stacking predictor predicts as good as the best predictor of the base layer and even sometimes outperforms it by combining the different strengths of the these predictors. However, training a stacking predictor is computationally expensive.
Note: For **StackingClassifier**, when using `stack_method_='predict_proba'`, the first column is dropped when the problem is a binary classification problem. Indeed, both probability columns predicted by each estimator are perfectly collinear.

Note: Multiple stacking layers can be achieved by assigning `final_estimator` to a **StackingClassifier** or **StackingRegressor**:

```python
>>> final_layer_rfr = RandomForestRegressor(
...     n_estimators=10, max_features=1, max_leaf_nodes=5, random_state=42)
>>> final_layer_gbr = GradientBoostingRegressor(
...     n_estimators=10, max_features=1, max_leaf_nodes=5, random_state=42)
>>> final_layer = StackingRegressor(
...     estimators=[('rf', final_layer_rfr),
...                 ('gbrt', final_layer_gbr)],
...     final_estimator=RidgeCV())
>>> multi_layerRegressor = StackingRegressor(
...     estimators=[('ridge', RidgeCV()),
...                 ('lasso', LassoCV(random_state=42)),
...                 ('knr', KNeighborsRegressor(n_neighbors=20,
...                                  metric='euclidean'))],
...     final_estimator=final_layer)
>>> multi_layerRegressor.fit(X_train, y_train)
StackingRegressor(...)
>>> print('R2 score: {:.2f}')
... .format(multi_layerRegressor.score(X_test, y_test))
R2 score: 0.53
```

**4.1.12 Multiclass and multioutput algorithms**

This section of the user guide covers functionality related to multi-learning problems, including **multiclass**, **multilabel**, and **multioutput** classification and regression.

The modules in this section implement **meta-estimators**, which require a base estimator to be provided in their constructor. Meta-estimators extend the functionality of the base estimator to support multi-learning problems, which is accomplished by transforming the multi-learning problem into a set of simpler problems, then fitting one estimator per problem.

This section covers two modules: **sklearn.multiclass** and **sklearn.multioutput**. The chart below demonstrates the problem types that each module is responsible for, and the corresponding meta-estimators that each module provides.
The table below provides a quick reference on the differences between problem types. More detailed explanations can be found in subsequent sections of this guide.

Below is a summary of scikit-learn estimators that have multi-learning support built-in, grouped by strategy. You don’t need the meta-estimators provided by this section if you’re using one of these estimators. However, meta-estimators can provide additional strategies beyond what is built-in:

- **Inherently multiclass:**
  - naive_bayes.BernoulliNB
  - tree.DecisionTreeClassifier
  - tree.ExtraTreeClassifier
  - ensemble.ExtraTreesClassifier
  - naive_bayes.GaussianNB
  - neighbors.KNeighborsClassifier
  - semi_supervised.LabelPropagation
  - semi_supervised.LabelSpreading
  - discriminant_analysis.LinearDiscriminantAnalysis
  - svm.LinearSVC (setting multi_class="crammer_singer")
  - linear_model.LogisticRegression (setting multi_class="multinomial")
  - linear_model.LogisticRegressionCV (setting multi_class="multinomial")
  - neural_network.MLPClassifier

---

4.1. Supervised learning
- `neighbors.NearestCentroid`
- `discriminant_analysis.QuadraticDiscriminantAnalysis`
- `neighbors.RadiusNeighborsClassifier`
- `ensemble.RandomForestClassifier`
- `linear_model.RidgeClassifier`
- `linear_model.RidgeClassifierCV`

**Multiclass as One-Vs-One:**
- `svm.NuSVC`
- `svm.SVC`.
- `gaussian_process.GaussianProcessClassifier` (setting `multi_class = "one_vs_one"`)

**Multiclass as One-Vs-The-Rest:**
- `ensemble.GradientBoostingClassifier`
- `gaussian_process.GaussianProcessClassifier` (setting `multi_class = "one_vs_rest"`)
- `svm.LinearSVC` (setting `multi_class="ovr"`)
- `linear_model.LogisticRegression` (setting `multi_class="ovr"`)
- `linear_model.LogisticRegressionCV` (setting `multi_class="ovr"`)
- `linear_model.SGDClassifier`
- `linear_model.Perceptron`
- `linear_model.PassiveAggressiveClassifier`

**Support multilabel:**
- `tree.DecisionTreeClassifier`
- `tree.ExtraTreeClassifier`
- `ensemble.ExtraTreesClassifier`
- `neighbors.KNeighborsClassifier`
- `neural_network.MLPClassifier`
- `neighbors.RadiusNeighborsClassifier`
- `ensemble.RandomForestClassifier`
- `linear_model.RidgeClassifierCV`

**Support multiclass-multioutput:**
- `tree.DecisionTreeClassifier`
- `tree.ExtraTreeClassifier`
- `ensemble.ExtraTreesClassifier`
- `neighbors.KNeighborsClassifier`
- `neighbors.RadiusNeighborsClassifier`
- `ensemble.RandomForestClassifier`
Multiclass classification

**Warning:** All classifiers in scikit-learn do multiclass classification out-of-the-box. You don’t need to use the `sklearn.multiclass` module unless you want to experiment with different multiclass strategies.

Multiclass classification is a classification task with more than two classes. Each sample can only be labeled as one class.

For example, classification using features extracted from a set of images of fruit, where each image may either be of an orange, an apple, or a pear. Each image is one sample and is labeled as one of the 3 possible classes. Multiclass classification makes the assumption that each sample is assigned to one and only one label - one sample cannot, for example, be both a pear and an apple.

While all scikit-learn classifiers are capable of multiclass classification, the meta-estimators offered by `sklearn.multiclass` permit changing the way they handle more than two classes because this may have an effect on classifier performance (either in terms of generalization error or required computational resources).

### Target format

Valid `multiclass` representations for `type_of_target(y)` are:

- 1d or column vector containing more than two discrete values. An example of a vector `y` for 4 samples:

  ```python
  >>> import numpy as np
  >>> y = np.array(['apple', 'pear', 'apple', 'orange'])
  >>> print(y)
  ['apple' 'pear' 'apple' 'orange']
  ```

- Dense or sparse `binary` matrix of shape `(n_samples, n_classes)` with a single sample per row, where each column represents one class. An example of both a dense and sparse `binary` matrix `y` for 4 samples, where the columns, in order, are apple, orange, and pear:

  ```python
  >>> import numpy as np
  >>> from sklearn.preprocessing import LabelBinarizer
  >>> y = np.array(['apple', 'pear', 'apple', 'orange'])
  >>> y_dense = LabelBinarizer().fit_transform(y)
  >>> print(y_dense)
  [[1 0 0]
  [0 0 1]
  [1 0 0]
  [0 1 0]]
  >>> from scipy import sparse
  >>> y_sparse = sparse.csr_matrix(y_dense)
  >>> print(y_sparse)
  (0, 0) 1
  (1, 2) 1
  (2, 0) 1
  (3, 1) 1
  ```

For more information about `LabelBinarizer`, refer to Transforming the prediction target (`y`).

**4.1. Supervised learning** 381
OneVsRestClassifier

The `one-vs-rest` strategy, also known as `one-vs-all`, is implemented in `OneVsRestClassifier`. The strategy consists in fitting one classifier per class. For each classifier, the class is fitted against all the other classes. In addition to its computational efficiency (only `n_classes` classifiers are needed), one advantage of this approach is its interpretability. Since each class is represented by one and only one classifier, it is possible to gain knowledge about the class by inspecting its corresponding classifier. This is the most commonly used strategy and is a fair default choice.

Below is an example of multiclass learning using OvR:

```python
>>> from sklearn import datasets
>>> from sklearn.multiclass import OneVsRestClassifier
>>> from sklearn.svm import LinearSVC

>>> X, y = datasets.load_iris(return_X_y=True)
>>> OneVsRestClassifier(LinearSVC(random_state=0)).fit(X, y).predict(X)
array([0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0],
```

`OneVsRestClassifier` also supports multilabel classification. To use this feature, feed the classifier an indicator matrix, in which cell `[i, j]` indicates the presence of label `j` in sample `i`. 
Examples:

- Multilabel classification

**OneVsOneClassifier**

OneVsOneClassifier constructs one classifier per pair of classes. At prediction time, the class which received the most votes is selected. In the event of a tie (among two classes with an equal number of votes), it selects the class with the highest aggregate classification confidence by summing over the pair-wise classification confidence levels computed by the underlying binary classifiers.

Since it requires to fit \( n_{classes} \times (n_{classes} - 1) / 2 \) classifiers, this method is usually slower than one-vs-the-rest, due to its \( O(n_{classes}^2) \) complexity. However, this method may be advantageous for algorithms such as kernel algorithms which don’t scale well with \( n_{samples} \). This is because each individual learning problem only involves a small subset of the data whereas, with one-vs-the-rest, the complete dataset is used \( n_{classes} \) times. The decision function is the result of a monotonic transformation of the one-versus-one classification.

Below is an example of multiclass learning using OvO:

```python
>>> from sklearn import datasets
>>> from sklearn.multiclass import OneVsOneClassifier
>>> from sklearn.svm import LinearSVC

>>> X, y = datasets.load_iris(return_X_y=True)
>>> OneVsOneClassifier(LinearSVC(random_state=0)).fit(X, y).predict(X)
array([0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
      0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
      0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
      1, 2, 1, 2, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
      1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
      2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
      2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
      2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
      2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2])
```

**OutputCodeClassifier**

Error-Correcting Output Code-based strategies are fairly different from one-vs-the-rest and one-vs-one. With these strategies, each class is represented in a Euclidean space, where each dimension can only be 0 or 1. Another way to put it is that each class is represented by a binary code (an array of 0 and 1). The matrix which keeps track of the location/code of each class is called the code book. The code size is the dimensionality of the aforementioned space. Intuitively, each class should be represented by a code as unique as possible and a good code book should be designed to optimize classification accuracy. In this implementation, we simply use a randomly-generated code book as advocated in\(^3\) although more elaborate methods may be added in the future.

At fitting time, one binary classifier per bit in the code book is fitted. At prediction time, the classifiers are used to project new points in the class space and the class closest to the points is chosen.

In OutputCodeClassifier, the code_size attribute allows the user to control the number of classifiers which will be used. It is a percentage of the total number of classes.

---

scikit-learn user guide, Release 0.24.dev0

A number between 0 and 1 will require fewer classifiers than one-vs-the-rest. In theory, log2(n_classes) /
n_classes is sufficient to represent each class unambiguously. However, in practice, it may not lead to good
accuracy since log2(n_classes) is much smaller than n_classes.
A number greater than 1 will require more classifiers than one-vs-the-rest. In this case, some classifiers will in theory
correct for the mistakes made by other classifiers, hence the name “error-correcting”. In practice, however, this may
not happen as classifier mistakes will typically be correlated. The error-correcting output codes have a similar effect
to bagging.
Below is an example of multiclass learning using Output-Codes:
>>> from sklearn import datasets
>>> from sklearn.multiclass import OutputCodeClassifier
>>> from sklearn.svm import LinearSVC
>>> X, y = datasets.load_iris(return_X_y=True)
>>> clf = OutputCodeClassifier(LinearSVC(random_state=0),
...
code_size=2, random_state=0)
>>> clf.fit(X, y).predict(X)
array([0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 2, 1, 1, 1, 1, 1, 1, 1,
1, 2, 1, 1, 1, 1, 1, 1, 2, 1, 1, 1, 1, 1, 2, 2, 2, 1,
1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
2, 2, 2, 2, 1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 1, 2, 2, 2,

Multilabel classification
Multilabel classification (closely related to multioutput classification) is a classification task labeling each sample
with m labels from n_classes possible classes, where m can be 0 to n_classes inclusive. This can be thought
of as predicting properties of a sample that are not mutually exclusive. Formally, a binary output is assigned to each
class, for every sample. Positive classes are indicated with 1 and negative classes with 0 or -1. It is thus comparable
to running n_classes binary classification tasks, for example with MultiOutputClassifier. This approach
treats each label independently whereas multilabel classifiers may treat the multiple classes simultaneously, accounting
for correlated behavior among them.
For example, prediction of the topics relevant to a text document or video. The document or video may be about one
of ‘religion’, ‘politics’, ‘finance’ or ‘education’, several of the topic classes or all of the topic classes.

384

Chapter 4. User Guide


Target format

A valid representation of multilabel $y$ is an either dense or sparse binary matrix of shape $(n_{\text{samples}}, n_{\text{classes}})$. Each column represents a class. The 1’s in each row denote the positive classes a sample has been labeled with. An example of a dense matrix $y$ for 3 samples:

```python
>>> y = np.array([[1, 0, 0, 1], [0, 0, 1, 1], [0, 0, 0, 0]])
>>> print(y)
[[1 0 0 1]
 [0 0 1 1]
 [0 0 0 0]]
```

Dense binary matrices can also be created using `MultiLabelBinarizer`. For more information, refer to `Transfoming the prediction target ($y$)`.

An example of the same $y$ in sparse matrix form:

```python
>>> y_sparse = sparse.csr_matrix(y)
>>> print(y_sparse)
(0, 0) 1
(0, 3) 1
(1, 2) 1
(1, 3) 1
```

MultiOutputClassifier

Multilabel classification support can be added to any classifier with `MultiOutputClassifier`. This strategy consists of fitting one classifier per target. This allows multiple target variable classifications. The purpose of this class is to extend estimators to be able to estimate a series of target functions ($f_1, f_2, f_3, \ldots, f_n$) that are trained on a single X predictor matrix to predict a series of responses ($y_1, y_2, y_3, \ldots, y_n$).

Below is an example of multilabel classification:

```python
>>> from sklearn.datasets import make_classification
>>> from sklearn.multioutput import MultiOutputClassifier
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.utils import shuffle
>>> import numpy as np

>>> X, y1 = make_classification(n_samples=10, n_features=100, n_informative=30, n_classes=3, random_state=1)
>>> y2 = shuffle(y1, random_state=1)
>>> y3 = shuffle(y1, random_state=2)
>>> Y = np.vstack((y1, y2, y3)).T
>>> n_samples, n_features = X.shape # 10,100
>>> n_outputs = Y.shape[1] # 3
>>> n_classes = 3
>>> forest = RandomForestClassifier(random_state=1)
>>> multi_target_forest = MultiOutputClassifier(forest, n_jobs=-1)
>>> multi_target_forest.fit(X, Y).predict(X)
array([[2, 2, 0],
 [1, 2, 1],
 [2, 1, 0],
 [0, 0, 2],
 [0, 2, 1],
 [0, 0, 2],
 [1, 1, 0],
 [1, 1, 0],
 ...], dtype=object)
```
ClassifierChains

ClassifierChains (see ClassifierChain) are a way of combining a number of binary classifiers into a single multi-label model that is capable of exploiting correlations among targets.

For a multi-label classification problem with N classes, N binary classifiers are assigned an integer between 0 and N-1. These integers define the order of models in the chain. Each classifier is then fit on the available training data plus the true labels of the classes whose models were assigned a lower number.

When predicting, the true labels will not be available. Instead the predictions of each model are passed on to the subsequent models in the chain to be used as features.

Clearly the order of the chain is important. The first model in the chain has no information about the other labels while the last model in the chain has features indicating the presence of all of the other labels. In general one does not know the optimal ordering of the models in the chain so typically many randomly ordered chains are fit and their predictions are averaged together.

References:

Multiclass-multioutput classification

Multiclass-multioutput classification (also known as multitask classification) is a classification task which labels each sample with a set of non-binary properties. Both the number of properties and the number of classes per property is greater than 2. A single estimator thus handles several joint classification tasks. This is both a generalization of the multilabel classification task, which only considers binary attributes, as well as a generalization of the multiclass classification task, where only one property is considered.

For example, classification of the properties “type of fruit” and “colour” for a set of images of fruit. The property “type of fruit” has the possible classes: “apple”, “pear” and “orange”. The property “colour” has the possible classes: “green”, “red”, “yellow” and “orange”. Each sample is an image of a fruit, a label is output for both properties and each label is one of the possible classes of the corresponding property.

Note that all classifiers handling multiclass-multioutput (also known as multitask classification) tasks, support the multilabel classification task as a special case. Multitask classification is similar to the multioutput classification task with different model formulations. For more information, see the relevant estimator documentation.

Warning: At present, no metric in sklearn.metrics supports the multiclass-multioutput classification task.
Target format

A valid representation of `multioutput y` is a dense matrix of shape `(n_samples, n_classes)` of class labels. A column wise concatenation of 1d `multiclass` variables. An example of `y` for 3 samples:

```python
>>> y = np.array([['apple', 'green'], ['orange', 'orange'], ['pear', 'green']])
```

```python
>>> print(y)
[['apple' 'green']
 ['orange' 'orange']
 ['pear' 'green']]
```

Multioutput regression

Multioutput regression predicts multiple numerical properties for each sample. Each property is a numerical variable and the number of properties to be predicted for each sample is greater than or equal to 2. Some estimators that support multioutput regression are faster than just running `n_output` estimators.

For example, prediction of both wind speed and wind direction, in degrees, using data obtained at a certain location. Each sample would be data obtained at one location and both wind speed and direction would be output for each sample.

Target format

A valid representation of `multioutput y` is a dense matrix of shape `(n_samples, n_classes)` of floats. A column wise concatenation of `continuous` variables. An example of `y` for 3 samples:

```python
>>> y = np.array([[31.4, 94], [40.5, 109], [25.0, 30]])
```

```python
>>> print(y)
[ [ 31.4 94. ]
 [ 40.5 109. ]
 [ 25. 30. ]]
```

MultiOutputRegressor

Multioutput regression support can be added to any regressor with `MultiOutputRegressor`. This strategy consists of fitting one regressor per target. Since each target is represented by exactly one regressor it is possible to gain knowledge about the target by inspecting its corresponding regressor. As `MultiOutputRegressor` fits one regressor per target it can not take advantage of correlations between targets.

Below is an example of multioutput regression:

```python
>>> from sklearn.datasets import make_regression
>>> from sklearn.multioutput import MultiOutputRegressor
>>> from sklearn.ensemble import GradientBoostingRegressor

>>> X, y = make_regression(n_samples=10, n_targets=3, random_state=1)

>>> MultiOutputRegressor(GradientBoostingRegressor(random_state=0)).fit(X, y).
```

```python
array([[-154.75474165, -147.03498585, -50.03812219],
       [  7.12165031,  5.12914884, -81.46081961],
       [-187.8948621 , -100.44373091,  13.88978285],
       [-141.62745778,  95.02891072, -191.48204257],
       [ 97.03260883, 165.34867495,  139.52003279],
       [ 123.92529176,  21.25719016,  -7.84253 ]],
```

(continues on next page)
RegressorChain

Regressor chains (see `RegressorChain`) is analogous to `ClassifierChain` as a way of combining a number of regressions into a single multi-target model that is capable of exploiting correlations among targets.

4.1.13 Feature selection

The classes in the `sklearn.feature_selection` module can be used for feature selection/dimensionality reduction on sample sets, either to improve estimators’ accuracy scores or to boost their performance on very high-dimensional datasets.

Removing features with low variance

`VarianceThreshold` is a simple baseline approach to feature selection. It removes all features whose variance doesn’t meet some threshold. By default, it removes all zero-variance features, i.e. features that have the same value in all samples.

As an example, suppose that we have a dataset with boolean features, and we want to remove all features that are either one or zero (on or off) in more than 80% of the samples. Boolean features are Bernoulli random variables, and the variance of such variables is given by

\[
\text{Var}[X] = p(1 - p)
\]

so we can select using the threshold \( .8 \times (1 - .8) \):

```python
>>> from sklearn.feature_selection import VarianceThreshold
>>> X = [[0, 0, 1], [0, 1, 0], [1, 0, 0], [0, 1, 1], [0, 1, 0], [0, 1, 1]]
>>> sel = VarianceThreshold(threshold=(.8 * (1 - .8)))
>>> sel.fit_transform(X)
array([[0, 1],
[1, 0],
[0, 0],
[1, 1],
[1, 0],
[1, 1]])
```

As expected, `VarianceThreshold` has removed the first column, which has a probability \( p = 5/6 > .8 \) of containing a zero.
Univariate feature selection

Univariate feature selection works by selecting the best features based on univariate statistical tests. It can be seen as a preprocessing step to an estimator. Scikit-learn exposes feature selection routines as objects that implement the `transform` method:

- `SelectKBest` removes all but the $k$ highest scoring features
- `SelectPercentile` removes all but a user-specified highest scoring percentage of features
- using common univariate statistical tests for each feature: false positive rate `SelectFpr`, false discovery rate `SelectFdr`, or family wise error `SelectFwe`.
- `GenericUnivariateSelect` allows to perform univariate feature selection with a configurable strategy. This allows to select the best univariate selection strategy with hyper-parameter search estimator.

For instance, we can perform a $\chi^2$ test to the samples to retrieve only the two best features as follows:

```python
>>> from sklearn.datasets import load_iris
>>> from sklearn.feature_selection import SelectKBest
>>> from sklearn.feature_selection import chi2

>>> X, y = load_iris(return_X_y=True)
>>> X.shape
(150, 4)
>>> X_new = SelectKBest(chi2, k=2).fit_transform(X, y)
>>> X_new.shape
(150, 2)
```

These objects take as input a scoring function that returns univariate scores and p-values (or only scores for `SelectKBest` and `SelectPercentile`):

- For regression: `f_regression`, `mutual_info_regression`
- For classification: `chi2`, `f_classif`, `mutual_info_classif`

The methods based on F-test estimate the degree of linear dependency between two random variables. On the other hand, mutual information methods can capture any kind of statistical dependency, but being nonparametric, they require more samples for accurate estimation.

Feature selection with sparse data

If you use sparse data (i.e. data represented as sparse matrices), `chi2`, `mutual_info_regression`, `mutual_info_classif` will deal with the data without making it dense.

**Warning:** Beware not to use a regression scoring function with a classification problem, you will get useless results.

**Examples:**

- `Univariate Feature Selection`
- `Comparison of F-test and mutual information`
Recursive feature elimination

Given an external estimator that assigns weights to features (e.g., the coefficients of a linear model), recursive feature elimination (RFE) is to select features by recursively considering smaller and smaller sets of features. First, the estimator is trained on the initial set of features and the importance of each feature is obtained either through any specific attribute (such as `coef_`, `feature_importances_`) or callable. Then, the least important features are pruned from current set of features. That procedure is recursively repeated on the pruned set until the desired number of features to select is eventually reached.

`RFECV` performs RFE in a cross-validation loop to find the optimal number of features.

Examples:

- **Recursive feature elimination**: A recursive feature elimination example showing the relevance of pixels in a digit classification task.
- **Recursive feature elimination with cross-validation**: A recursive feature elimination example with automatic tuning of the number of features selected with cross-validation.

Feature selection using SelectFromModel

`SelectFromModel` is a meta-transformer that can be used along with any estimator that importance of each feature through a specific attribute (such as `coef_`, `feature_importances_`) or callable after fitting. The features are considered unimportant and removed, if the corresponding importance of the feature values are below the provided threshold parameter. Apart from specifying the threshold numerically, there are built-in heuristics for finding a threshold using a string argument. Available heuristics are “mean”, “median” and float multiples of these like “0.1*mean”. In combination with the threshold criteria, one can use the `max_features` parameter to set a limit on the number of features to select.

For examples on how it is to be used refer to the sections below.

Examples

- **Model-based and sequential feature selection**

L1-based feature selection

Linear models penalized with the L1 norm have sparse solutions: many of their estimated coefficients are zero. When the goal is to reduce the dimensionality of the data to use with another classifier, they can be used along with `SelectFromModel` to select the non-zero coefficients. In particular, sparse estimators useful for this purpose are the `Lasso` for regression, and of `LogisticRegression` and `LinearSVC` for classification:

```python
>>> from sklearn.svm import LinearSVC
>>> from sklearn.datasets import load_iris
>>> from sklearn.feature_selection import SelectFromModel

>>> X, y = load_iris(return_X_y=True)
>>> X.shape
(150, 4)
>>> lsvc = LinearSVC(C=0.01, penalty="11", dual=False).fit(X, y)
>>> model = SelectFromModel(lsvc, prefit=True)
>>> X_new = model.transform(X)
```
>>> X_new.shape
(150, 3)

With SVMs and logistic-regression, the parameter C controls the sparsity: the smaller C the fewer features selected. With Lasso, the higher the alpha parameter, the fewer features selected.

Examples:

• Classification of text documents using sparse features: Comparison of different algorithms for document classification including L1-based feature selection.

L1-recovery and compressive sensing

For a good choice of alpha, the Lasso can fully recover the exact set of non-zero variables using only few observations, provided certain specific conditions are met. In particular, the number of samples should be “sufficiently large”, or L1 models will perform at random, where “sufficiently large” depends on the number of non-zero coefficients, the logarithm of the number of features, the amount of noise, the smallest absolute value of non-zero coefficients, and the structure of the design matrix X. In addition, the design matrix must display certain specific properties, such as not being too correlated.

There is no general rule to select an alpha parameter for recovery of non-zero coefficients. It can be set by cross-validation (LassoCV or LassoLarsCV), though this may lead to under-penalized models: including a small number of non-relevant variables is not detrimental to prediction score. BIC (LassoLarsIC) tends, on the opposite, to set high values of alpha.

Tree-based feature selection

Tree-based estimators (see the sklearn.tree module and forest of trees in the sklearn.ensemble module) can be used to compute impurity-based feature importances, which in turn can be used to discard irrelevant features (when coupled with the SelectFromModel meta-transformer):

```python
>>> from sklearn.ensemble import ExtraTreesClassifier
>>> from sklearn.datasets import load_iris
>>> from sklearn.feature_selection import SelectFromModel
>>> X, y = load_iris(return_X_y=True)
>>> X.shape
(150, 4)
>>> clf = ExtraTreesClassifier(n_estimators=50)
>>> clf.fit(X, y)
>>> clf.feature_importances_
array([0.04..., 0.05..., 0.4..., 0.4...])
>>> model = SelectFromModel(clf, prefit=True)
>>> X_new = model.transform(X)
>>> X_new.shape
(150, 2)
```
Examples:

- *Feature importances with forests of trees:* example on synthetic data showing the recovery of the actually meaningful features.
- *Pixel importances with a parallel forest of trees:* example on face recognition data.

Sequential Feature Selection

Sequential Feature Selection [sfs] (SFS) is available in the `SequentialFeatureSelector` transformer. SFS can be either forward or backward:

Forward-SFS is a greedy procedure that iteratively finds the best new feature to add to the set of selected features. Concretely, we initially start with zero feature and find the one feature that maximizes a cross-validated score when an estimator is trained on this single feature. Once that first feature is selected, we repeat the procedure by adding a new feature to the set of selected features. The procedure stops when the desired number of selected features is reached, as determined by the `n_features_to_select` parameter.

Backward-SFS follows the same idea but works in the opposite direction: instead of starting with no feature and greedily adding features, we start with all the features and greedily remove features from the set. The `direction` parameter controls whether forward or backward SFS is used.

In general, forward and backward selection do not yield equivalent results. Also, one may be much faster than the other depending on the requested number of selected features: if we have 10 features and ask for 7 selected features, forward selection would need to perform 7 iterations while backward selection would only need to perform 3.

SFS differs from `RFE` and `SelectFromModel` in that it does not require the underlying model to expose a `coef_` or `feature_importances_` attribute. It may however be slower considering that more models need to be evaluated, compared to the other approaches. For example in backward selection, the iteration going from \( m \) features to \( m - 1 \) features using \( k \)-fold cross-validation requires fitting \( m \times k \) models, while `RFE` would require only a single fit, and `SelectFromModel` always just does a single fit and requires no iterations.

Examples

- *Model-based and sequential feature selection*

References:

Feature selection as part of a pipeline

Feature selection is usually used as a pre-processing step before doing the actual learning. The recommended way to do this in scikit-learn is to use a `Pipeline`:

```python
clf = Pipeline([  
    ('feature_selection', SelectFromModel(LinearSVC(penalty="l1"))),  
    ('classification', RandomForestClassifier())  
])
clf.fit(X, y)
```

In this snippet we make use of a `LinearSVC` coupled with `SelectFromModel` to evaluate feature importances and select the most relevant features. Then, a `RandomForestClassifier` is trained on the transformed output,
i.e. using only relevant features. You can perform similar operations with the other feature selection methods and also classifiers that provide a way to evaluate feature importances of course. See the *Pipeline* examples for more details.

### 4.1.14 Semi-Supervised

Semi-supervised learning is a situation in which in your training data some of the samples are not labeled. The semi-supervised estimators in `sklearn.semi_supervised` are able to make use of this additional unlabeled data to better capture the shape of the underlying data distribution and generalize better to new samples. These algorithms can perform well when we have a very small amount of labeled points and a large amount of unlabeled points.

**Unlabeled entries in \( y \)**

It is important to assign an identifier to unlabeled points along with the labeled data when training the model with the `fit` method. The identifier that this implementation uses is the integer value \(-1\).

**Label Propagation**

Label propagation denotes a few variations of semi-supervised graph inference algorithms.

#### A few features available in this model:

- Can be used for classification and regression tasks
- Kernel methods to project data into alternate dimensional spaces

`scikit-learn` provides two label propagation models: `LabelPropagation` and `LabelSpreading`. Both work by constructing a similarity graph over all items in the input dataset.

![Fig. 2: An illustration of label-propagation: the structure of unlabeled observations is consistent with the class structure, and thus the class label can be propagated to the unlabeled observations of the training set.](image)

*LabelPropagation* and *LabelSpreading* differ in modifications to the similarity matrix that graph and the clamping effect on the label distributions. Clamping allows the algorithm to change the weight of the true ground labeled data to some degree. The *LabelPropagation* algorithm performs hard clamping of input labels, which means \( \alpha = 0 \). This clamping factor can be relaxed, to say \( \alpha = 0.2 \), which means that we will always retain 80 percent of our original label distribution, but the algorithm gets to change its confidence of the distribution within 20 percent.
LabelPropagation uses the raw similarity matrix constructed from the data with no modifications. In contrast, LabelSpreading minimizes a loss function that has regularization properties, as such it is often more robust to noise. The algorithm iterates on a modified version of the original graph and normalizes the edge weights by computing the normalized graph Laplacian matrix. This procedure is also used in Spectral clustering.

Label propagation models have two built-in kernel methods. Choice of kernel effects both scalability and performance of the algorithms. The following are available:

- rbf \( \exp(-\gamma|x-y|^2), \gamma > 0 \). \( \gamma \) is specified by keyword gamma.
- knn \( 1[x' \in kNN(x)] \). \( k \) is specified by keyword n_neighbors.

The RBF kernel will produce a fully connected graph which is represented in memory by a dense matrix. This matrix may be very large and combined with the cost of performing a full matrix multiplication calculation for each iteration of the algorithm can lead to prohibitively long running times. On the other hand, the KNN kernel will produce a much more memory-friendly sparse matrix which can drastically reduce running times.

Examples

- Decision boundary of label propagation versus SVM on the Iris dataset
- Label Propagation learning a complex structure
- Label Propagation digits: Demonstrating performance
- Label Propagation digits active learning

References

4.1.15 Isotonic regression

The class IsotonicRegression fits a non-decreasing real function to 1-dimensional data. It solves the following problem:

\[
\text{minimize } \sum_i w_i (y_i - \hat{y}_i)^2 \\
\text{subject to } \hat{y}_i \leq \hat{y}_j \text{ whenever } X_i \leq X_j,
\]

where the weights \( w_i \) are strictly positive, and both \( X \) and \( Y \) are arbitrary real quantities.

The increasing parameter changes the constraint to \( \hat{y}_i \geq \hat{y}_j \) whenever \( X_i \leq X_j \). Setting it to ‘auto’ will automatically choose the constraint based on Spearman’s rank correlation coefficient.

IsotonicRegression produces a series of predictions \( \hat{y}_i \) for the training data which are the closest to the targets \( y \) in terms of mean squared error. These predictions are interpolated for predicting to unseen data. The predictions of IsotonicRegression thus form a function that is piecewise linear:
4.1.16 Probability calibration

When performing classification you often want not only to predict the class label, but also obtain a probability of the respective label. This probability gives you some kind of confidence on the prediction. Some models can give you poor estimates of the class probabilities and some even do not support probability prediction (e.g., some instances of `SGDClassifier`). The calibration module allows you to better calibrate the probabilities of a given model, or to add support for probability prediction.

Well calibrated classifiers are probabilistic classifiers for which the output of the `predict_proba` method can be directly interpreted as a confidence level. For instance, a well calibrated (binary) classifier should classify the samples such that among the samples to which it gave a `predict_proba` value close to 0.8, approximately 80% actually belong to the positive class.

**Calibration curves**

The following plot compares how well the probabilistic predictions of different classifiers are calibrated, using `calibration_curve`. The x axis represents the average predicted probability in each bin. The y axis is the fraction of positives, i.e. the proportion of samples whose class is the positive class (in each bin).

`LogisticRegression` returns well calibrated predictions by default as it directly optimizes Log loss. In contrast, the other methods return biased probabilities; with different biases per method:

`GaussianNB` tends to push probabilities to 0 or 1 (note the counts in the histograms). This is mainly because it makes the assumption that features are conditionally independent given the class, which is not the case in this dataset which contains 2 redundant features.

`RandomForestClassifier` shows the opposite behavior: the histograms show peaks at approximately 0.2 and 0.9 probability, while probabilities close to 0 or 1 are very rare. An explanation for this is given by Niculescu-Mizil and Caruana\(^1\): “Methods such as bagging and random forests that average predictions from a base set of models can have difficulty making predictions near 0 and 1 because variance in the underlying base models will bias predictions that should be near zero or one away from these values. Because predictions are restricted to the interval [0,1], errors caused by variance tend to be one-sided near zero and one. For example, if a model should predict \( p = 0 \) for a case,

\(^1\) Predicting Good Probabilities with Supervised Learning, A. Niculescu-Mizil & R. Caruana, ICML 2005
the only way bagging can achieve this is if all bagged trees predict zero. If we add noise to the trees that bagging is averaging over, this noise will cause some trees to predict values larger than 0 for this case, thus moving the average prediction of the bagged ensemble away from 0. We observe this effect most strongly with random forests because the base-level trees trained with random forests have relatively high variance due to feature subsetting.” As a result, the calibration curve also referred to as the reliability diagram (Wilks 1995\(^2\)) shows a characteristic sigmoid shape, indicating that the classifier could trust its “intuition” more and return probabilities closer to 0 or 1 typically.

Linear Support Vector Classification (LinearSVC) shows an even more sigmoid curve than RandomForestClassifier, which is typical for maximum-margin methods (compare Niculescu-Mizil and Caruana\(^1\)), which focus on difficult to classify samples that are close to the decision boundary (the support vectors).

## Calibrating a classifier

Calibrating a classifier consists of fitting a regressor (called a calibrator) that maps the output of the classifier (as given by decision_function or predict_proba) to a calibrated probability in [0, 1]. Denoting the output of the classifier for a given sample by \( f_i \), the calibrator tries to predict \( p(y_i = 1 | f_i) \).

The samples that are used to fit the calibrator should not be the same samples used to fit the classifier, as this would introduce bias. The classifier performance on its training data would be better than for novel data. Using the classifier output from training data to fit the calibrator would thus result in a biased calibrator that maps to probabilities closer to 0 and 1 than it should.

## Usage

The CalibratedClassifierCV class is used to calibrate a classifier.

CalibratedClassifierCV uses a cross-validation approach to fit both the classifier and the regressor. The data is split into \( k \) (train_set, test_set) couples (as determined by cv). The classifier (base_estimator) is trained on the train set, and its predictions on the test set are used to fit a regressor. This ensures that the data used to fit the classifier is always disjoint from the data used to fit the calibrator. After fitting, we end up with \( k \) (classifier, regressor) couples where each regressor maps the output of its corresponding classifier into [0, 1]. Each couple is exposed in the calibrated_classifiers_ attribute, where each entry is a calibrated classifier with a predict_proba method that outputs calibrated probabilities. The output of predict_proba for the main CalibratedClassifierCV instance corresponds to the average of the predicted probabilities of the \( k \) estimators in the calibrated_classifiers_ list. The output of predict is the class that has the highest probability.

Alternatively an already fitted classifier can be calibrated by setting cv="prefit". In this case, the data is not split and all of it is used to fit the regressor. It is up to the user make sure that the data used for fitting the classifier is disjoint from the data used for fitting the regressor.

sklearn.metrics.brier_score_loss may be used to assess how well a classifier is calibrated. However, this metric should be used with care because a lower Brier score does not always mean a better calibrated model. This is because the Brier score metric is a combination of calibration loss and refinement loss. Calibration loss is defined as the mean squared deviation from empirical probabilities derived from the slope of ROC segments. Refinement loss can be defined as the expected optimal loss as measured by the area under the optimal cost curve. As refinement loss can change independently from calibration loss, a lower Brier score does not necessarily mean a better calibrated model.

CalibratedClassifierCV supports the use of two ‘calibration’ regressors: ‘sigmoid’ and ‘isotonic’.

---

---

4.1. Supervised learning
Sigmoid

The sigmoid regressor is based on Platt’s logistic model:

\[ p(y_i = 1|f_i) = \frac{1}{1 + \exp(Af_i + B)} \]

where \( y_i \) is the true label of sample \( i \) and \( f_i \) is the output of the un-calibrated classifier for sample \( i \). \( A \) and \( B \) are real numbers to be determined when fitting the regressor via maximum likelihood.

The sigmoid method assumes the calibration curve can be corrected by applying a sigmoid function to the raw predictions. This assumption has been empirically justified in the case of Support Vector Machines with common kernel functions on various benchmark datasets in section 2.1 of Platt 1999 but does not necessarily hold in general. Additionally, the logistic model works best if the calibration error is symmetrical, meaning the classifier output for each binary class is normally distributed with the same variance. This is can be a problem for highly imbalanced classification problems, where outputs do not have equal variance.

In general this method is most effective when the un-calibrated model is under-confident and has similar calibration errors for both high and low outputs.

Isotonic

The ‘isotonic’ method fits a non-parametric isotonic regressor, which outputs a step-wise non-decreasing function (see sklearn.isotonic). It minimizes:

\[ \sum_{i=1}^{n} (y_i - \hat{f}_i)^2 \]

subject to \( \hat{f}_i \geq \hat{f}_j \) whenever \( f_i \geq f_j \). \( y_i \) is the true label of sample \( i \) and \( \hat{f}_i \) is the output of the calibrated classifier for sample \( i \) (i.e., the calibrated probability). This method is more general when compared to ‘sigmoid’ as the only restriction is that the mapping function is monotonically increasing. It is thus more powerful as it can correct any monotonic distortion of the un-calibrated model. However, it is more prone to overfitting, especially on small datasets.

Overall, ‘isotonic’ will perform as well as or better than ‘sigmoid’ when there is enough data (greater than ~ 1000 samples) to avoid overfitting.

Multiclass support

Both isotonic and sigmoid regressors only support 1-dimensional data (e.g., binary classification output) but are extended for multiclass classification if the base estimator supports multiclass predictions. For multiclass predictions, CalibratedClassifierCV calibrates for each class separately in a OneVsRestClassifier fashion. When predicting probabilities, the calibrated probabilities for each class are predicted separately. As those probabilities do not necessarily sum to one, a postprocessing is performed to normalize them.

Examples:

4.1.17 Neural network models (supervised)

**Warning:** This implementation is not intended for large-scale applications. In particular, scikit-learn offers no GPU support. For much faster, GPU-based implementations, as well as frameworks offering much more flexibility to build deep learning architectures, see Related Projects.

**Multi-layer Perceptron**

Multi-layer Perceptron (MLP) is a supervised learning algorithm that learns a function \( f(\cdot) : R^m \rightarrow R^o \) by training on a dataset, where \( m \) is the number of dimensions for input and \( o \) is the number of dimensions for output. Given a set of features \( X = x_1, x_2, ..., x_m \) and a target \( y \), it can learn a non-linear function approximator for either classification or regression. It is different from logistic regression, in that between the input and the output layer, there can be one or more non-linear layers, called hidden layers. Figure 1 shows a one hidden layer MLP with scalar output.

![Figure 1: One hidden layer MLP.](image)

The leftmost layer, known as the input layer, consists of a set of neurons \( \{x_i | x_1, x_2, ..., x_m \} \) representing the input features. Each neuron in the hidden layer transforms the values from the previous layer with a weighted linear summation \( w_1 x_1 + w_2 x_2 + ... + w_m x_m \), followed by a non-linear activation function \( g(\cdot) : R \rightarrow R \) - like the hyperbolic tan function. The output layer receives the values from the last hidden layer and transforms them into output values.

The module contains the public attributes `coefs_` and `intercepts_`. `coefs_` is a list of weight matrices, where weight matrix at index \( i \) represents the weights between layer \( i \) and layer \( i + 1 \). `intercepts_` is a list of bias vectors, where the vector at index \( i \) represents the bias values added to layer \( i + 1 \).
The advantages of Multi-layer Perceptron are:

- Capability to learn non-linear models.
- Capability to learn models in real-time (on-line learning) using `partial_fit`.

The disadvantages of Multi-layer Perceptron (MLP) include:

- MLP with hidden layers have a non-convex loss function where there exists more than one local minimum. Therefore different random weight initializations can lead to different validation accuracy.
- MLP requires tuning a number of hyperparameters such as the number of hidden neurons, layers, and iterations.
- MLP is sensitive to feature scaling.

Please see *Tips on Practical Use* section that addresses some of these disadvantages.

### Classification

Class `MLPClassifier` implements a multi-layer perceptron (MLP) algorithm that trains using Backpropagation. MLP trains on two arrays: array X of size (n_samples, n_features), which holds the training samples represented as floating point feature vectors; and array y of size (n_samples,), which holds the target values (class labels) for the training samples:

```python
>>> from sklearn.neural_network import MLPClassifier
>>> X = [[0., 0.], [1., 1.]]
>>> y = [0, 1]
>>> clf = MLPClassifier(solver='lbfgs', alpha=1e-5,
                      hidden_layer_sizes=(5, 2), random_state=1)
... MLPClassifier(alpha=1e-05, hidden_layer_sizes=(5, 2), random_state=1,
...                 solver='lbfgs')
```

After fitting (training), the model can predict labels for new samples:

```python
>>> clf.predict([[2., 2.], [-1., -2.]])
array([1, 0])
```

MLP can fit a non-linear model to the training data. `clf.coefs_` contains the weight matrices that constitute the model parameters:

```python
>>> [coef.shape for coef in clf.coefs_]
[(2, 5), (5, 2), (2, 1)]
```

Currently, `MLPClassifier` supports only the Cross-Entropy loss function, which allows probability estimates by running the `predict_proba` method.

MLP trains using Backpropagation. More precisely, it trains using some form of gradient descent and the gradients are calculated using Backpropagation. For classification, it minimizes the Cross-Entropy loss function, giving a vector of probability estimates \( P(y|x) \) per sample \( x \):

```python
>>> clf.predict_proba([[2., 2.], [1., 2.]])
array([[1.967e-04, 9.998e-01],
       [1.967e-04, 9.998e-01]]
```

`MLPClassifier` supports multi-class classification by applying *Softmax* as the output function.
Further, the model supports *multi-label classification* in which a sample can belong to more than one class. For each class, the raw output passes through the logistic function. Values larger or equal to 0.5 are rounded to 1, otherwise to 0. For a predicted output of a sample, the indices where the value is 1 represents the assigned classes of that sample:

```python
>>> X = [[0., 0.], [1., 1.]]
>>> y = [[0, 1], [1, 1]]
>>> clf = MLPClassifier(solver='lbfgs', alpha=1e-5,
...                   hidden_layer_sizes=(15,), random_state=1)
...  
>>> clf.fit(X, y)
MLPClassifier(alpha=1e-05, hidden_layer_sizes=(15,), random_state=1,
              solver='lbfgs')
>>> clf.predict([[1., 2.]])
array([[1, 1]])
>>> clf.predict([[0., 0.]])
array([[0, 1]])
```

See the examples below and the docstring of `MLPClassifier.fit` for further information.

### Examples:

- *Compare Stochastic learning strategies for MLPClassifier*
- *Visualization of MLP weights on MNIST*

### Regression

Class `MLPRegressor` implements a multi-layer perceptron (MLP) that trains using backpropagation with no activation function in the output layer, which can also be seen as using the identity function as activation function. Therefore, it uses the square error as the loss function, and the output is a set of continuous values.

`MLPRegressor` also supports multi-output regression, in which a sample can have more than one target.

### Regularization

Both `MLPRegressor` and `MLPClassifier` use parameter `alpha` for regularization (L2 regularization) term which helps in avoiding overfitting by penalizing weights with large magnitudes. Following plot displays varying decision function with value of alpha.

See the examples below for further information.

### Examples:

- *Varying regularization in Multi-layer Perceptron*
Algorithms

MLP trains using Stochastic Gradient Descent, Adam, or L-BFGS. Stochastic Gradient Descent (SGD) updates parameters using the gradient of the loss function with respect to a parameter that needs adaptation, i.e.

\[ w \leftarrow w - \eta \left( \alpha \frac{\partial R(w)}{\partial w} + \frac{\partial \text{Loss}}{\partial w} \right) \]

where \( \eta \) is the learning rate which controls the step-size in the parameter space search. \( \text{Loss} \) is the loss function used for the network.

More details can be found in the documentation of SGD.

Adam is similar to SGD in a sense that it is a stochastic optimizer, but it can automatically adjust the amount to update parameters based on adaptive estimates of lower-order moments.

With SGD or Adam, training supports online and mini-batch learning.

L-BFGS is a solver that approximates the Hessian matrix which represents the second-order partial derivative of a function. Further it approximates the inverse of the Hessian matrix to perform parameter updates. The implementation uses the Scipy version of L-BFGS.

If the selected solver is ‘L-BFGS’, training does not support online nor mini-batch learning.

Complexity

Suppose there are \( n \) training samples, \( m \) features, \( k \) hidden layers, each containing \( h \) neurons - for simplicity, and \( o \) output neurons. The time complexity of backpropagation is \( O(n \cdot m \cdot h^k \cdot o \cdot i) \), where \( i \) is the number of iterations. Since backpropagation has a high time complexity, it is advisable to start with smaller number of hidden neurons and few hidden layers for training.
Mathematical formulation

Given a set of training examples \((x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)\) where \(x_i \in \mathbb{R}^n\) and \(y_i \in \{0, 1\}\), a one hidden layer one hidden neuron MLP learns the function \(f(x) = W_2 g(W_1^T x + b_1) + b_2\) where \(W_1 \in \mathbb{R}^m\) and \(W_2, b_1, b_2 \in \mathbb{R}\) are model parameters. \(W_1, W_2\) represent the weights of the input layer and hidden layer, respectively; and \(b_1, b_2\) represent the bias added to the hidden layer and the output layer, respectively. \(g(\cdot) : \mathbb{R} \rightarrow \mathbb{R}\) is the activation function, set by default as the hyperbolic tan. It is given as,

\[
g(z) = \frac{e^z - e^{-z}}{e^z + e^{-z}}
\]

For binary classification, \(f(x)\) passes through the logistic function \(g(z) = 1/(1+e^{-z})\) to obtain output values between zero and one. A threshold, set to 0.5, would assign samples of outputs larger or equal 0.5 to the positive class, and the rest to the negative class.

If there are more than two classes, \(f(x)\) itself would be a vector of size (n_classes,). Instead of passing through logistic function, it passes through the softmax function, which is written as,

\[
\text{softmax}(z)_i = \frac{\exp(z_i)}{\sum_{k=1}^{K} \exp(z_k)}
\]

where \(z_i\) represents the \(i\)th element of the input to softmax, which corresponds to class \(i\), and \(K\) is the number of classes. The result is a vector containing the probabilities that sample \(x\) belong to each class. The output is the class with the highest probability.

In regression, the output remains as \(f(x)\); therefore, output activation function is just the identity function.

MLP uses different loss functions depending on the problem type. The loss function for classification is Cross-Entropy, which in binary case is given as,

\[
\text{Loss}(\hat{y}, y, W) = -y \ln \hat{y} - (1 - y) \ln (1 - \hat{y}) + \alpha \|W\|_2^2
\]

where \(\alpha \|W\|_2^2\) is an L2-regularization term (aka penalty) that penalizes complex models; and \(\alpha > 0\) is a non-negative hyperparameter that controls the magnitude of the penalty.

For regression, MLP uses the Square Error loss function; written as,

\[
\text{Loss}(\hat{y}, y, W) = \frac{1}{2} \|\hat{y} - y\|_2^2 + \frac{\alpha}{2} \|W\|_2^2
\]

Starting from initial random weights, multi-layer perceptron (MLP) minimizes the loss function by repeatedly updating these weights. After computing the loss, a backward pass propagates it from the output layer to the previous layers, providing each weight parameter with an update value meant to decrease the loss.

In gradient descent, the gradient \(\nabla \text{Loss}_W\) of the loss with respect to the weights is computed and deducted from \(W\). More formally, this is expressed as,

\[
W^{i+1} = W^i - \epsilon \nabla \text{Loss}_W^i
\]

where \(i\) is the iteration step, and \(\epsilon\) is the learning rate with a value larger than 0.

The algorithm stops when it reaches a preset maximum number of iterations; or when the improvement in loss is below a certain, small number.
Tips on Practical Use

- Multi-layer Perceptron is sensitive to feature scaling, so it is highly recommended to scale your data. For example, scale each attribute on the input vector $X$ to $[0, 1]$ or $[-1, +1]$, or standardize it to have mean 0 and variance 1. Note that you must apply the same scaling to the test set for meaningful results. You can use `StandardScaler` for standardization.

```python
>>> from sklearn.preprocessing import StandardScaler
>>> scaler = StandardScaler()
>>> # Don't cheat - fit only on training data
>>> scaler.fit(X_train)
>>> X_train = scaler.transform(X_train)
>>> # apply same transformation to test data
>>> X_test = scaler.transform(X_test)
```

An alternative and recommended approach is to use `StandardScaler` in a `Pipeline`

- Finding a reasonable regularization parameter $\alpha$ is best done using `GridSearchCV`, usually in the range $10.0^{-\text{np.arange(1, 7)}}$.

- Empirically, we observed that L-BFGS converges faster and with better solutions on small datasets. For relatively large datasets, however, Adam is very robust. It usually converges quickly and gives pretty good performance. SGD with momentum or nesterov’s momentum, on the other hand, can perform better than those two algorithms if learning rate is correctly tuned.

More control with `warm_start`

If you want more control over stopping criteria or learning rate in SGD, or want to do additional monitoring, using `warm_start=True` and `max_iter=1` and iterating yourself can be helpful:

```python
>>> X = [[0., 0.], [1., 1.]]
>>> y = [0, 1]
>>> clf = MLPClassifier(hidden_layer_sizes=(15,), random_state=1, max_iter=1, warm_start=True)
>>> for i in range(10):
...   clf.fit(X, y)
...   # additional monitoring / inspection
MLPClassifier(...)
```

4.2 Unsupervised learning

4.2.1 Gaussian mixture models

`sklearn.mixture` is a package which enables one to learn Gaussian Mixture Models (diagonal, spherical, tied and full covariance matrices supported), sample them, and estimate them from data. Facilities to help determine the appropriate number of components are also provided.

![Gaussian Mixture Model](image)

Fig. 4: **Two-component Gaussian mixture model**: data points, and equi-probability surfaces of the model.

A Gaussian mixture model is a probabilistic model that assumes all the data points are generated from a mixture of a finite number of Gaussian distributions with unknown parameters. One can think of mixture models as generalizing k-means clustering to incorporate information about the covariance structure of the data as well as the centers of the latent Gaussians.

Scikit-learn implements different classes to estimate Gaussian mixture models, that correspond to different estimation strategies, detailed below.

**Gaussian Mixture**

The `GaussianMixture` object implements the *expectation-maximization* (EM) algorithm for fitting mixture-of-Gaussian models. It can also draw confidence ellipsoids for multivariate models, and compute the Bayesian Information Criterion to assess the number of clusters in the data. A `GaussianMixture.fit` method is provided that learns a Gaussian Mixture Model from train data. Given test data, it can assign to each sample the Gaussian it mostly probably belong to using the `GaussianMixture.predict` method.

The `GaussianMixture` comes with different options to constrain the covariance of the difference classes estimated: spherical, diagonal, tied or full covariance.

**Examples:**

- See *GMM covariances* for an example of using the Gaussian mixture as clustering on the iris dataset.
- See *Density Estimation for a Gaussian mixture* for an example on plotting the density estimation.
Pros and cons of class GaussianMixture

Pros

Speed  It is the fastest algorithm for learning mixture models

Agnostic  As this algorithm maximizes only the likelihood, it will not bias the means towards zero, or bias the cluster sizes to have specific structures that might or might not apply.

Cons

Singularities  When one has insufficiently many points per mixture, estimating the covariance matrices becomes difficult, and the algorithm is known to diverge and find solutions with infinite likelihood unless one regularizes the covariances artificially.

Number of components  This algorithm will always use all the components it has access to, needing held-out data or information theoretical criteria to decide how many components to use in the absence of external cues.
Selecting the number of components in a classical Gaussian Mixture Model

The BIC criterion can be used to select the number of components in a Gaussian Mixture in an efficient way. In theory, it recovers the true number of components only in the asymptotic regime (i.e. if much data is available and assuming that the data was actually generated i.i.d. from a mixture of Gaussian distribution). Note that using a Variational Bayesian Gaussian mixture avoids the specification of the number of components for a Gaussian mixture model.

![BIC score per model](image)

**Examples:**

- See Gaussian Mixture Model Selection for an example of model selection performed with classical Gaussian mixture.

Estimation algorithm Expectation-maximization

The main difficulty in learning Gaussian mixture models from unlabeled data is that it is one usually doesn’t know which points came from which latent component (if one has access to this information it gets very easy to fit a separate Gaussian distribution to each set of points). Expectation-maximization is a well-founded statistical algorithm to get around this problem by an iterative process. First one assumes random components (randomly centered on data points, learned from k-means, or even just normally distributed around the origin) and computes for each point a probability of being generated by each component of the model. Then, one tweaks the parameters to maximize the likelihood of the data given those assignments. Repeating this process is guaranteed to always converge to a local optimum.
Variational Bayesian Gaussian Mixture

The *BayesianGaussianMixture* object implements a variant of the Gaussian mixture model with variational inference algorithms. The API is similar as the one defined by *GaussianMixture*.

**Estimation algorithm: variational inference**

Variational inference is an extension of expectation-maximization that maximizes a lower bound on model evidence (including priors) instead of data likelihood. The principle behind variational methods is the same as expectation-maximization (that is both are iterative algorithms that alternate between finding the probabilities for each point to be generated by each mixture and fitting the mixture to these assigned points), but variational methods add regularization by integrating information from prior distributions. This avoids the singularities often found in expectation-maximization solutions but introduces some subtle biases to the model. Inference is often notably slower, but not usually as much so as to render usage unpractical.

Due to its Bayesian nature, the variational algorithm needs more hyper-parameters than expectation-maximization, the most important of these being the concentration parameter `weight_concentration_prior`. Specifying a low value for the concentration prior will make the model put most of the weight on few components set the remaining components weights very close to zero. High values of the concentration prior will allow a larger number of components to be active in the mixture.

The parameters implementation of the *BayesianGaussianMixture* class proposes two types of prior for the weights distribution: a finite mixture model with Dirichlet distribution and an infinite mixture model with the Dirichlet Process. In practice Dirichlet Process inference algorithm is approximated and uses a truncated distribution with a fixed maximum number of components (called the Stick-breaking representation). The number of components actually used almost always depends on the data.

The next figure compares the results obtained for the different type of the weight concentration prior (parameter `weight_concentration_prior_type`) for different values of `weight_concentration_prior`. Here, we can see the value of the `weight_concentration_prior` parameter has a strong impact on the effective number of active components obtained. We can also notice that large values for the concentration weight prior lead to more uniform weights when the type of prior is ‘dirichlet_distribution’ while this is not necessarily the case for the ‘dirichlet_process’ type (used by default).
The examples below compare Gaussian mixture models with a fixed number of components, to the variational Gaussian mixture models with a Dirichlet process prior. Here, a classical Gaussian mixture is fitted with 5 components on a dataset composed of 2 clusters. We can see that the variational Gaussian mixture with a Dirichlet process prior is able to limit itself to only 2 components whereas the Gaussian mixture fits the data with a fixed number of components that has to be set a priori by the user. In this case the user has selected \texttt{n_components=5} which does not match the true generative distribution of this toy dataset. Note that with very little observations, the variational Gaussian mixture models with a Dirichlet process prior can take a conservative stand, and fit only one component.

On the following figure we are fitting a dataset not well-depicted by a Gaussian mixture. Adjusting the
weight_concentration_prior, parameter of the BayesianGaussianMixture controls the number of components used to fit this data. We also present on the last two plots a random sampling generated from the two resulting mixtures.

**Examples:**

- See [Gaussian Mixture Model Ellipsoids](#) for an example on plotting the confidence ellipsoids for both GaussianMixture and BayesianGaussianMixture.

- Gaussian Mixture Model Sine Curve shows using GaussianMixture and BayesianGaussianMixture to fit a sine wave.

- See [Concentration Prior Type Analysis of Variation Bayesian Gaussian Mixture](#) for an example plotting the confidence ellipsoids for the BayesianGaussianMixture with different weight_concentration_prior_type for different values of the parameter weight_concentration_prior.

**Pros and cons of variational inference with BayesianGaussianMixture**

**Pros**

Automatic selection when weight_concentration_prior is small enough and n_components is larger than what is found necessary by the model, the Variational Bayesian mixture model has a natural tendency to set some mixture weights values close to zero. This makes it possible to let the model choose a suitable number of effective components automatically. Only an upper bound of this number needs to be provided. Note however that the “ideal” number of active components is very application specific and is typically ill-defined in a data exploration setting.

Less sensitivity to the number of parameters unlike finite models, which will almost always use all components as much as they can, and hence will produce wildly different solutions for different numbers of components, the variational inference with a Dirichlet process prior
4.2. Unsupervised learning

Bayesian Gaussian mixture models with a Dirichlet process prior for $\gamma_0 = 0.01$.

Bayesian Gaussian mixture models with a Dirichlet process prior for $\gamma_0 = 100$.

Gaussian mixture with a Dirichlet process prior for $\gamma_0 = 0.01$ sampled with 2000 samples.

Gaussian mixture with a Dirichlet process prior for $\gamma_0 = 100$ sampled with 2000 samples.
Regularization due to the incorporation of prior information, variational solutions have less pathological special cases than expectation-maximization solutions.

Cons

**Speed** the extra parametrization necessary for variational inference make inference slower, although not by much.

**Hyperparameters** this algorithm needs an extra hyperparameter that might need experimental tuning via cross-validation.

**Bias** there are many implicit biases in the inference algorithms (and also in the Dirichlet process if used), and whenever there is a mismatch between these biases and the data it might be possible to fit better models using a finite mixture.

The Dirichlet Process

Here we describe variational inference algorithms on Dirichlet process mixture. The Dirichlet process is a prior probability distribution on *clusterings with an infinite, unbounded, number of partitions*. Variational techniques let us incorporate this prior structure on Gaussian mixture models at almost no penalty in inference time, comparing with a finite Gaussian mixture model.

An important question is how can the Dirichlet process use an infinite, unbounded number of clusters and still be consistent. While a full explanation doesn’t fit this manual, one can think of its stick breaking process analogy to help understanding it. The stick breaking process is a generative story for the Dirichlet process. We start with a unit-length stick and in each step we break off a portion of the remaining stick. Each time, we associate the length of the piece of the stick to the proportion of points that falls into a group of the mixture. At the end, to represent the infinite mixture, we associate the last remaining piece of the stick to the proportion of points that don’t fall into all the other groups. The length of each piece is a random variable with probability proportional to the concentration parameter. Smaller value of the concentration will divide the unit-length into larger pieces of the stick (defining more concentrated distribution). Larger concentration values will create smaller pieces of the stick (increasing the number of components with non zero weights).

Variational inference techniques for the Dirichlet process still work with a finite approximation to this infinite mixture model, but instead of having to specify a priori how many components one wants to use, one just specifies the concentration parameter and an upper bound on the number of mixture components (this upper bound, assuming it is higher than the “true” number of components, affects only algorithmic complexity, not the actual number of components used).

### 4.2.2 Manifold learning

Look for the bare necessities
The simple bare necessities
Forget about your worries and your strife
I mean the bare necessities
Old Mother Nature’s recipes
That bring the bare necessities of life

– Baloo’s song [The Jungle Book]
Manifold learning is an approach to non-linear dimensionality reduction. Algorithms for this task are based on the idea that the dimensionality of many data sets is only artificially high.

**Introduction**

High-dimensional datasets can be very difficult to visualize. While data in two or three dimensions can be plotted to show the inherent structure of the data, equivalent high-dimensional plots are much less intuitive. To aid visualization of the structure of a dataset, the dimension must be reduced in some way.

The simplest way to accomplish this dimensionality reduction is by taking a random projection of the data. Though this allows some degree of visualization of the data structure, the randomness of the choice leaves much to be desired. In a random projection, it is likely that the more interesting structure within the data will be lost.

To address this concern, a number of supervised and unsupervised linear dimensionality reduction frameworks have been designed, such as Principal Component Analysis (PCA), Independent Component Analysis, Linear Discriminant Analysis, and others. These algorithms define specific rubrics to choose an “interesting” linear projection of the data. These methods can be powerful, but often miss important non-linear structure in the data.
Manifold Learning can be thought of as an attempt to generalize linear frameworks like PCA to be sensitive to non-linear structure in data. Though supervised variants exist, the typical manifold learning problem is unsupervised: it learns the high-dimensional structure of the data from the data itself, without the use of predetermined classifications.

**Examples:**

- See *Manifold learning on handwritten digits: Locally Linear Embedding, Isomap…* for an example of dimensionality reduction on handwritten digits.

- See *Comparison of Manifold Learning methods* for an example of dimensionality reduction on a toy “S-curve” dataset.

The manifold learning implementations available in scikit-learn are summarized below

**Isomap**

One of the earliest approaches to manifold learning is the Isomap algorithm, short for Isometric Mapping. Isomap can be viewed as an extension of Multi-dimensional Scaling (MDS) or Kernel PCA. Isomap seeks a lower-dimensional embedding which maintains geodesic distances between all points. Isomap can be performed with the object `Isomap`. 
Complexity

The Isomap algorithm comprises three stages:

1. **Nearest neighbor search.** Isomap uses *BallTree* for efficient neighbor search. The cost is approximately $O[D \log(k) N \log(N)]$, for $k$ nearest neighbors of $N$ points in $D$ dimensions.

2. **Shortest-path graph search.** The most efficient known algorithms for this are *Dijkstra’s Algorithm*, which is approximately $O[N^2(k + \log(N))]$, or the *Floyd-Warshall algorithm*, which is $O[N^3]$. The algorithm can be selected by the user with the `path_method` keyword of *Isomap*. If unspecified, the code attempts to choose the best algorithm for the input data.

3. **Partial eigenvalue decomposition.** The embedding is encoded in the eigenvectors corresponding to the $d$ largest eigenvalues of the $N \times N$ isomap kernel. For a dense solver, the cost is approximately $O[dN^2]$. This cost can often be improved using the *ARPACK* solver. The eigensolver can be specified by the user with the `eigen_solver` keyword of *Isomap*. If unspecified, the code attempts to choose the best algorithm for the input data.

The overall complexity of Isomap is $O[D \log(k) N \log(N)] + O[N^2(k + \log(N))] + O[dN^2]$.

- $N$: number of training data points
- $D$: input dimension
- $k$: number of nearest neighbors
- $d$: output dimension

- “A global geometric framework for nonlinear dimensionality reduction” Tenenbaum, J.B.; De Silva, V.; & Langford, J.C. Science 290 (5500)

Locally Linear Embedding

Locally linear embedding (LLE) seeks a lower-dimensional projection of the data which preserves distances within local neighborhoods. It can be thought of as a series of local Principal Component Analyses which are globally compared to find the best non-linear embedding.

Locally linear embedding can be performed with function `locally_linear_embedding` or its object-oriented counterpart `LocallyLinearEmbedding`.

Complexity

The standard LLE algorithm comprises three stages:

1. **Nearest Neighbors Search.** See discussion under Isomap above.

2. **Weight Matrix Construction.** $O[D N k^3]$. The construction of the LLE weight matrix involves the solution of a $k \times k$ linear equation for each of the $N$ local neighborhoods

3. **Partial Eigenvalue Decomposition.** See discussion under Isomap above.

The overall complexity of standard LLE is $O[D \log(k) N \log(N)] + O[D N k^3] + O[dN^2]$.

- $N$: number of training data points
- $D$: input dimension
• \( k \): number of nearest neighbors
• \( d \): output dimension

References:

Modified Locally Linear Embedding

One well-known issue with LLE is the regularization problem. When the number of neighbors is greater than the number of input dimensions, the matrix defining each local neighborhood is rank-deficient. To address this, standard LLE applies an arbitrary regularization parameter \( r \), which is chosen relative to the trace of the local weight matrix. Though it can be shown formally that as \( r \to 0 \), the solution converges to the desired embedding, there is no guarantee that the optimal solution will be found for \( r > 0 \). This problem manifests itself in embeddings which distort the underlying geometry of the manifold.

One method to address the regularization problem is to use multiple weight vectors in each neighborhood. This is the essence of modified locally linear embedding (MLLE). MLLE can be performed with function `locally_linear_embedding` or its object-oriented counterpart `LocallyLinearEmbedding`, with the keyword `method = 'modified'`. It requires \( n_{neighbors} > n_{components} \).

Complexity

The MLLE algorithm comprises three stages:

1. Nearest Neighbors Search. Same as standard LLE
2. Weight Matrix Construction. Approximately \( O[D N k^3] + O[N(k - D)k^2] \). The first term is exactly equivalent to that of standard LLE. The second term has to do with constructing the weight matrix from multiple weights. In practice, the added cost of constructing the MLLE weight matrix is relatively small compared to the cost of stages 1 and 3.
3. Partial Eigenvalue Decomposition. Same as standard LLE

The overall complexity of MLLE is \( O[D \log(k)N \log(N)] + O[D N k^3] + O[N(k - D)k^2] + O[d N^2] \).
• $N$: number of training data points
• $D$: input dimension
• $k$: number of nearest neighbors
• $d$: output dimension

References:

• “MLLE: Modified Locally Linear Embedding Using Multiple Weights” Zhang, Z. & Wang, J.

Hessian Eigenmapping

Hessian Eigenmapping (also known as Hessian-based LLE: HLLE) is another method of solving the regularization problem of LLE. It revolves around a hessian-based quadratic form at each neighborhood which is used to recover the locally linear structure. Though other implementations note its poor scaling with data size, sklearn implements some algorithmic improvements which make its cost comparable to that of other LLE variants for small output dimension. HLLE can be performed with function `locally_linear_embedding` or its object-oriented counterpart `LocallyLinearEmbedding`, with the keyword `method = 'hessian'`. It requires $n_{neighbors} > n_{components} \times (n_{components} + 3) / 2$. 
Complexity

The HLLE algorithm comprises three stages:

1. **Nearest Neighbors Search.** Same as standard LLE

2. **Weight Matrix Construction.** Approximately $O[D Nk^3] + O[N d^6]$. The first term reflects a similar cost to that of standard LLE. The second term comes from a QR decomposition of the local hessian estimator.

3. **Partial Eigenvalue Decomposition.** Same as standard LLE

- $N$: number of training data points
- $D$: input dimension
- $k$: number of nearest neighbors
- $d$: output dimension

**References:**

Spectral Embedding

Spectral Embedding is an approach to calculating a non-linear embedding. Scikit-learn implements Laplacian Eigenmaps, which finds a low dimensional representation of the data using a spectral decomposition of the graph Laplacian. The graph generated can be considered as a discrete approximation of the low dimensional manifold in the high dimensional space. Minimization of a cost function based on the graph ensures that points close to each other on the manifold are mapped close to each other in the low dimensional space, preserving local distances. Spectral embedding can be performed with the function `spectral_embedding` or its object-oriented counterpart `SpectralEmbedding`.

Complexity

The Spectral Embedding (Laplacian Eigenmaps) algorithm comprises three stages:

1. **Weighted Graph Construction.** Transform the raw input data into graph representation using affinity (adjacency) matrix representation.

2. **Graph Laplacian Construction.** Unnormalized Graph Laplacian is constructed as $L = D - A$ and normalized one as $L = D^{-\frac{1}{2}}(D - A)D^{-\frac{1}{2}}$.

3. **Partial Eigenvalue Decomposition.** Eigenvalue decomposition is done on graph Laplacian

The overall complexity of spectral embedding is $O[D \log(k) N \log(N)] + O[D Nk^3] + O[d N^2]$.

- $N$: number of training data points
- $D$: input dimension
- $k$: number of nearest neighbors
- $d$: output dimension
Local Tangent Space Alignment

Though not technically a variant of LLE, Local tangent space alignment (LTSA) is algorithmically similar enough to LLE that it can be put in this category. Rather than focusing on preserving neighborhood distances as in LLE, LTSA seeks to characterize the local geometry at each neighborhood via its tangent space, and performs a global optimization to align these local tangent spaces to learn the embedding. LTSA can be performed with function `locally_linear_embedding` or its object-oriented counterpart `LocallyLinearEmbedding`, with the keyword method = 'ltsa'.

![Local Tangent Space Alignment of the digits (time 0.41s)](image)

Complexity

The LTSA algorithm comprises three stages:

1. **Nearest Neighbors Search.** Same as standard LLE
2. **Weight Matrix Construction.** Approximately $O[D N k^3 + k^2 d]$. The first term reflects a similar cost to that of standard LLE.
3. **Partial Eigenvalue Decomposition.** Same as standard LLE

The overall complexity of standard LTSA is $O[D \log(k) N \log(N)] + O[D N k^3] + O[k^2 d] + O[d N^2]$.

- $N$ : number of training data points
- $D$ : input dimension
- $k$ : number of nearest neighbors
- $d$ : output dimension

Multi-dimensional Scaling (MDS)

Multidimensional scaling (MDS) seeks a low-dimensional representation of the data in which the distances respect well the distances in the original high-dimensional space.

In general, MDS is a technique used for analyzing similarity or dissimilarity data. It attempts to model similarity or dissimilarity data as distances in a geometric spaces. The data can be ratings of similarity between objects, interaction frequencies of molecules, or trade indices between countries.

There exists two types of MDS algorithm: metric and non metric. In the scikit-learn, the class MDS implements both. In Metric MDS, the input similarity matrix arises from a metric (and thus respects the triangular inequality), the distances between output two points are then set to be as close as possible to the similarity or dissimilarity data. In the non-metric version, the algorithms will try to preserve the order of the distances, and hence seek for a monotonic relationship between the distances in the embedded space and the similarities/dissimilarities.

Let $S$ be the similarity matrix, and $X$ the coordinates of the $n$ input points. Disparities $\hat{d}_{ij}$ are transformation of the similarities chosen in some optimal ways. The objective, called the stress, is then defined by $\sum_{i<j} d_{ij}(X) - \hat{d}_{ij}(X)$.
Metric MDS

The simplest metric MDS model, called absolute MDS, disparities are defined by $\hat{d}_{ij} = S_{ij}$. With absolute MDS, the value $S_{ij}$ should then correspond exactly to the distance between point $i$ and $j$ in the embedding point.

Most commonly, disparities are set to $\hat{d}_{ij} = bS_{ij}$.

Nonmetric MDS

Non metric MDS focuses on the ordination of the data. If $S_{ij} < S_{jk}$, then the embedding should enforce $d_{ij} < d_{jk}$. A simple algorithm to enforce that is to use a monotonic regression of $d_{ij}$ on $S_{ij}$, yielding disparities $\hat{d}_{ij}$ in the same order as $S_{ij}$.

A trivial solution to this problem is to set all the points on the origin. In order to avoid that, the disparities $\hat{d}_{ij}$ are normalized.

t-distributed Stochastic Neighbor Embedding (t-SNE)

T-SNE (TSNE) converts affinities of data points to probabilities. The affinities in the original space are represented by Gaussian joint probabilities and the affinities in the embedded space are represented by Student’s t-distributions. This allows t-SNE to be particularly sensitive to local structure and has a few other advantages over existing techniques:

- Revealing the structure at many scales on a single map
- Revealing data that lie in multiple, different, manifolds or clusters
- Reducing the tendency to crowd points together at the center

While Isomap, LLE and variants are best suited to unfold a single continuous low dimensional manifold, t-SNE will focus on the local structure of the data and will tend to extract clustered local groups of samples as highlighted on the S-curve example. This ability to group samples based on the local structure might be beneficial to visually disentangle a dataset that comprises several manifolds at once as is the case in the digits dataset.

The Kullback-Leibler (KL) divergence of the joint probabilities in the original space and the embedded space will be minimized by gradient descent. Note that the KL divergence is not convex, i.e. multiple restarts with different initializations will end up in local minima of the KL divergence. Hence, it is sometimes useful to try different seeds and select the embedding with the least KL divergence.

The disadvantages to using t-SNE are roughly:

- t-SNE is computationally expensive, and can take several hours on million-sample datasets where PCA will finish in seconds or minutes
- The Barnes-Hut t-SNE method is limited to two or three dimensional embeddings.
- The algorithm is stochastic and multiple restarts with different seeds can yield different embeddings. However, it is perfectly legitimate to pick the embedding with the least error.
- Global structure is not explicitly preserved. This problem is mitigated by initializing points with PCA (using init='pca').
Optimizing t-SNE

The main purpose of t-SNE is visualization of high-dimensional data. Hence, it works best when the data will be embedded on two or three dimensions.

Optimizing the KL divergence can be a little bit tricky sometimes. There are five parameters that control the optimization of t-SNE and therefore possibly the quality of the resulting embedding:

- perplexity
- early exaggeration factor
- learning rate
- maximum number of iterations
- angle (not used in the exact method)

The perplexity is defined as $k = 2^S$ where $S$ is the Shannon entropy of the conditional probability distribution. The perplexity of a $k$-sided die is $k$, so that $k$ is effectively the number of nearest neighbors t-SNE considers when generating the conditional probabilities. Larger perplexities lead to more nearest neighbors and less sensitive to small structure. Conversely a lower perplexity considers a smaller number of neighbors, and thus ignores more global information in favour of the local neighborhood. As dataset sizes get larger more points will be required to get a reasonable sample of the local neighborhood, and hence larger perplexities may be required. Similarly noisier datasets will require larger perplexity values to encompass enough local neighbors to see beyond the background noise.

The maximum number of iterations is usually high enough and does not need any tuning. The optimization consists of two phases: the early exaggeration phase and the final optimization. During early exaggeration the joint probabilities in the original space will be artificially increased by multiplication with a given factor. Larger factors result in larger gaps between natural clusters in the data. If the factor is too high, the KL divergence could increase during this phase. Usually it does not have to be tuned. A critical parameter is the learning rate. If it is too low gradient descent will get stuck in a bad local minimum. If it is too high the KL divergence will increase during optimization. More tips can be found in Laurens van der Maaten’s FAQ (see references). The last parameter, angle, is a tradeoff between performance and accuracy. Larger angles imply that we can approximate larger regions by a single point, leading to better speed but less accurate results.

“How to Use t-SNE Effectively” provides a good discussion of the effects of the various parameters, as well as interactive plots to explore the effects of different parameters.

Barnes-Hut t-SNE

The Barnes-Hut t-SNE that has been implemented here is usually much slower than other manifold learning algorithms. The optimization is quite difficult and the computation of the gradient is $O(dN\log(N))$, where $d$ is the number of output dimensions and $N$ is the number of samples. The Barnes-Hut method improves on the exact method where t-SNE complexity is $O(dN^2)$, but has several other notable differences:

- The Barnes-Hut implementation only works when the target dimensionality is 3 or less. The 2D case is typical when building visualizations.

- Barnes-Hut only works with dense input data. Sparse data matrices can only be embedded with the exact method or can be approximated by a dense low rank projection for instance using TruncatedSVD

- Barnes-Hut is an approximation of the exact method. The approximation is parameterized with the angle parameter, therefore the angle parameter is unused when method=”exact”

- Barnes-Hut is significantly more scalable. Barnes-Hut can be used to embed hundred of thousands of data points while the exact method can handle thousands of samples before becoming computationally intractable
For visualization purpose (which is the main use case of t-SNE), using the Barnes-Hut method is strongly recommended. The exact t-SNE method is useful for checking the theoretically properties of the embedding possibly in higher dimensional space but limit to small datasets due to computational constraints.

Also note that the digits labels roughly match the natural grouping found by t-SNE while the linear 2D projection of the PCA model yields a representation where label regions largely overlap. This is a strong clue that this data can be well separated by non linear methods that focus on the local structure (e.g. an SVM with a Gaussian RBF kernel). However, failing to visualize well separated homogeneously labeled groups with t-SNE in 2D does not necessarily imply that the data cannot be correctly classified by a supervised model. It might be the case that 2 dimensions are not low enough to accurately represents the internal structure of the data.

Tips on practical use

- Make sure the same scale is used over all features. Because manifold learning methods are based on a nearest-neighbor search, the algorithm may perform poorly otherwise. See StandardScaler for convenient ways of scaling heterogeneous data.

- The reconstruction error computed by each routine can be used to choose the optimal output dimension. For a $d$-dimensional manifold embedded in a $D$-dimensional parameter space, the reconstruction error will decrease as $\text{n\_components}$ is increased until $\text{n\_components} == d$.

- Note that noisy data can “short-circuit” the manifold, in essence acting as a bridge between parts of the manifold that would otherwise be well-separated. Manifold learning on noisy and/or incomplete data is an active area of research.

- Certain input configurations can lead to singular weight matrices, for example when more than two points in the dataset are identical, or when the data is split into disjointed groups. In this case, solver='arpack' will fail to find the null space. The easiest way to address this is to use solver='dense' which will work on a singular matrix, though it may be very slow depending on the number of input points. Alternatively, one can attempt to understand the source of the singularity: if it is due to disjoint sets, increasing $\text{n\_neighbors}$ may help. If it is due to identical points in the dataset, removing these points may help.

*Totally Random Trees Embedding* can also be useful to derive non-linear representations of feature space, also it does not perform dimensionality reduction.
4.2.3 Clustering

Clustering of unlabeled data can be performed with the module `sklearn.cluster`.

Each clustering algorithm comes in two variants: a class, that implements the `fit` method to learn the clusters on train data, and a function, that, given train data, returns an array of integer labels corresponding to the different clusters. For the class, the labels over the training data can be found in the `labels_` attribute.

Input data

One important thing to note is that the algorithms implemented in this module can take different kinds of matrix as input. All the methods accept standard data matrices of shape `(n_samples, n_features)`. These can be obtained from the classes in the `sklearn.feature_extraction` module. For `AffinityPropagation`, `SpectralClustering` and `DBSCAN` one can also input similarity matrices of shape `(n_samples, n_samples)`. These can be obtained from the functions in the `sklearn.metrics.pairwise` module.

Non-flat geometry clustering is useful when the clusters have a specific shape, i.e. a non-flat manifold, and the standard euclidean distance is not the right metric. This case arises in the two top rows of the figure above.

Gaussian mixture models, useful for clustering, are described in another chapter of the documentation dedicated to mixture models. **KMeans** can be seen as a special case of Gaussian mixture model with equal covariance per component.
K-means

The KMeans algorithm clusters data by trying to separate samples in n groups of equal variance, minimizing a criterion known as the inertia or within-cluster sum-of-squares (see below). This algorithm requires the number of clusters to be specified. It scales well to large number of samples and has been used across a large range of application areas in many different fields.

The k-means algorithm divides a set of \( N \) samples \( X \) into \( K \) disjoint clusters \( C \), each described by the mean \( \mu_j \) of the samples in the cluster. The means are commonly called the cluster “centroids”; note that they are not, in general, points from \( X \), although they live in the same space.

The K-means algorithm aims to choose centroids that minimise the inertia, or within-cluster sum-of-squares criterion:

\[
\sum_{i=0}^{n} \min_{\mu_j \in C}(||x_i - \mu_j||^2)
\]

Inertia can be recognized as a measure of how internally coherent clusters are. It suffers from various drawbacks:

- Inertia makes the assumption that clusters are convex and isotropic, which is not always the case. It responds poorly to elongated clusters, or manifolds with irregular shapes.

- Inertia is not a normalized metric: we just know that lower values are better and zero is optimal. But in very high-dimensional spaces, Euclidean distances tend to become inflated (this is an instance of the so-called “curse of dimensionality”). Running a dimensionality reduction algorithm such as Principal component analysis (PCA) prior to k-means clustering can alleviate this problem and speed up the computations.
K-means is often referred to as Lloyd’s algorithm. In basic terms, the algorithm has three steps. The first step chooses the initial centroids, with the most basic method being to choose $k$ samples from the dataset $X$. After initialization, K-means consists of looping between the two other steps. The first step assigns each sample to its nearest centroid. The second step creates new centroids by taking the mean value of all of the samples assigned to each previous centroid. The difference between the old and the new centroids are computed and the algorithm repeats these last two steps until this value is less than a threshold. In other words, it repeats until the centroids do not move significantly.
K-means is equivalent to the expectation-maximization algorithm with a small, all-equal, diagonal covariance matrix. The algorithm can also be understood through the concept of Voronoi diagrams. First the Voronoi diagram of the points is calculated using the current centroids. Each segment in the Voronoi diagram becomes a separate cluster. Secondly, the centroids are updated to the mean of each segment. The algorithm then repeats this until a stopping criterion is fulfilled. Usually, the algorithm stops when the relative decrease in the objective function between iterations is less than the given tolerance value. This is not the case in this implementation: iteration stops when centroids move less than the tolerance.

Given enough time, K-means will always converge, however this may be to a local minimum. This is highly dependent on the initialization of the centroids. As a result, the computation is often done several times, with different initializations of the centroids. One method to help address this issue is the k-means++ initialization scheme, which has been implemented in scikit-learn (use the init='k-means++' parameter). This initializes the centroids to be (generally) distant from each other, leading to provably better results than random initialization, as shown in the reference.

The algorithm supports sample weights, which can be given by a parameter sample_weight. This allows to assign more weight to some samples when computing cluster centers and values of inertia. For example, assigning a weight of 2 to a sample is equivalent to adding a duplicate of that sample to the dataset $X$.

K-means can be used for vector quantization. This is achieved using the transform method of a trained model of KMeans.

### Low-level parallelism

KMeans benefits from OpenMP based parallelism through Cython. Small chunks of data (256 samples) are processed in parallel, which in addition yields a low memory footprint. For more details on how to control the number of threads, please refer to our Parallelism notes.

### Mini Batch K-Means

The MiniBatchKMeans is a variant of the KMeans algorithm which uses mini-batches to reduce the computation time, while still attempting to optimise the same objective function. Mini-batches are subsets of the input data, randomly sampled in each training iteration. These mini-batches drastically reduce the amount of computation required to converge to a local solution. In contrast to other algorithms that reduce the convergence time of k-means, mini-batch k-means produces results that are generally only slightly worse than the standard algorithm.

The algorithm iterates between two major steps, similar to vanilla k-means. In the first step, $b$ samples are drawn randomly from the dataset, to form a mini-batch. These are then assigned to the nearest centroid. In the second step,
the centroids are updated. In contrast to k-means, this is done on a per-sample basis. For each sample in the mini-batch, the assigned centroid is updated by taking the streaming average of the sample and all previous samples assigned to that centroid. This has the effect of decreasing the rate of change for a centroid over time. These steps are performed until convergence or a predetermined number of iterations is reached.

MiniBatchKMeans converges faster than KMeans, but the quality of the results is reduced. In practice this difference in quality can be quite small, as shown in the example and cited reference.

Affinity Propagation

AffinityPropagation creates clusters by sending messages between pairs of samples until convergence. A dataset is then described using a small number of exemplars, which are identified as those most representative of other samples. The messages sent between pairs represent the suitability for one sample to be the exemplar of the other, which is updated in response to the values from other pairs. This updating happens iteratively until convergence, at which point the final exemplars are chosen, and hence the final clustering is given.

Affinity Propagation can be interesting as it chooses the number of clusters based on the data provided. For this purpose, the two important parameters are the preference, which controls how many exemplars are used, and the damping factor which damps the responsibility and availability messages to avoid numerical oscillations when updating these messages.

The main drawback of Affinity Propagation is its complexity. The algorithm has a time complexity of the order $O(N^2 T)$, where $N$ is the number of samples and $T$ is the number of iterations until convergence. Further, the memory
complexity is of the order $O(N^2)$ if a dense similarity matrix is used, but reducible if a sparse similarity matrix is used. This makes Affinity Propagation most appropriate for small to medium sized datasets.

Examples:

- Demo of affinity propagation clustering algorithm: Affinity Propagation on a synthetic 2D datasets with 3 classes.
- Visualizing the stock market structure: Affinity Propagation on Financial time series to find groups of companies

Algorithm description: The messages sent between points belong to one of two categories. The first is the responsibility $r(i, k)$, which is the accumulated evidence that sample $k$ should be the exemplar for sample $i$. The second is the availability $a(i, k)$ which is the accumulated evidence that sample $i$ should choose sample $k$ to be its exemplar, and considers the values for all other samples that $k$ should be an exemplar. In this way, exemplars are chosen by samples if they are (1) similar enough to many samples and (2) chosen by many samples to be representative of themselves.

More formally, the responsibility of a sample $k$ to be the exemplar of sample $i$ is given by:

$$r(i, k) \leftarrow s(i, k) - \max[a(i, k') + s(i, k') \forall k' \neq k]$$

Where $s(i, k)$ is the similarity between samples $i$ and $k$. The availability of sample $k$ to be the exemplar of sample $i$ is given by:

$$a(i, k) \leftarrow \min[0, r(k, k) + \sum_{i' \text{ s.t. } i' \notin \{i, k\}} r(i', k)]$$

To begin with, all values for $r$ and $a$ are set to zero, and the calculation of each iterates until convergence. As discussed above, in order to avoid numerical oscillations when updating the messages, the damping factor $\lambda$ is introduced to iteration process:

$$r_{t+1}(i, k) = \lambda \cdot r_t(i, k) + (1 - \lambda) \cdot r_{t+1}(i, k)$$

$$a_{t+1}(i, k) = \lambda \cdot a_t(i, k) + (1 - \lambda) \cdot a_{t+1}(i, k)$$

where $t$ indicates the iteration times.
Mean Shift

MeanShift clustering aims to discover blobs in a smooth density of samples. It is a centroid based algorithm, which works by updating candidates for centroids to be the mean of the points within a given region. These candidates are then filtered in a post-processing stage to eliminate near-duplicates to form the final set of centroids.

Given a candidate centroid \( x_i \) for iteration \( t \), the candidate is updated according to the following equation:

\[
x_i^{t+1} = m(x_i^t)
\]

Where \( N(x_i) \) is the neighborhood of samples within a given distance around \( x_i \) and \( m \) is the mean shift vector that is computed for each centroid that points towards a region of the maximum increase in the density of points. This is computed using the following equation, effectively updating a centroid to be the mean of the samples within its neighborhood:

\[
m(x_i) = \frac{\sum_{x_j \in N(x_i)} K(x_j - x_i)x_j}{\sum_{x_j \in N(x_i)} K(x_j - x_i)}
\]

The algorithm automatically sets the number of clusters, instead of relying on a parameter bandwidth, which dictates the size of the region to search through. This parameter can be set manually, but can be estimated using the provided estimate_bandwidth function, which is called if the bandwidth is not set.

The algorithm is not highly scalable, as it requires multiple nearest neighbor searches during the execution of the algorithm. The algorithm is guaranteed to converge, however the algorithm will stop iterating when the change in centroids is small.

Labelling a new sample is performed by finding the nearest centroid for a given sample.

Examples:

- A demo of the mean-shift clustering algorithm: Mean Shift clustering on a synthetic 2D datasets with 3 classes.

Spectral clustering

*SpectralClustering* performs a low-dimension embedding of the affinity matrix between samples, followed by clustering, e.g., by KMeans, of the components of the eigenvectors in the low dimensional space. It is especially computationally efficient if the affinity matrix is sparse and the *amg* solver is used for the eigenvalue problem (Note, the *amg* solver requires that the pyamg module is installed.)

The present version of SpectralClustering requires the number of clusters to be specified in advance. It works well for a small number of clusters, but is not advised for many clusters.

For two clusters, SpectralClustering solves a convex relaxation of the normalised cuts problem on the similarity graph: cutting the graph in two so that the weight of the edges cut is small compared to the weights of the edges inside each cluster. This criteria is especially interesting when working on images, where graph vertices are pixels, and weights of the edges of the similarity graph are computed using a function of a gradient of the image.

---

**Warning:** Transforming distance to well-behaved similarities

Note that if the values of your similarity matrix are not well distributed, e.g. with negative values or with a distance matrix rather than a similarity, the spectral problem will be singular and the problem not solvable. In which case it is advised to apply a transformation to the entries of the matrix. For instance, in the case of a signed distance matrix, is common to apply a heat kernel:

```python
similarity = np.exp(-beta * distance / distance.std())
```

See the examples for such an application.

---

**Examples:**

- *Spectral clustering for image segmentation:* Segmenting objects from a noisy background using spectral clustering.
- *Segmenting the picture of greek coins in regions:* Spectral clustering to split the image of coins in regions.
Different label assignment strategies

Different label assignment strategies can be used, corresponding to the `assign_labels` parameter of `SpectralClustering`. "kmeans" strategy can match finer details, but can be unstable. In particular, unless you control the `random_state`, it may not be reproducible from run-to-run, as it depends on random initialization. The alternative "discretize" strategy is 100% reproducible, but tends to create parcels of fairly even and geometrical shape.

```python
assign_labels="kmeans" assign_labels="discretize"
```

Spectral Clustering Graphs

Spectral Clustering can also be used to partition graphs via their spectral embeddings. In this case, the affinity matrix is the adjacency matrix of the graph, and SpectralClustering is initialized with `affinity='precomputed'`:

```python
>>> from sklearn.cluster import SpectralClustering
... sc = SpectralClustering(3, affinity='precomputed', n_init=100,
... assign_labels='discretize')
>>> sc.fit_predict(adjacency_matrix)
```

Hierarchical clustering

Hierarchical clustering is a general family of clustering algorithms that build nested clusters by merging or splitting them successively. This hierarchy of clusters is represented as a tree (or dendrogram). The root of the tree is the unique cluster that gathers all the samples, the leaves being the clusters with only one sample. See the Wikipedia page for more details.

The `AgglomerativeClustering` object performs a hierarchical clustering using a bottom up approach: each observation starts in its own cluster, and clusters are successively merged together. The linkage criteria determines the metric used for the merge strategy:

- **Ward** minimizes the sum of squared differences within all clusters. It is a variance-minimizing approach and in this sense is similar to the k-means objective function but tackled with an agglomerative hierarchical approach.
- **Maximum** or **complete linkage** minimizes the maximum distance between observations of pairs of clusters.
- **Average linkage** minimizes the average of the distances between all observations of pairs of clusters.
- **Single linkage** minimizes the distance between the closest observations of pairs of clusters.

`AgglomerativeClustering` can also scale to large number of samples when it is used jointly with a connectivity matrix, but is computationally expensive when no connectivity constraints are added between samples: it considers at each step all the possible merges.

**FeatureAgglomeration**

The `FeatureAgglomeration` uses agglomerative clustering to group together features that look very similar, thus decreasing the number of features. It is a dimensionality reduction tool, see `Unsupervised dimensionality reduction`.

**Different linkage type: Ward, complete, average, and single linkage**

`AgglomerativeClustering` supports Ward, single, average, and complete linkage strategies.
Agglomerative cluster has a “rich get richer” behavior that leads to uneven cluster sizes. In this regard, single linkage is the worst strategy, and Ward gives the most regular sizes. However, the affinity (or distance used in clustering) cannot be varied with Ward, thus for non-Euclidean metrics, average linkage is a good alternative. Single linkage, while not robust to noisy data, can be computed very efficiently and can therefore be useful to provide hierarchical clustering of larger datasets. Single linkage can also perform well on non-globular data.

Examples:

- Various Agglomerative Clustering on a 2D embedding of digits: exploration of the different linkage strategies in a real dataset.
Visualization of cluster hierarchy

It’s possible to visualize the tree representing the hierarchical merging of clusters as a dendrogram. Visual inspection can often be useful for understanding the structure of the data, though more so in the case of small sample sizes.

![Hierarchical Clustering Dendrogram](image)

Adding connectivity constraints

An interesting aspect of `AgglomerativeClustering` is that connectivity constraints can be added to this algorithm (only adjacent clusters can be merged together), through a connectivity matrix that defines for each sample the neighboring samples following a given structure of the data. For instance, in the swiss-roll example below, the connectivity constraints forbid the merging of points that are not adjacent on the swiss roll, and thus avoid forming clusters that extend across overlapping folds of the roll.

![Swiss Roll Example](image)

These constraint are useful to impose a certain local structure, but they also make the algorithm faster, especially when the number of the samples is high.

The connectivity constraints are imposed via an connectivity matrix: a scipy sparse matrix that has elements only at the intersection of a row and a column with indices of the dataset that should be connected. This matrix can be constructed from a-priori information: for instance, you may wish to cluster web pages by only merging pages with a link pointing from one to another. It can also be learned from the data, for instance using `sklearn.neighbors.kneighbors_graph` to restrict merging to nearest neighbors as in this example, or using `sklearn.feature_extraction.image.grid_to_graph` to enable only merging of neighboring pixels on an image, as in the `coin` example.
Examples:

- **A demo of structured Ward hierarchical clustering on an image of coins**: Ward clustering to split the image of coins into regions.
- **Hierarchical clustering: structured vs unstructured ward**: Example of Ward algorithm on a swiss-roll, comparison of structured approaches versus unstructured approaches.
- **Feature agglomeration vs. univariate selection**: Example of dimensionality reduction with feature agglomeration based on Ward hierarchical clustering.
- **Agglomerative clustering with and without structure**

---

**Warning: Connectivity constraints with single, average and complete linkage**

Connectivity constraints and single, complete or average linkage can enhance the ‘rich getting richer’ aspect of agglomerative clustering, particularly so if they are built with `sklearn.neighbors.kneighbors_graph`. In the limit of a small number of clusters, they tend to give a few macroscopically occupied clusters and almost empty ones. (see the discussion in **Agglomerative clustering with and without structure**). Single linkage is the most brittle linkage option with regard to this issue.

---

![Images](image1.png)

![Images](image2.png)

![Images](image3.png)

![Images](image4.png)
Varying the metric

Single, average and complete linkage can be used with a variety of distances (or affinities), in particular Euclidean distance ($l_2$), Manhattan distance (or Cityblock, or $l_1$), cosine distance, or any precomputed affinity matrix.

- $l_1$ distance is often good for sparse features, or sparse noise: i.e. many of the features are zero, as in text mining using occurrences of rare words.
- cosine distance is interesting because it is invariant to global scalings of the signal.

The guidelines for choosing a metric is to use one that maximizes the distance between samples in different classes, and minimizes that within each class.
Examples:

- **Agglomerative clustering with different metrics**

**DBSCAN**

The DBSCAN algorithm views clusters as areas of high density separated by areas of low density. Due to this rather generic view, clusters found by DBSCAN can be any shape, as opposed to k-means which assumes that clusters are convex shaped. The central component to the DBSCAN is the concept of core samples, which are samples that are in areas of high density. A cluster is therefore a set of core samples, each close to each other (measured by some distance measure) and a set of non-core samples that are close to a core sample (but are not themselves core samples). There are two parameters to the algorithm, `min_samples` and `eps`, which define formally what we mean when we say dense. Higher `min_samples` or lower `eps` indicate higher density necessary to form a cluster.

More formally, we define a core sample as being a sample in the dataset such that there exist `min_samples` other samples within a distance of `eps`, which are defined as neighbors of the core sample. This tells us that the core sample is in a dense area of the vector space. A cluster is a set of core samples that can be built by recursively taking a core sample, finding all of its neighbors that are core samples, finding all of their neighbors that are core samples, and so on. A cluster also has a set of non-core samples, which are samples that are neighbors of a core sample in the cluster but are not themselves core samples. Intuitively, these samples are on the fringes of a cluster.

Any core sample is part of a cluster, by definition. Any sample that is not a core sample, and is at least `eps` in distance from any core sample, is considered an outlier by the algorithm.

While the parameter `min_samples` primarily controls how tolerant the algorithm is towards noise (on noisy and large data sets it may be desirable to increase this parameter), the parameter `eps` is crucial to choose appropriately for the data set and distance function and usually cannot be left at the default value. It controls the local neighborhood of the points. When chosen too small, most data will not be clustered at all (and labeled as −1 for “noise”). When chosen too large, it causes close clusters to be merged into one cluster, and eventually the entire data set to be returned as a single cluster. Some heuristics for choosing this parameter have been discussed in the literature, for example based on a knee in the nearest neighbor distances plot (as discussed in the references below).

In the figure below, the color indicates cluster membership, with large circles indicating core samples found by the algorithm. Smaller circles are non-core samples that are still part of a cluster. Moreover, the outliers are indicated by black points below.
Examples:

- Demo of DBSCAN clustering algorithm

Implementation

The DBSCAN algorithm is deterministic, always generating the same clusters when given the same data in the same order. However, the results can differ when data is provided in a different order. First, even though the core samples will always be assigned to the same clusters, the labels of those clusters will depend on the order in which those samples are encountered in the data. Second and more importantly, the clusters to which non-core samples are assigned can differ depending on the data order. This would happen when a non-core sample has a distance lower than $\varepsilon$ to two core samples in different clusters. By the triangular inequality, those two core samples must be more distant than $\varepsilon$ from each other, or they would be in the same cluster. The non-core sample is assigned to whichever cluster is generated first in a pass through the data, and so the results will depend on the data ordering.

The current implementation uses ball trees and kd-trees to determine the neighborhood of points, which avoids calculating the full distance matrix (as was done in scikit-learn versions before 0.14). The possibility to use custom metrics is retained; for details, see NearestNeighbors.

Memory consumption for large sample sizes

This implementation is by default not memory efficient because it constructs a full pairwise similarity matrix in the case where kd-trees or ball-trees cannot be used (e.g., with sparse matrices). This matrix will consume $n^2$ floats. A couple of mechanisms for getting around this are:

- Use OPTICS clustering in conjunction with the extract_dbscan method. OPTICS clustering also calculates the full pairwise matrix, but only keeps one row in memory at a time (memory complexity $n$).

- A sparse radius neighborhood graph (where missing entries are presumed to be out of $\varepsilon$) can be precomputed in a memory-efficient way and dbscan can be run over this with metric='precomputed'. See sklearn.neighbors.NearestNeighbors.radius_neighbors_graph.

- The dataset can be compressed, either by removing exact duplicates if these occur in your data, or by using BIRCH. Then you only have a relatively small number of representatives for a large number of points. You can then provide a sample_weight when fitting DBSCAN.

References:

OPTICS

The **OPTICS** algorithm shares many similarities with the **DBSCAN** algorithm, and can be considered a generalization of DBSCAN that relaxes the eps requirement from a single value to a value range. The key difference between DBSCAN and OPTICS is that the OPTICS algorithm builds a reachability graph, which assigns each sample both a reachability distance, and a spot within the cluster ordering attribute; these two attributes are assigned when the model is fitted, and are used to determine cluster membership. If OPTICS is run with the default value of inf set for max_eps, then DBSCAN style cluster extraction can be performed repeatedly in linear time for any given eps value using the `cluster_optics_dbscan` method. Setting max_eps to a lower value will result in shorter run times, and can be thought of as the maximum neighborhood radius from each point to find other potential reachable points.

The reachability distances generated by OPTICS allow for variable density extraction of clusters within a single data set. As shown in the above plot, combining reachability distances and data set ordering produces a reachability plot, where point density is represented on the Y-axis, and points are ordered such that nearby points are adjacent. ‘Cutting’ the reachability plot at a single value produces DBSCAN like results; all points above the ‘cut’ are classified as noise, and each time that there is a break when reading from left to right signifies a new cluster. The default cluster extraction with OPTICS looks at the steep slopes within the graph to find clusters, and the user can define what counts as a steep slope using the parameter xi. There are also other possibilities for analysis on the graph itself, such as generating hierarchical representations of the data through reachability-plot dendrograms, and the hierarchy of clusters detected by the algorithm can be accessed through the `cluster_hierarchy` parameter. The plot above has been color-coded so that cluster colors in planar space match the linear segment clusters of the reachability plot. Note that the blue and red clusters are adjacent in the reachability plot, and can be hierarchically represented as children of a larger parent cluster.

**Examples:**

- Demo of OPTICS clustering algorithm
Comparison with DBSCAN

The results from OPTICS `cluster_optics_dbscan` method and DBSCAN are very similar, but not always identical; specifically, labeling of periphery and noise points. This is in part because the first samples of each dense area processed by OPTICS have a large reachability value while being close to other points in their area, and will thus sometimes be marked as noise rather than periphery. This affects adjacent points when they are considered as candidates for being marked as either periphery or noise.

Note that for any single value of $\text{eps}$, DBSCAN will tend to have a shorter run time than OPTICS; however, for repeated runs at varying $\text{eps}$ values, a single run of OPTICS may require less cumulative runtime than DBSCAN. It is also important to note that OPTICS’ output is close to DBSCAN’s only if $\text{eps}$ and $\text{max_eps}$ are close.

Computational Complexity

Spatial indexing trees are used to avoid calculating the full distance matrix, and allow for efficient memory usage on large sets of samples. Different distance metrics can be supplied via the `metric` keyword.

For large datasets, similar (but not identical) results can be obtained via HDBSCAN. The HDBSCAN implementation is multithreaded, and has better algorithmic runtime complexity than OPTICS, at the cost of worse memory scaling. For extremely large datasets that exhaust system memory using HDBSCAN, OPTICS will maintain $n$ (as opposed to $n^2$) memory scaling; however, tuning of the `max_eps` parameter will likely need to be used to give a solution in a reasonable amount of wall time.

Birch

The Birch builds a tree called the Clustering Feature Tree (CFT) for the given data. The data is essentially lossy compressed to a set of Clustering Feature nodes (CF Nodes). The CF Nodes have a number of subclusters called Clustering Feature subclusters (CF Subclusters) and these CF Subclusters located in the non-terminal CF Nodes can have CF Nodes as children.

The CF Subclusters hold the necessary information for clustering which prevents the need to hold the entire input data in memory. This information includes:

- Number of samples in a subcluster.
- Linear Sum - An n-dimensional vector holding the sum of all samples
- Squared Sum - Sum of the squared L2 norm of all samples.
- Centroids - To avoid recalculation linear sum / n_samples.
- Squared norm of the centroids.

The Birch algorithm has two parameters, the threshold and the branching factor. The branching factor limits the number of subclusters in a node and the threshold limits the distance between the entering sample and the existing subclusters.

This algorithm can be viewed as an instance or data reduction method, since it reduces the input data to a set of subclusters which are obtained directly from the leaves of the CFT. This reduced data can be further processed by
feeding it into a global clusterer. This global clusterer can be set by `n_clusters`. If `n_clusters` is set to None, the subclusters from the leaves are directly read off, otherwise a global clustering step labels these subclusters into global clusters (labels) and the samples are mapped to the global label of the nearest subcluster.

Algorithm description:

- A new sample is inserted into the root of the CF Tree which is a CF Node. It is then merged with the subcluster of the root, that has the smallest radius after merging, constrained by the threshold and branching factor conditions. If the subcluster has any child node, then this is done repeatedly till it reaches a leaf. After finding the nearest subcluster in the leaf, the properties of this subcluster and the parent subclusters are recursively updated.

- If the radius of the subcluster obtained by merging the new sample and the nearest subcluster is greater than the square of the threshold and if the number of subclusters is greater than the branching factor, then a space is temporarily allocated to this new sample. The two farthest subclusters are taken and the subclusters are divided into two groups on the basis of the distance between these subclusters.

- If this split node has a parent subcluster and there is room for a new subcluster, then the parent is split into two. If there is no room, then this node is again split into two and the process is continued recursively, till it reaches the root.

Birch or MiniBatchKMeans?

- Birch does not scale very well to high dimensional data. As a rule of thumb if `n_features` is greater than twenty, it is generally better to use MiniBatchKMeans.

- If the number of instances of data needs to be reduced, or if one wants a large number of subclusters either as a preprocessing step or otherwise, Birch is more useful than MiniBatchKMeans.

How to use partial_fit?

To avoid the computation of global clustering, for every call of `partial_fit` the user is advised

1. To set `n_clusters=None` initially
2. Train all data by multiple calls to `partial_fit`.
3. Set `n_clusters` to a required value using `brc.set_params(n_clusters=n_clusters)`.
4. Call `partial_fit` finally with no arguments, i.e. `brc.partial_fit()` which performs the global clustering.

Clustering performance evaluation

Evaluating the performance of a clustering algorithm is not as trivial as counting the number of errors or the precision and recall of a supervised classification algorithm. In particular any evaluation metric should not take the absolute values of the cluster labels into account but rather if this clustering define separations of the data similar to some ground truth set of classes or satisfying some assumption such that members belong to the same class are more similar than members of different classes according to some similarity metric.

Adjusted Rand index

Given the knowledge of the ground truth class assignments `labels_true` and our clustering algorithm assignments of the same samples `labels_pred`, the adjusted Rand index is a function that measures the similarity of the two assignments, ignoring permutations and with chance normalization:

```python
>>> from sklearn import metrics

>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]

>>> metrics.adjusted_rand_score(labels_true, labels_pred)
0.24...
```

One can permute 0 and 1 in the predicted labels, rename 2 to 3, and get the same score:

```python
>>> labels_pred = [1, 1, 0, 0, 3, 3]

>>> metrics.adjusted_rand_score(labels_true, labels_pred)
0.24...
```

Furthermore, `adjusted_rand_score` is symmetric: swapping the argument does not change the score. It can thus be used as a consensus measure:

```python
>>> metrics.adjusted_rand_score(labels_pred, labels_true)
0.24...
```

Perfect labeling is scored 1.0:

```python
>>> labels_pred = labels_true[:]

>>> metrics.adjusted_rand_score(labels_true, labels_pred)
1.0
```

Bad (e.g. independent labelings) have negative or close to 0.0 scores:

```python
>>> labels_true = [0, 1, 2, 0, 3, 4, 5, 1]
>>> labels_pred = [1, 1, 0, 0, 2, 2, 2, 2]

>>> metrics.adjusted_rand_score(labels_true, labels_pred)
-0.12...
```
Advantages

- Random (uniform) label assignments have a ARI score close to 0.0 for any value of $n\_clusters$ and $n\_samples$ (which is not the case for raw Rand index or the V-measure for instance).
- Bounded range [-1, 1]: negative values are bad (independent labelings), similar clusterings have a positive ARI, 1.0 is the perfect match score.
- No assumption is made on the cluster structure: can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes.

Drawbacks

- Contrary to inertia, ARI requires knowledge of the ground truth classes while is almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

However ARI can also be useful in a purely unsupervised setting as a building block for a Consensus Index that can be used for clustering model selection (TODO).

Examples:

- Adjustment for chance in clustering performance evaluation: Analysis of the impact of the dataset size on the value of clustering measures for random assignments.

Mathematical formulation

If C is a ground truth class assignment and K the clustering, let us define $a$ and $b$ as:

- $a$, the number of pairs of elements that are in the same set in C and in the same set in K
- $b$, the number of pairs of elements that are in different sets in C and in different sets in K

The raw (unadjusted) Rand index is then given by:

$$RI = \frac{a + b}{C^2_{n\_samples}}$$

Where $C^2_{n\_samples}$ is the total number of possible pairs in the dataset (without ordering).

However the RI score does not guarantee that random label assignments will get a value close to zero (esp. if the number of clusters is in the same order of magnitude as the number of samples).

To counter this effect we can discount the expected RI $E[RI]$ of random labelings by defining the adjusted Rand index as follows:

$$ARI = \frac{RI - E[RI]}{\max(RI) - E[RI]}$$

Mutual Information based scores

Given the knowledge of the ground truth class assignments `labels_true` and our clustering algorithm assignments of the same samples `labels_pred`, the Mutual Information is a function that measures the agreement of the two assignments, ignoring permutations. Two different normalized versions of this measure are available, Normalized Mutual Information (NMI) and Adjusted Mutual Information (AMI). NMI is often used in the literature, while AMI was proposed more recently and is normalized against chance:

```python
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]

>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
0.22504...
```

One can permute 0 and 1 in the predicted labels, rename 2 to 3 and get the same score:

```python
>>> labels_pred = [1, 1, 0, 0, 3, 3]
>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
0.22504...
```

All, `mutual_info_score`, `adjusted_mutual_info_score` and `normalized_mutual_info_score` are symmetric: swapping the argument does not change the score. Thus they can be used as a consensus measure:

```python
>>> metrics.adjusted_mutual_info_score(labels_pred, labels_true)
0.22504...
```

Perfect labeling is scored 1.0:

```python
>>> labels_pred = labels_true[:]

>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
1.0

>>> metrics.normalized_mutual_info_score(labels_true, labels_pred)
1.0
```

This is not true for `mutual_info_score`, which is therefore harder to judge:

```python
>>> metrics.mutual_info_score(labels_true, labels_pred)
0.69...
```

Bad (e.g. independent labelings) have non-positive scores:

```python
>>> labels_true = [0, 1, 2, 0, 3, 4, 5, 1]
>>> labels_pred = [1, 1, 0, 0, 2, 2, 2, 2]

>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
-0.10526...
```
Advantages

- **Random (uniform) label assignments have a AMI score close to 0.0** for any value of `n_clusters` and `n_samples` (which is not the case for raw Mutual Information or the V-measure for instance).

- **Upper bound of 1**: Values close to zero indicate two label assignments that are largely independent, while values close to one indicate significant agreement. Further, an AMI of exactly 1 indicates that the two label assignments are equal (with or without permutation).

Drawbacks

- Contrary to inertia, **MI-based measures require the knowledge of the ground truth classes** while almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

  However MI-based measures can also be useful in purely unsupervised setting as a building block for a Consensus Index that can be used for clustering model selection.

- **NMI and MI are not adjusted against chance.**

Examples:

- **Adjustment for chance in clustering performance evaluation**: Analysis of the impact of the dataset size on the value of clustering measures for random assignments. This example also includes the Adjusted Rand Index.

Mathematical formulation

Assume two label assignments (of the same N objects), $U$ and $V$. Their entropy is the amount of uncertainty for a partition set, defined by:

$$H(U) = -\sum_{i=1}^{\mid U\mid} P(i) \log(P(i))$$

where $P(i) = |U_i|/N$ is the probability that an object picked at random from $U$ falls into class $U_i$. Likewise for $V$:

$$H(V) = -\sum_{j=1}^{\mid V\mid} P'(j) \log(P'(j))$$

With $P'(j) = |V_j|/N$. The mutual information (MI) between $U$ and $V$ is calculated by:

$$\text{MI}(U, V) = \sum_{i=1}^{\mid U\mid} \sum_{j=1}^{\mid V\mid} P(i,j) \log \left( \frac{P(i,j)}{P(i)P'(j)} \right)$$

where $P(i,j) = |U_i \cap V_j|/N$ is the probability that an object picked at random falls into both classes $U_i$ and $V_j$.

It also can be expressed in set cardinality formulation:

$$\text{MI}(U, V) = \sum_{i=1}^{\mid U\mid} \sum_{j=1}^{\mid V\mid} \frac{|U_i \cap V_j|}{N} \log \left( \frac{N|U_i \cap V_j|}{|U_i||V_j|} \right)$$
The normalized mutual information is defined as

$$\text{NMI}(U, V) = \frac{\text{MI}(U, V)}{\text{mean}(H(U), H(V))}$$

This value of the mutual information and also the normalized variant is not adjusted for chance and will tend to increase as the number of different labels (clusters) increases, regardless of the actual amount of “mutual information” between the label assignments.

The expected value for the mutual information can be calculated using the following equation [VEB2009]. In this equation, $a_i = |U_i|$ (the number of elements in $U_i$) and $b_j = |V_j|$ (the number of elements in $V_j$).

$$E[\text{MI}(U, V)] = \sum_{i=1}^{U} \sum_{j=1}^{V} \min(a_i, b_j) \sum_{n_{ij}=0}^{\min(a_i+b_j-N)} \frac{n_{ij}}{N} \log \left( \frac{N.n_{ij}}{a_i b_j} \right) \frac{a_i!b_j!(N-a_i)!(N-b_j)!}{N!n_{ij}!(a_i-n_{ij})!(b_j-n_{ij})!(N-a_i-b_j+n_{ij})!}$$

Using the expected value, the adjusted mutual information can then be calculated using a similar form to that of the adjusted Rand index:

$$\text{AMI} = \frac{\text{MI} - E[\text{MI}]}{\text{mean}(H(U), H(V)) - E[\text{MI}]}$$

For normalized mutual information and adjusted mutual information, the normalizing value is typically some generalized mean of the entropies of each clustering. Various generalized means exist, and no firm rules exist for preferring one over the others. The decision is largely a field-by-field basis; for instance, in community detection, the arithmetic mean is most common. Each normalizing method provides “qualitatively similar behaviours” [YAT2016]. In our implementation, this is controlled by the average_method parameter.

Vinh et al. (2010) named variants of NMI and AMI by their averaging method [VEB2010]. Their ‘sqrt’ and ‘sum’ averages are the geometric and arithmetic means; we use these more broadly common names.

Homogeneity, completeness and V-measure

Given the knowledge of the ground truth class assignments of the samples, it is possible to define some intuitive metric using conditional entropy analysis.

In particular Rosenberg and Hirschberg (2007) define the following two desirable objectives for any cluster assignment:

- **homogeneity**: each cluster contains only members of a single class.
- **completeness**: all members of a given class are assigned to the same cluster.

We can turn those concept as scores `homogeneity_score` and `completeness_score`. Both are bounded below by 0.0 and above by 1.0 (higher is better):
Their harmonic mean called **V-measure** is computed by `v_measure_score`:

```python
>>> metrics.v_measure_score(labels_true, labels_pred)
0.51...
```

This function’s formula is as follows:

\[
v = \frac{(1 + \beta) \times \text{homogeneity} \times \text{completeness}}{(\beta \times \text{homogeneity} + \text{completeness})}
\]

beta defaults to a value of 1.0, but for using a value less than 1 for beta:

```python
>>> metrics.v_measure_score(labels_true, labels_pred, beta=0.6)
0.54...
```

more weight will be attributed to homogeneity, and using a value greater than 1:

```python
>>> metrics.v_measure_score(labels_true, labels_pred, beta=1.8)
0.48...
```

more weight will be attributed to completeness.

The V-measure is actually equivalent to the mutual information (NMI) discussed above, with the aggregation function being the arithmetic mean [B2011].

Homogeneity, completeness and V-measure can be computed at once using `homogeneity_completeness_v_measure` as follows:

```python
>>> metrics.homogeneity_completeness_v_measure(labels_true, labels_pred)
(0.66..., 0.42..., 0.51...)
```

The following clustering assignment is slightly better, since it is homogeneous but not complete:

```python
>>> labels_pred = [0, 0, 0, 1, 2, 2]
>>> metrics.homogeneity_completeness_v_measure(labels_true, labels_pred)
(1.0, 0.68..., 0.81...)
```

**Note:** `v_measure_score` is symmetric: it can be used to evaluate the agreement of two independent assignments on the same dataset.

This is not the case for `completeness_score` and `homogeneity_score`: both are bound by the relationship:

\[
\text{homogeneity_score}(a, b) = \text{completeness_score}(b, a)
\]
Advantages

- **Bounded scores**: 0.0 is as bad as it can be, 1.0 is a perfect score.
- Intuitive interpretation: clustering with bad V-measure can be qualitatively analyzed in terms of homogeneity and completeness to better feel what ‘kind’ of mistakes is done by the assignment.
- **No assumption is made on the cluster structure**: can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes.

Drawbacks

- The previously introduced metrics are not normalized with regards to random labeling: this means that depending on the number of samples, clusters and ground truth classes, a completely random labeling will not always yield the same values for homogeneity, completeness and hence v-measure. In particular random labeling won’t yield zero scores especially when the number of clusters is large.

  This problem can safely be ignored when the number of samples is more than a thousand and the number of clusters is less than 10. **For smaller sample sizes or larger number of clusters it is safer to use an adjusted index such as the Adjusted Rand Index (ARI).**

- These metrics require the knowledge of the ground truth classes while almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).
Examples:

- Adjustment for chance in clustering performance evaluation: Analysis of the impact of the dataset size on the value of clustering measures for random assignments.

Mathematical formulation

Homogeneity and completeness scores are formally given by:

\[ h = 1 - \frac{H(C|K)}{H(C)} \]

\[ c = 1 - \frac{H(K|C)}{H(K)} \]

where \( H(C|K) \) is the conditional entropy of the classes given the cluster assignments and is given by:

\[ H(C|K) = -\sum_{c=1}^{|C|} \sum_{k=1}^{|K|} n_{c,k} \cdot \log \left( \frac{n_{c,k}}{n_k} \right) \]

and \( H(C) \) is the entropy of the classes and is given by:

\[ H(C) = -\sum_{c=1}^{|C|} n_c \cdot \log \left( \frac{n_c}{n} \right) \]

with \( n \) the total number of samples, \( n_c \) and \( n_k \) the number of samples respectively belonging to class \( c \) and cluster \( k \), and finally \( n_{c,k} \) the number of samples from class \( c \) assigned to cluster \( k \).

The conditional entropy of clusters given class \( H(K|C) \) and the entropy of clusters \( H(K) \) are defined in a symmetric manner.

Rosenberg and Hirschberg further define V-measure as the harmonic mean of homogeneity and completeness:

\[ v = 2 \cdot \frac{h \cdot c}{h + c} \]

References

- V-Measure: A conditional entropy-based external cluster evaluation measure Andrew Rosenberg and Julia Hirschberg, 2007

Fowlkes-Mallows scores

The Fowlkes-Mallows index (sklearn.metrics.fowlkes_mallows_score) can be used when the ground truth class assignments of the samples is known. The Fowlkes-Mallows score FMI is defined as the geometric mean of the pairwise precision and recall:

\[ \text{FMI} = \frac{TP}{\sqrt{(TP + FP)(TP + FN)}} \]

Where \( TP \) is the number of True Positive (i.e. the number of pair of points that belong to the same clusters in both the true labels and the predicted labels), \( FP \) is the number of False Positive (i.e. the number of pair of points that belong
to the same clusters in the true labels and not in the predicted labels) and FN is the number of False Negative (i.e. the number of pair of points that belongs in the same clusters in the predicted labels and not in the true labels).

The score ranges from 0 to 1. A high value indicates a good similarity between two clusters.

```python
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]

>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
0.47140...
```

One can permute 0 and 1 in the predicted labels, rename 2 to 3 and get the same score:

```python
>>> labels_pred = [1, 1, 0, 0, 3, 3]

>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
0.47140...
```

Perfect labeling is scored 1.0:

```python
>>> labels_pred = labels_true[:]

>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
1.0
```

Bad (e.g. independent labelings) have zero scores:

```python
>>> labels_true = [0, 1, 2, 0, 3, 4, 5, 1]
>>> labels_pred = [1, 1, 0, 0, 2, 2, 2, 2]

>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
0.0
```

Advantages

- **Random (uniform) label assignments have a FMI score close to 0.0** for any value of n_clusters and n_samples (which is not the case for raw Mutual Information or the V-measure for instance).
- **Upper-bounded at 1**: Values close to zero indicate two label assignments that are largely independent, while values close to one indicate significant agreement. Further, values of exactly 0 indicate purely independent label assignments and a FMI of exactly 1 indicates that the two label assignments are equal (with or without permutation).
- **No assumption is made on the cluster structure**: can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes.
Drawbacks

- Contrary to inertia, **FMI-based measures require the knowledge of the ground truth classes** while almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

- Wikipedia entry for the Fowlkes-Mallows Index

Silhouette Coefficient

If the ground truth labels are not known, evaluation must be performed using the model itself. The Silhouette Coefficient (``sklearn.metrics.silhouette_score``) is an example of such an evaluation, where a higher Silhouette Coefficient score relates to a model with better defined clusters. The Silhouette Coefficient is defined for each sample and is composed of two scores:

- **a**: The mean distance between a sample and all other points in the same class.
- **b**: The mean distance between a sample and all other points in the next nearest cluster.

The Silhouette Coefficient \( s \) for a single sample is then given as:

\[
s = \frac{b - a}{\max(a, b)}
\]

The Silhouette Coefficient for a set of samples is given as the mean of the Silhouette Coefficient for each sample.

```python
>>> from sklearn import metrics
>>> from sklearn.metrics import pairwise_distances
>>> from sklearn import datasets
>>> X, y = datasets.load_iris(return_X_y=True)
```

In normal usage, the Silhouette Coefficient is applied to the results of a cluster analysis.

```python
>>> import numpy as np
>>> from sklearn.cluster import KMeans
>>> kmeans_model = KMeans(n_clusters=3, random_state=1).fit(X)
>>> labels = kmeans_model.labels_
>>> metrics.silhouette_score(X, labels, metric='euclidean')
0.55...
```

References

Advantages

- The score is bounded between -1 for incorrect clustering and +1 for highly dense clustering. Scores around zero indicate overlapping clusters.
- The score is higher when clusters are dense and well separated, which relates to a standard concept of a cluster.

Drawbacks

- The Silhouette Coefficient is generally higher for convex clusters than other concepts of clusters, such as density based clusters like those obtained through DBSCAN.

Examples:

- Selecting the number of clusters with silhouette analysis on KMeans clustering: In this example the silhouette analysis is used to choose an optimal value for n_clusters.

Calinski-Harabasz Index

If the ground truth labels are not known, the Calinski-Harabasz index (sklearn.metrics.calinski_harabasz_score) - also known as the Variance Ratio Criterion - can be used to evaluate the model, where a higher Calinski-Harabasz score relates to a model with better defined clusters.

The index is the ratio of the sum of between-clusters dispersion and of inter-cluster dispersion for all clusters (where dispersion is defined as the sum of distances squared):

```python
>>> from sklearn import metrics
>>> from sklearn.metrics import pairwise_distances
>>> from sklearn import datasets

>>> X, y = datasets.load_iris(return_X_y=True)
```

In normal usage, the Calinski-Harabasz index is applied to the results of a cluster analysis:

```python
>>> import numpy as np
>>> from sklearn.cluster import KMeans
>>> kmeans_model = KMeans(n_clusters=3, random_state=1).fit(X)
>>> labels = kmeans_model.labels_
>>> metrics.calinski_harabasz_score(X, labels)
561.62...
```

Advantages

- The score is higher when clusters are dense and well separated, which relates to a standard concept of a cluster.
- The score is fast to compute.
Drawbacks

- The Calinski-Harabasz index is generally higher for convex clusters than other concepts of clusters, such as density based clusters like those obtained through DBSCAN.

Mathematical formulation

For a set of data $E$ of size $n_E$ which has been clustered into $k$ clusters, the Calinski-Harabasz score $s$ is defined as the ratio of the between-clusters dispersion mean and the within-cluster dispersion:

$$ s = \frac{\text{tr}(B_k)}{\text{tr}(W_k)} \times \frac{n_E - k}{k - 1} $$

where $\text{tr}(B_k)$ is trace of the between group dispersion matrix and $\text{tr}(W_k)$ is the trace of the within-cluster dispersion matrix defined by:

$$ W_k = \sum_{q=1}^{k} \sum_{x \in C_q} (x - c_q)(x - c_q)^T $$

$$ B_k = \sum_{q=1}^{k} n_q (c_q - c_E)(c_q - c_E)^T $$

with $C_q$ the set of points in cluster $q$, $c_q$ the center of cluster $q$, $c_E$ the center of $E$, and $n_q$ the number of points in cluster $q$.

References

Davies-Bouldin Index

If the ground truth labels are not known, the Davies-Bouldin index (sklearn.metrics.davies_bouldin_score) can be used to evaluate the model, where a lower Davies-Bouldin index relates to a model with better separation between the clusters.

This index signifies the average ‘similarity’ between clusters, where the similarity is a measure that compares the distance between clusters with the size of the clusters themselves.

Zero is the lowest possible score. Values closer to zero indicate a better partition.

In normal usage, the Davies-Bouldin index is applied to the results of a cluster analysis as follows:

```python
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> X = iris.data
>>> from sklearn.cluster import KMeans
>>> from sklearn.metrics import davies_bouldin_score
>>> kmeans = KMeans(n_clusters=3, random_state=1).fit(X)
>>> labels = kmeans.labels_
>>> davies_bouldin_score(X, labels)
0.6619...
```
Advantages

- The computation of Davies-Bouldin is simpler than that of Silhouette scores.
- The index is computed only quantities and features inherent to the dataset.

Drawbacks

- The Davies-Boulding index is generally higher for convex clusters than other concepts of clusters, such as density based clusters like those obtained from DBSCAN.
- The usage of centroid distance limits the distance metric to Euclidean space.

Mathematical formulation

The index is defined as the average similarity between each cluster \( C_i \) for \( i = 1, \ldots, k \) and its most similar one \( C_j \). In the context of this index, similarity is defined as a measure \( R_{ij} \) that trades off:

- \( s_i \), the average distance between each point of cluster \( i \) and the centroid of that cluster – also known as cluster diameter.
- \( d_{ij} \), the distance between cluster centroids \( i \) and \( j \).

A simple choice to construct \( R_{ij} \) so that it is nonnegative and symmetric is:

\[
R_{ij} = \frac{s_i + s_j}{d_{ij}}
\]

Then the Davies-Bouldin index is defined as:

\[
DB = \frac{1}{k} \sum_{i=1}^{k} \max_{i \neq j} R_{ij}
\]

Contingency Matrix

Contingency matrix \((\text{sklearn.metrics.cluster.contingency_matrix})\) reports the intersection cardinality for every true/predicted cluster pair. The contingency matrix provides sufficient statistics for all clustering metrics where the samples are independent and identically distributed and one doesn’t need to account for some instances not being clustered.

Here is an example:
>>> from sklearn.metrics.cluster import contingency_matrix
>>> x = ["a", "a", "a", "b", "b", "b"]
>>> y = [0, 0, 1, 1, 2, 2]
>>> contingency_matrix(x, y)
array([[2, 1, 0],
       [1, 1, 2]])

The first row of output array indicates that there are three samples whose true cluster is “a”. Of them, two are in predicted cluster 0, one is in 1, and none is in 2. And the second row indicates that there are three samples whose true cluster is “b”. Of them, none is in predicted cluster 0, one is in 1 and two are in 2.

A **confusion matrix** for classification is a square contingency matrix where the order of rows and columns correspond to a list of classes.

### Advantages

- Allows to examine the spread of each true cluster across predicted clusters and vice versa.
- The contingency table calculated is typically utilized in the calculation of a similarity statistic (like the others listed in this document) between the two clusterings.

### Drawbacks

- Contingency matrix is easy to interpret for a small number of clusters, but becomes very hard to interpret for a large number of clusters.
- It doesn’t give a single metric to use as an objective for clustering optimisation.

### References

- Wikipedia entry for contingency matrix

### 4.2.4 Biclustering

Biclustering can be performed with the module `sklearn.cluster.bicluster`. Biclustering algorithms simultaneously cluster rows and columns of a data matrix. These clusters of rows and columns are known as biclusters. Each determines a submatrix of the original data matrix with some desired properties.

For instance, given a matrix of shape $(10, 10)$, one possible bicluster with three rows and two columns induces a submatrix of shape $(3, 2)$:

```python
>>> import numpy as np
>>> data = np.arange(100).reshape(10, 10)
>>> rows = np.array([0, 2, 3])[:, np.newaxis]
>>> columns = np.array([1, 2])
>>> data[rows, columns]
array([[ 1,  2],
       [21, 22],
       [31, 32]])
```

For visualization purposes, given a bicluster, the rows and columns of the data matrix may be rearranged to make the bicluster contiguous.
Algorithms differ in how they define biclusters. Some of the common types include:

- constant values, constant rows, or constant columns
- unusually high or low values
- submatrices with low variance
- correlated rows or columns

Algorithms also differ in how rows and columns may be assigned to biclusters, which leads to different bicluster structures. Block diagonal or checkerboard structures occur when rows and columns are divided into partitions.

If each row and each column belongs to exactly one bicluster, then rearranging the rows and columns of the data matrix reveals the biclusters on the diagonal. Here is an example of this structure where biclusters have higher average values than the other rows and columns:

![Fig. 6: An example of biclusters formed by partitioning rows and columns.](image)

In the checkerboard case, each row belongs to all column clusters, and each column belongs to all row clusters. Here is an example of this structure where the variance of the values within each bicluster is small:

![Fig. 7: An example of checkerboard biclusters.](image)

After fitting a model, row and column cluster membership can be found in the `rows_` and `columns_` attributes. `rows_[i]` is a binary vector with nonzero entries corresponding to rows that belong to bicluster `i`. Similarly, `columns_[i]` indicates which columns belong to bicluster `i`. 

4.2. Unsupervised learning
Some models also have `row_labels_` and `column_labels_` attributes. These models partition the rows and columns, such as in the block diagonal and checkerboard bicluster structures.

**Note:** Biclustering has many other names in different fields including co-clustering, two-mode clustering, two-way clustering, block clustering, coupled two-way clustering, etc. The names of some algorithms, such as the Spectral Co-Clustering algorithm, reflect these alternate names.

### Spectral Co-Clustering

The `SpectralCoclustering` algorithm finds biclusters with values higher than those in the corresponding other rows and columns. Each row and each column belongs to exactly one bicluster, so rearranging the rows and columns to make partitions contiguous reveals these high values along the diagonal.

**Note:** The algorithm treats the input data matrix as a bipartite graph: the rows and columns of the matrix correspond to the two sets of vertices, and each entry corresponds to an edge between a row and a column. The algorithm approximates the normalized cut of this graph to find heavy subgraphs.

### Mathematical formulation

An approximate solution to the optimal normalized cut may be found via the generalized eigenvalue decomposition of the Laplacian of the graph. Usually this would mean working directly with the Laplacian matrix. If the original data matrix $A$ has shape $m \times n$, the Laplacian matrix for the corresponding bipartite graph has shape $(m + n) \times (m + n)$. However, in this case it is possible to work directly with $A$, which is smaller and more efficient.

The input matrix $A$ is preprocessed as follows:

$$A_n = R^{-1/2}AC^{-1/2}$$

Where $R$ is the diagonal matrix with entry $i$ equal to $\sum_j A_{ij}$ and $C$ is the diagonal matrix with entry $j$ equal to $\sum_i A_{ij}$.

The singular value decomposition, $A_n = U\Sigma V^\top$, provides the partitions of the rows and columns of $A$. A subset of the left singular vectors gives the row partitions, and a subset of the right singular vectors gives the column partitions.

The $\ell = \lceil \log_2 k \rceil$ singular vectors, starting from the second, provide the desired partitioning information. They are used to form the matrix $Z$:

$$Z = \begin{bmatrix} R^{-1/2}U \\ C^{-1/2}V \end{bmatrix}$$

where the columns of $U$ are $u_2, \ldots, u_{\ell+1}$, and similarly for $V$.

Then the rows of $Z$ are clustered using `k-means`. The first $n_{\text{rows}}$ labels provide the row partitioning, and the remaining $n_{\text{columns}}$ labels provide the column partitioning.

### Examples:

- **A demo of the Spectral Co-Clustering algorithm**: A simple example showing how to generate a data matrix with biclusters and apply this method to it.
• Biclustering documents with the Spectral Co-clustering algorithm: An example of finding biclusters in the twenty newsgroup dataset.

References:

Spectral Biclustering

The SpectralBiclustering algorithm assumes that the input data matrix has a hidden checkerboard structure. The rows and columns of a matrix with this structure may be partitioned so that the entries of any bicluster in the Cartesian product of row clusters and column clusters are approximately constant. For instance, if there are two row partitions and three column partitions, each row will belong to three biclusters, and each column will belong to two biclusters.

The algorithm partitions the rows and columns of a matrix so that a corresponding blockwise-constant checkerboard matrix provides a good approximation to the original matrix.

Mathematical formulation

The input matrix \( A \) is first normalized to make the checkerboard pattern more obvious. There are three possible methods:

1. **Independent row and column normalization**, as in Spectral Co-Clustering. This method makes the rows sum to a constant and the columns sum to a different constant.

2. **Bistochastization**: repeated row and column normalization until convergence. This method makes both rows and columns sum to the same constant.

3. **Log normalization**: the log of the data matrix is computed: \( L = \log A \). Then the column mean \( \overline{L}_j \), row mean \( \overline{L}_i \), and overall mean \( \overline{L} \) of \( L \) are computed. The final matrix is computed according to the formula

   \[
   K_{ij} = L_{ij} - \overline{L}_i - \overline{L}_j + \overline{L}.
   \]

After normalizing, the first few singular vectors are computed, just as in the Spectral Co-Clustering algorithm.

If log normalization was used, all the singular vectors are meaningful. However, if independent normalization or bistochastization were used, the first singular vectors, \( u_1 \) and \( v_1 \), are discarded. From now on, the “first” singular vectors refers to \( u_2 \ldots u_{p+1} \) and \( v_2 \ldots v_{p+1} \) except in the case of log normalization.

Given these singular vectors, they are ranked according to which can be best approximated by a piecewise-constant vector. The approximations for each vector are found using one-dimensional k-means and scored using the Euclidean distance. Some subset of the best left and right singular vector are selected. Next, the data is projected to this best subset of singular vectors and clustered.

For instance, if \( p \) singular vectors were calculated, the \( q \) best are found as described, where \( q < p \). Let \( U \) be the matrix with columns the \( q \) best left singular vectors, and similarly \( V \) for the right. To partition the rows, the rows of \( A \) are projected to a \( q \) dimensional space: \( A \ast V \). Treating the \( m \) rows of this \( m \times q \) matrix as samples and clustering using k-means yields the row labels. Similarly, projecting the columns to \( A^T \ast U \) and clustering this \( n \times q \) matrix yields the column labels.
Examples:

References:

- Kluger, Yuval, et. al., 2003. Spectral biclustering of microarray data: co-clustering genes and conditions.

Biclustering evaluation

There are two ways of evaluating a biclustering result: internal and external. Internal measures, such as cluster stability, rely only on the data and the result themselves. Currently there are no internal bicluster measures in scikit-learn. External measures refer to an external source of information, such as the true solution. When working with real data the true solution is usually unknown, but biclustering artificial data may be useful for evaluating algorithms precisely because the true solution is known.

To compare a set of found biclusters to the set of true biclusters, two similarity measures are needed: a similarity measure for individual biclusters, and a way to combine these individual similarities into an overall score.

To compare individual biclusters, several measures have been used. For now, only the Jaccard index is implemented:

\[
J(A, B) = \frac{|A \cap B|}{|A| + |B| - |A \cap B|}
\]

where \(A\) and \(B\) are biclusters, \(|A \cap B|\) is the number of elements in their intersection. The Jaccard index achieves its minimum of 0 when the biclusters do not overlap at all and its maximum of 1 when they are identical.

Several methods have been developed to compare two sets of biclusters. For now, only \texttt{consensus_score} (Hochreiter et. al., 2010) is available:

1. Compute bicluster similarities for pairs of biclusters, one in each set, using the Jaccard index or a similar measure.
2. Assign biclusters from one set to another in a one-to-one fashion to maximize the sum of their similarities. This step is performed using the Hungarian algorithm.
3. The final sum of similarities is divided by the size of the larger set.

The minimum consensus score, 0, occurs when all pairs of biclusters are totally dissimilar. The maximum score, 1, occurs when both sets are identical.

4.2.5 Decomposing signals in components (matrix factorization problems)

Principal component analysis (PCA)

Exact PCA and probabilistic interpretation

PCA is used to decompose a multivariate dataset in a set of successive orthogonal components that explain a maximum amount of the variance. In scikit-learn, PCA is implemented as a transformer object that learns $n$ components in its fit method, and can be used on new data to project it on these components.

PCA centers but does not scale the input data for each feature before applying the SVD. The optional parameter whiten=True makes it possible to project the data onto the singular space while scaling each component to unit variance. This is often useful if the models down-stream make strong assumptions on the isotropy of the signal: this is for example the case for Support Vector Machines with the RBF kernel and the K-Means clustering algorithm.

Below is an example of the iris dataset, which is comprised of 4 features, projected on the 2 dimensions that explain most variance:

![PCA of IRIS dataset](image)

The PCA object also provides a probabilistic interpretation of the PCA that can give a likelihood of data based on the amount of variance it explains. As such it implements a score method that can be used in cross-validation:

Examples:

- Comparison of LDA and PCA 2D projection of Iris dataset
- Model selection with Probabilistic PCA and Factor Analysis (FA)
Incremental PCA

The PCA object is very useful, but has certain limitations for large datasets. The biggest limitation is that PCA only supports batch processing, which means all of the data to be processed must fit in main memory. The IncrementalPCA object uses a different form of processing and allows for partial computations which almost exactly match the results of PCA while processing the data in a minibatch fashion. IncrementalPCA makes it possible to implement out-of-core Principal Component Analysis either by:

- Using its partial_fit method on chunks of data fetched sequentially from the local hard drive or a network database.
- Calling its fit method on a sparse matrix or a memory mapped file using numpy.memmap.

IncrementalPCA only stores estimates of component and noise variances, in order update explained_variance_ratio_ incrementally. This is why memory usage depends on the number of samples per batch, rather than the number of samples to be processed in the dataset.

As in PCA, IncrementalPCA centers but does not scale the input data for each feature before applying the SVD.

Examples:

- Incremental PCA
PCA using randomized SVD

It is often interesting to project data to a lower-dimensional space that preserves most of the variance, by dropping the singular vector of components associated with lower singular values.

For instance, if we work with 64x64 pixel gray-level pictures for face recognition, the dimensionality of the data is 4096 and it is slow to train an RBF support vector machine on such wide data. Furthermore we know that the intrinsic dimensionality of the data is much lower than 4096 since all pictures of human faces look somewhat alike. The samples lie on a manifold of much lower dimension (say around 200 for instance). The PCA algorithm can be used to linearly transform the data while both reducing the dimensionality and preserve most of the explained variance at the same time.

The class `PCA` used with the optional parameter `svd_solver='randomized'` is very useful in that case: since we are going to drop most of the singular vectors it is much more efficient to limit the computation to an approximated estimate of the singular vectors we will keep to actually perform the transform.

For instance, the following shows 16 sample portraits (centered around 0.0) from the Olivetti dataset. On the right hand side are the first 16 singular vectors reshaped as portraits. Since we only require the top 16 singular vectors of a dataset with size $n_{\text{samples}} = 400$ and $n_{\text{features}} = 64 \times 64 = 4096$, the computation time is less than 1s:

If we note $n_{\text{max}} = \max(n_{\text{samples}}, n_{\text{features}})$ and $n_{\text{min}} = \min(n_{\text{samples}}, n_{\text{features}})$, the time complexity of the randomized PCA is $O(n_{\text{max}}^2 \cdot n_{\text{components}})$ instead of $O(n_{\text{max}}^2 \cdot n_{\text{min}})$ for the exact method implemented in `PCA`. 

4.2. Unsupervised learning
The memory footprint of randomized PCA is also proportional to \(2 \cdot n_{\text{max}} \cdot n_{\text{components}}\) instead of \(n_{\text{max}} \cdot n_{\text{min}}\) for the exact method.

Note: the implementation of inverse_transform in PCA with svd_solver='randomized' is not the exact inverse transform of transform even when whiten=False (default).

**Examples:**

- Faces recognition example using eigenfaces and SVMs
- Faces dataset decompositions

**References:**

- “Finding structure with randomness: Stochastic algorithms for constructing approximate matrix decompositions” Halko, et al., 2009

### Kernel PCA

*KernelPCA* is an extension of PCA which achieves non-linear dimensionality reduction through the use of kernels (see *Pairwise metrics, Affinities and Kernels*). It has many applications including denoising, compression and structured prediction (kernel dependency estimation). *KernelPCA* supports both transform and inverse_transform.

**Examples:**

- Kernel PCA
Sparse principal components analysis (SparsePCA and MiniBatchSparsePCA)

SparsePCA is a variant of PCA, with the goal of extracting the set of sparse components that best reconstruct the data.

Mini-batch sparse PCA (MiniBatchSparsePCA) is a variant of SparsePCA that is faster but less accurate. The increased speed is reached by iterating over small chunks of the set of features, for a given number of iterations.

Principal component analysis (PCA) has the disadvantage that the components extracted by this method have exclusively dense expressions, i.e. they have non-zero coefficients when expressed as linear combinations of the original variables. This can make interpretation difficult. In many cases, the real underlying components can be more naturally imagined as sparse vectors; for example in face recognition, components might naturally map to parts of faces.

Sparse principal components yields a more parsimonious, interpretable representation, clearly emphasizing which of the original features contribute to the differences between samples.

The following example illustrates 16 components extracted using sparse PCA from the Olivetti faces dataset. It can be seen how the regularization term induces many zeros. Furthermore, the natural structure of the data causes the non-zero coefficients to be vertically adjacent. The model does not enforce this mathematically: each component is a vector $h \in \mathbb{R}^{4096}$, and there is no notion of vertical adjacency except during the human-friendly visualization as 64x64 pixel images. The fact that the components shown below appear local is the effect of the inherent structure of the data, which makes such local patterns minimize reconstruction error. There exist sparsity-inducing norms that take into account adjacency and different kinds of structure; see [Jen09] for a review of such methods. For more details on how to use Sparse PCA, see the Examples section, below.

![Eigenfaces - PCA using randomized SVD - Train time 0.1](image-url)
Note that there are many different formulations for the Sparse PCA problem. The one implemented here is based on [Mrl09]. The optimization problem solved is a PCA problem (dictionary learning) with an $\ell_1$ penalty on the components:

$$(U^*, V^*) = \arg\min_{U, V} \frac{1}{2} ||X - UV||^2_2 + \alpha ||V||_1$$

subject to $||U_k||_2 = 1$ for all $0 \leq k < n_{\text{components}}$

The sparsity-inducing $\ell_1$ norm also prevents learning components from noise when few training samples are available. The degree of penalization (and thus sparsity) can be adjusted through the hyperparameter $\alpha$. Small values lead to a gently regularized factorization, while larger values shrink many coefficients to zero.

Note: While in the spirit of an online algorithm, the class `MiniBatchSparsePCA` does not implement `partial_fit` because the algorithm is online along the features direction, not the samples direction.

Examples:

- *Faces dataset decompositions*

**Truncated singular value decomposition and latent semantic analysis**

`TruncatedSVD` implements a variant of singular value decomposition (SVD) that only computes the $k$ largest singular values, where $k$ is a user-specified parameter.

When truncated SVD is applied to term-document matrices (as returned by `CountVectorizer` or `TfidfVectorizer`), this transformation is known as latent semantic analysis (LSA), because it transforms such matrices to a “semantic” space of low dimensionality. In particular, LSA is known to combat the effects of synonymy and polysemy (both of which roughly mean there are multiple meanings per word), which cause term-document matrices to be overly sparse and exhibit poor similarity under measures such as cosine similarity.
**Note:** LSA is also known as latent semantic indexing, LSI, though strictly that refers to its use in persistent indexes for information retrieval purposes.

Mathematically, truncated SVD applied to training samples $X$ produces a low-rank approximation $X$:

$$X \approx X_k = U_k \Sigma_k V_k^T$$

After this operation, $U_k \Sigma_k V_k^T$ is the transformed training set with $k$ features (called `n_components` in the API).

To also transform a test set $X$, we multiply it with $V_k$:

$$X' = XV_k$$

**Note:** Most treatments of LSA in the natural language processing (NLP) and information retrieval (IR) literature swap the axes of the matrix $X$ so that it has shape $n_{features} \times n_{samples}$. We present LSA in a different way that matches the scikit-learn API better, but the singular values found are the same.

`TruncatedSVD` is very similar to PCA, but differs in that the matrix $X$ does not need to be centered. When the columnwise (per-feature) means of $X$ are subtracted from the feature values, truncated SVD on the resulting matrix is equivalent to PCA. In practical terms, this means that the `TruncatedSVD` transformer accepts `scipy.sparse` matrices without the need to densify them, as densifying may fill up memory even for medium-sized document collections.

While the `TruncatedSVD` transformer works with any feature matrix, using it on tf–idf matrices is recommended over raw frequency counts in an LSA/document processing setting. In particular, sublinear scaling and inverse document frequency should be turned on (`sublinear_tf=True, use_idf=True`) to bring the feature values closer to a Gaussian distribution, compensating for LSA’s erroneous assumptions about textual data.

**Examples:**

- Clustering text documents using k-means

**References:**

- Christopher D. Manning, Prabhakar Raghavan and Hinrich Schütze (2008), *Introduction to Information Retrieval*, Cambridge University Press, chapter 18: Matrix decompositions & latent semantic indexing

**Dictionary Learning**

**Sparse coding with a precomputed dictionary**

The `SparseCoder` object is an estimator that can be used to transform signals into sparse linear combination of atoms from a fixed, precomputed dictionary such as a discrete wavelet basis. This object therefore does not implement a `fit` method. The transformation amounts to a sparse coding problem: finding a representation of the data as a linear combination of as few dictionary atoms as possible. All variations of dictionary learning implement the following transform methods, controllable via the `transform_method` initialization parameter:

- Orthogonal matching pursuit (*Orthogonal Matching Pursuit (OMP)*)
• Least-angle regression (*Least Angle Regression*)
• Lasso computed by least-angle regression
• Lasso using coordinate descent (*Lasso*)
• Thresholding

Thresholding is very fast but it does not yield accurate reconstructions. They have been shown useful in literature for classification tasks. For image reconstruction tasks, orthogonal matching pursuit yields the most accurate, unbiased reconstruction.

The dictionary learning objects offer, via the `split_code` parameter, the possibility to separate the positive and negative values in the results of sparse coding. This is useful when dictionary learning is used for extracting features that will be used for supervised learning, because it allows the learning algorithm to assign different weights to negative loadings of a particular atom, from to the corresponding positive loading.

The split code for a single sample has length $2 \times n\_components$ and is constructed using the following rule: First, the regular code of length $n\_components$ is computed. Then, the first $n\_components$ entries of the `split_code` are filled with the positive part of the regular code vector. The second half of the split code is filled with the negative part of the code vector, only with a positive sign. Therefore, the split code is non-negative.

**Examples:**

• Sparse coding with a precomputed dictionary

**Generic dictionary learning**

Dictionary learning (*DictionaryLearning*) is a matrix factorization problem that amounts to finding a (usually overcomplete) dictionary that will perform well at sparsely encoding the fitted data.

Representing data as sparse combinations of atoms from an overcomplete dictionary is suggested to be the way the mammalian primary visual cortex works. Consequently, dictionary learning applied on image patches has been shown to give good results in image processing tasks such as image completion, inpainting and denoising, as well as for supervised recognition tasks.

Dictionary learning is an optimization problem solved by alternatively updating the sparse code, as a solution to multiple Lasso problems, considering the dictionary fixed, and then updating the dictionary to best fit the sparse code.

\[
(U^*, V^*) = \arg\min_{U, V} \frac{1}{2} \|X - UV\|^2_2 + \alpha \|U\|_1 \\
\text{subject to } \|V_k\|_2 = 1 \text{ for all } 0 \leq k < n\_atoms
\]
After using such a procedure to fit the dictionary, the transform is simply a sparse coding step that shares the same implementation with all dictionary learning objects (see Sparse coding with a precomputed dictionary).

It is also possible to constrain the dictionary and/or code to be positive to match constraints that may be present in the data. Below are the faces with different positivity constraints applied. Red indicates negative values, blue indicates positive values, and white represents zeros.
The following image shows how a dictionary learned from 4x4 pixel image patches extracted from part of the image of a raccoon face looks like.

Examples:

- Image denoising using dictionary learning

References:

Mini-batch dictionary learning

`MiniBatchDictionaryLearning` implements a faster, but less accurate version of the dictionary learning algorithm that is better suited for large datasets.

By default, `MiniBatchDictionaryLearning` divides the data into mini-batches and optimizes in an online manner by cycling over the mini-batches for the specified number of iterations. However, at the moment it does not implement a stopping condition.

The estimator also implements `partial_fit`, which updates the dictionary by iterating only once over a mini-batch. This can be used for online learning when the data is not readily available from the start, or for when the data does not fit into the memory.

Clustering for dictionary learning

Note that when using dictionary learning to extract a representation (e.g. for sparse coding) clustering can be a good proxy to learn the dictionary. For instance the `MiniBatchKMeans` estimator is computationally efficient and implements on-line learning with a `partial_fit` method.

Example: Online learning of a dictionary of parts of faces

Factor Analysis

In unsupervised learning we only have a dataset $X = \{x_1, x_2, \ldots, x_n\}$. How can this dataset be described mathematically? A very simple continuous latent variable model for $X$ is

$$x_i = W h_i + \mu + \epsilon$$

The vector $h_i$ is called “latent” because it is unobserved. $\epsilon$ is considered a noise term distributed according to a Gaussian with mean 0 and covariance $\Psi$ (i.e. $\epsilon \sim \mathcal{N}(0, \Psi)$), $\mu$ is some arbitrary offset vector. Such a model is called “generative” as it describes how $x_i$ is generated from $h_i$. If we use all the $x_i$’s as columns to form a matrix $X$ and all the $h_i$’s as columns of a matrix $H$ then we can write (with suitably defined $M$ and $E$):

$$X = WH + M + E$$

In other words, we decomposed matrix $X$.

If $h_i$ is given, the above equation automatically implies the following probabilistic interpretation:

$$p(x_i|h_i) = \mathcal{N}(Wh_i + \mu, \Psi)$$
For a complete probabilistic model we also need a prior distribution for the latent variable \( h \). The most straightforward assumption (based on the nice properties of the Gaussian distribution) is \( h \sim \mathcal{N}(0, I) \). This yields a Gaussian as the marginal distribution of \( x \):

\[
p(x) = \mathcal{N}(\mu, WW^T + \Psi)
\]

Now, without any further assumptions the idea of having a latent variable \( h \) would be superfluous – \( x \) can be completely modelled with a mean and a covariance. We need to impose some more specific structure on one of these two parameters. A simple additional assumption regards the structure of the error covariance \( \Psi \):

- \( \Psi = \sigma^2 I \): This assumption leads to the probabilistic model of PCA.
- \( \Psi = \text{diag}(\psi_1, \psi_2, \ldots, \psi_n) \): This model is called FactorAnalysis, a classical statistical model. The matrix \( W \) is sometimes called the “factor loading matrix”.

Both models essentially estimate a Gaussian with a low-rank covariance matrix. Because both models are probabilistic they can be integrated in more complex models, e.g. Mixture of Factor Analysers. One gets very different models (e.g. FastICA) if non-Gaussian priors on the latent variables are assumed.

Factor analysis can produce similar components (the columns of its loading matrix) to PCA. However, one can not make any general statements about these components (e.g. whether they are orthogonal):

The main advantage for Factor Analysis over PCA is that it can model the variance in every direction of the input space independently (heteroscedastic noise):

4.2. Unsupervised learning
This allows better model selection than probabilistic PCA in the presence of heteroscedastic noise:

Factor Analysis is often followed by a rotation of the factors (with the parameter rotation), usually to improve interpretability. For example, Varimax rotation maximizes the sum of the variances of the squared loadings, i.e., it tends to produce sparser factors, which are influenced by only a few features each (the “simple structure”). See e.g., the first example below.

Examples:

- Factor Analysis (with rotation) to visualize patterns
- Model selection with Probabilistic PCA and Factor Analysis (FA)
Independent component analysis (ICA)

Independent component analysis separates a multivariate signal into additive subcomponents that are maximally independent. It is implemented in scikit-learn using the FastICA algorithm. Typically, ICA is not used for reducing dimensionality but for separating superimposed signals. Since the ICA model does not include a noise term, for the model to be correct, whitening must be applied. This can be done internally using the whiten argument or manually using one of the PCA variants.

It is classically used to separate mixed signals (a problem known as blind source separation), as in the example below:

ICA can also be used as yet another non-linear decomposition that finds components with some sparsity:

![Observations (mixed signal)](image1)

![True Sources](image2)

![ICA recovered signals](image3)

![PCA recovered signals](image4)
Examples:

- Blind source separation using FastICA
- FastICA on 2D point clouds
- Faces dataset decompositions

Non-negative matrix factorization (NMF or NNMF)

NMF\(^1\) is an alternative approach to decomposition that assumes that the data and the components are non-negative. NMF can be plugged in instead of PCA or its variants, in the cases where the data matrix does not contain negative values. It finds a decomposition of samples \(X\) into two matrices \(W\) and \(H\) of non-negative elements, by optimizing the distance \(d\) between \(X\) and the matrix product \(WH\). The most widely used distance function is the squared Frobenius norm, which is an obvious extension of the Euclidean norm to matrices:

\[
d_{\text{Fro}}(X, Y) = \frac{1}{2} ||X - Y||^2_{\text{Fro}} = \frac{1}{2} \sum_{i,j} (X_{ij} - Y_{ij})^2
\]

Unlike PCA, the representation of a vector is obtained in an additive fashion, by superimposing the components, without subtracting. Such additive models are efficient for representing images and text.

It has been observed in [Hoyer, 2004]\(^2\) that, when carefully constrained, NMF can produce a parts-based representation of the dataset, resulting in interpretable models. The following example displays 16 sparse components found by NMF from the images in the Olivetti faces dataset, in comparison with the PCA eigenfaces.

\(^1\) “Learning the parts of objects by non-negative matrix factorization” D. Lee, S. Seung, 1999

\(^2\) “Non-negative Matrix Factorization with Sparseness Constraints” P. Hoyer, 2004
The `init` attribute determines the initialization method applied, which has a great impact on the performance of the method. `NMF` implements the method Nonnegative Double Singular Value Decomposition. NNDSVD⁴ is based on two SVD processes, one approximating the data matrix, the other approximating positive sections of the resulting partial SVD factors utilizing an algebraic property of unit rank matrices. The basic NNDSVD algorithm is better fit for sparse factorization. Its variants NNDSVDa (in which all zeros are set equal to the mean of all elements of the data), and NNDSVDar (in which the zeros are set to random perturbations less than the mean of the data divided by 100) are recommended in the dense case.

Note that the Multiplicative Update (‘mu’) solver cannot update zeros present in the initialization, so it leads to poorer results when used jointly with the basic NNDSVD algorithm which introduces a lot of zeros; in this case, NNDSVDa or NNDSVDar should be preferred.

`NMF` can also be initialized with correctly scaled random non-negative matrices by setting `init="random"`. An integer seed or a `RandomState` can also be passed to `random_state` to control reproducibility.

In `NMF`, L1 and L2 priors can be added to the loss function in order to regularize the model. The L2 prior uses the Frobenius norm, while the L1 prior uses an elementwise L1 norm. As in ElasticNet, we control the combination of L1 and L2 with the `l1_ratio (ρ)` parameter, and the intensity of the regularization with the `alpha (α)` parameter. Then the priors terms are:

\[
\alpha \rho \|W\|_1 + \alpha (1 - \rho) \frac{1}{2} \|W\|_{\text{Fro}}^2 + \alpha \rho \|H\|_1 + \frac{\alpha (1 - \rho)}{2} \|H\|_{\text{Fro}}^2
\]

⁴ “SVD based initialization: A head start for nonnegative matrix factorization” C. Boutsidis, E. Gallopoulos, 2008
and the regularized objective function is:

$$d_{\text{Fro}}(X, WH) + \alpha \rho \| W \|_1 + \alpha \rho \| H \|_1 + \frac{\alpha (1 - \rho)}{2} \| W \|_{\text{Fro}}^2 + \frac{\alpha (1 - \rho)}{2} \| H \|_{\text{Fro}}^2$$

NMF regularizes both W and H by default. The regularization parameter allows for finer control, with which only W, only H, or both can be regularized.

**NMF with a beta-divergence**

As described previously, the most widely used distance function is the squared Frobenius norm, which is an obvious extension of the Euclidean norm to matrices:

$$d_{\text{Fro}}(X, Y) = \frac{1}{2} \| X - Y \|_{\text{Fro}}^2 = \frac{1}{2} \sum_{i,j} (X_{ij} - Y_{ij})^2$$

Other distance functions can be used in NMF as, for example, the (generalized) Kullback-Leibler (KL) divergence, also referred as I-divergence:

$$d_{\text{KL}}(X, Y) = \sum_{i,j} (X_{ij} \log \frac{X_{ij}}{Y_{ij}} - X_{ij} + Y_{ij})$$

Or, the Itakura-Saito (IS) divergence:

$$d_{\text{IS}}(X, Y) = \sum_{i,j} \frac{X_{ij}}{Y_{ij}} - \log \frac{X_{ij}}{Y_{ij}} - 1$$

These three distances are special cases of the beta-divergence family, with $\beta = 2, 1, 0$ respectively. The beta-divergence are defined by:

$$d_{\beta}(X, Y) = \sum_{i,j} \frac{1}{\beta(\beta - 1)} (X_{ij}^\beta + (\beta - 1)Y_{ij}^\beta - \beta X_{ij}Y_{ij}^{\beta - 1})$$

Note that this definition is not valid if $\beta \in (0; 1)$, yet it can be continuously extended to the definitions of $d_{\text{KL}}$ and $d_{\text{IS}}$ respectively.

NMF implements two solvers, using Coordinate Descent (‘cd’), and Multiplicative Update (‘mu’). The ‘mu’ solver can optimize every beta-divergence, including of course the Frobenius norm ($\beta = 2$), the (generalized) Kullback-Leibler divergence ($\beta = 1$) and the Itakura-Saito divergence ($\beta = 0$). Note that for $\beta \in (1; 2)$, the ‘mu’ solver is significantly faster than for other values of $\beta$. Note also that with a negative (or 0, i.e. ‘itakura-saito’) $\beta$, the input matrix cannot contain zero values.

The ‘cd’ solver can only optimize the Frobenius norm. Due to the underlying non-convexity of NMF, the different solvers may converge to different minima, even when optimizing the same distance function.

NMF is best used with the fit_transform method, which returns the matrix W. The matrix H is stored into the fitted model in the components_ attribute; the method transform will decompose a new matrix X_new based on these stored components:

```python
>>> import numpy as np
>>> X = np.array([[1, 1], [2, 1], [3, 1.2], [4, 1], [5, 0.8], [6, 1]])
>>> from sklearn.decomposition import NMF
```
```python
>>> model = NMF(n_components=2, init='random', random_state=0)
>>> W = model.fit_transform(X)
>>> H = model.components_
>>> X_new = np.array([[1, 0], [1, 6.1], [1, 0], [1, 4], [3.2, 1], [0, 4]])
>>> W_new = model.transform(X_new)
```

Examples:

- *Faces dataset decompositions*
- *Topic extraction with Non-negative Matrix Factorization and Latent Dirichlet Allocation*
- *Beta-divergence loss functions*

References:

**Latent Dirichlet Allocation (LDA)**

Latent Dirichlet Allocation is a generative probabilistic model for collections of discrete dataset such as text corpora. It is also a topic model that is used for discovering abstract topics from a collection of documents.

The graphical model of LDA is a three-level generative model:
Note on notations presented in the graphical model above, which can be found in Hoffman et al. (2013):

- The corpus is a collection of $D$ documents.
- A document is a sequence of $N$ words.
- There are $K$ topics in the corpus.
- The boxes represent repeated sampling.

In the graphical model, each node is a random variable and has a role in the generative process. A shaded node indicates an observed variable and an unshaded node indicates a hidden (latent) variable. In this case, words in the corpus are the only data that we observe. The latent variables determine the random mixture of topics in the corpus and the distribution of words in the documents. The goal of LDA is to use the observed words to infer the hidden topic structure.

When modeling text corpora, the model assumes the following generative process for a corpus with $D$ documents and $K$ topics, with $K$ corresponding to `n_components` in the API:

1. For each topic $k \in K$, draw $\beta_k \sim \text{Dirichlet}(\eta)$. This provides a distribution over the words, i.e. the probability of a word appearing in topic $k$. $\eta$ corresponds to `topic_word_prior`.
2. For each document $d \in D$, draw the topic proportions $\theta_d \sim \text{Dirichlet}(\alpha)$. $\alpha$ corresponds to `doc_topic_prior`.
3. For each word $i$ in document $d$:
   a. Draw the topic assignment $z_{di} \sim \text{Multinomial}(\theta_d)$
   b. Draw the observed word $w_{ij} \sim \text{Multinomial}(\beta_{z_{di}})$

For parameter estimation, the posterior distribution is:

$$p(z, \theta, \beta|w, \alpha, \eta) = \frac{p(z, \theta, \beta|\alpha, \eta) \cdot p(w|\alpha, \eta)}{p(w|\alpha, \eta)}$$

Since the posterior is intractable, variational Bayesian method uses a simpler distribution $q(z, \theta, \beta|\lambda, \phi, \gamma)$ to approximate it, and those variational parameters $\lambda, \phi, \gamma$ are optimized to maximize the Evidence Lower Bound (ELBO):

$$\log P(w|\alpha, \eta) \geq L(w, \phi, \gamma, \lambda) = E_q[\log p(w, z, \theta, \beta|\alpha, \eta)] - E_q[\log q(z, \theta, \beta)]$$

Maximizing ELBO is equivalent to minimizing the Kullback-Leibler(KL) divergence between $q(z, \theta, \beta)$ and the true posterior $p(z, \theta, \beta|w, \alpha, \eta)$.

`LatentDirichletAllocation` implements the online variational Bayes algorithm and supports both online and batch update methods. While the batch method updates variational variables after each full pass through the data, the online method updates variational variables from mini-batch data points.

**Note:** Although the online method is guaranteed to converge to a local optimum point, the quality of the optimum point and the speed of convergence may depend on mini-batch size and attributes related to learning rate setting.
When `LatentDirichletAllocation` is applied on a “document-term” matrix, the matrix will be decomposed into a “topic-term” matrix and a “document-topic” matrix. While “topic-term” matrix is stored as `components_` in the model, “document-topic” matrix can be calculated from `transform` method.

`LatentDirichletAllocation` also implements `partial_fit` method. This is used when data can be fetched sequentially.

**Examples:**

- Topic extraction with Non-negative Matrix Factorization and Latent Dirichlet Allocation

### 4.2.6 Covariance estimation

Many statistical problems require the estimation of a population’s covariance matrix, which can be seen as an estimation of data set scatter plot shape. Most of the time, such an estimation has to be done on a sample whose properties (size, structure, homogeneity) have a large influence on the estimation’s quality. The `sklearn.covariance` package provides tools for accurately estimating a population’s covariance matrix under various settings.

We assume that the observations are independent and identically distributed (i.i.d.).

**Empirical covariance**

The covariance matrix of a data set is known to be well approximated by the classical maximum likelihood estimator (or “empirical covariance”), provided the number of observations is large enough compared to the number of features (the variables describing the observations). More precisely, the Maximum Likelihood Estimator of a sample is an asymptotically unbiased estimator of the corresponding population’s covariance matrix.

The empirical covariance matrix of a sample can be computed using the `empirical_covariance` function of the package, or by fitting an `EmpiricalCovariance` object to the data sample with the `EmpiricalCovariance.fit` method. Be careful that results depend on whether the data are centered, so one may want to use the `assume_centered` parameter accurately. More precisely, if `assume_centered=False`, then the test set is supposed to have the same mean vector as the training set. If not, both should be centered by the user, and `assume_centered=True` should be used.

**Examples:**

- See Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood for an example on how to fit an `EmpiricalCovariance` object to data.
Shrunk Covariance

Basic shrinkage

Despite being an asymptotically unbiased estimator of the covariance matrix, the Maximum Likelihood Estimator is not a good estimator of the eigenvalues of the covariance matrix, so the precision matrix obtained from its inversion is not accurate. Sometimes, it even occurs that the empirical covariance matrix cannot be inverted for numerical reasons. To avoid such an inversion problem, a transformation of the empirical covariance matrix has been introduced: the shrinkage.

In scikit-learn, this transformation (with a user-defined shrinkage coefficient) can be directly applied to a pre-computed covariance with the `shrunk_covariance` method. Also, a shrunk estimator of the covariance can be fitted to data with a `ShrunkCovariance` object and its `ShrunkCovariance.fit` method. Again, results depend on whether the data are centered, so one may want to use the `assume_centered` parameter accurately.

Mathematically, this shrinkage consists in reducing the ratio between the smallest and the largest eigenvalues of the empirical covariance matrix. It can be done by simply shifting every eigenvalue according to a given offset, which is equivalent of finding the l2-penalized Maximum Likelihood Estimator of the covariance matrix. In practice, shrinkage boils down to a simple a convex transformation: \( \Sigma_{\text{shrunk}} = (1 - \alpha)\hat{\Sigma} + \alpha \frac{\text{Tr}^\Sigma}{p} \text{Id} \).

Choosing the amount of shrinkage, \( \alpha \) amounts to setting a bias/variance trade-off, and is discussed below.

Examples:

- See Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood for an example on how to fit a `ShrunkCovariance` object to data.

Ledoit-Wolf shrinkage

In their 2004 paper\(^1\), O. Ledoit and M. Wolf propose a formula to compute the optimal shrinkage coefficient \( \alpha \) that minimizes the Mean Squared Error between the estimated and the real covariance matrix.

The Ledoit-Wolf estimator of the covariance matrix can be computed on a sample with the `ledoit_wolf` function of the `sklearn.covariance` package, or it can be otherwise obtained by fitting a `LedoitWolf` object to the same sample.

Note: Case when population covariance matrix is isotropic

It is important to note that when the number of samples is much larger than the number of features, one would expect that no shrinkage would be necessary. The intuition behind this is that if the population covariance is full rank, when the number of sample grows, the sample covariance will also become positive definite. As a result, no shrinkage would necessary and the method should automatically do this.

This, however, is not the case in the Ledoit-Wolf procedure when the population covariance happens to be a multiple of the identity matrix. In this case, the Ledoit-Wolf shrinkage estimate approaches 1 as the number of samples increases. This indicates that the optimal estimate of the covariance matrix in the Ledoit-Wolf sense is multiple of the identity. Since the population covariance is already a multiple of the identity matrix, the Ledoit-Wolf solution is indeed a reasonable estimate.

---

Examples:

- See *Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood* for an example on how to fit a `LedoitWolf` object to data and for visualizing the performances of the Ledoit-Wolf estimator in terms of likelihood.

References:

**Oracle Approximating Shrinkage**

Under the assumption that the data are Gaussian distributed, Chen et al.\(^2\) derived a formula aimed at choosing a shrinkage coefficient that yields a smaller Mean Squared Error than the one given by Ledoit and Wolf’s formula. The resulting estimator is known as the Oracle Shrinkage Approximating estimator of the covariance.

The OAS estimator of the covariance matrix can be computed on a sample with the `oas` function of the `sklearn.covariance` package, or it can be otherwise obtained by fitting an `OAS` object to the same sample.

• See Ledoit-Wolf vs OAS estimation to visualize the Mean Squared Error difference between a LedoitWolf and an OAS estimator of the covariance.

Sparse inverse covariance

The matrix inverse of the covariance matrix, often called the precision matrix, is proportional to the partial correlation matrix. It gives the partial independence relationship. In other words, if two features are independent conditionally on the others, the corresponding coefficient in the precision matrix will be zero. This is why it makes sense to estimate a sparse precision matrix: the estimation of the covariance matrix is better conditioned by learning independence relations from the data. This is known as covariance selection.

In the small-samples situation, in which \( n_{\text{samples}} \) is on the order of \( n_{\text{features}} \) or smaller, sparse inverse covariance estimators tend to work better than shrunk covariance estimators. However, in the opposite situation, or for very correlated data, they can be numerically unstable. In addition, unlike shrinkage estimators, sparse estimators are able to recover off-diagonal structure.

The GraphicalLasso estimator uses an \( l_1 \) penalty to enforce sparsity on the precision matrix: the higher its alpha parameter, the more sparse the precision matrix. The corresponding GraphicalLassoCV object uses cross-validation to automatically set the alpha parameter.

Note: Structure recovery

Recovering a graphical structure from correlations in the data is a challenging thing. If you are interested in such recovery keep in mind that:

• Recovery is easier from a correlation matrix than a covariance matrix: standardize your observations before running GraphicalLasso
• If the underlying graph has nodes with much more connections than the average node, the algorithm will miss some of these connections.
Fig. 9: A comparison of maximum likelihood, shrinkage and sparse estimates of the covariance and precision matrix in the very small samples settings.

- If your number of observations is not large compared to the number of edges in your underlying graph, you will not recover it.
- Even if you are in favorable recovery conditions, the alpha parameter chosen by cross-validation (e.g. using the `GraphicalLassoCV` object) will lead to selecting too many edges. However, the relevant edges will have heavier weights than the irrelevant ones.

The mathematical formulation is the following:

$$\hat{K} = \arg\min_K \left( \text{tr}SK - \log\det K + \alpha \| K \|_1 \right)$$

Where $K$ is the precision matrix to be estimated, and $S$ is the sample covariance matrix. $\| K \|_1$ is the sum of the absolute values of off-diagonal coefficients of $K$. The algorithm employed to solve this problem is the GLasso algorithm, from the Friedman 2008 Biostatistics paper. It is the same algorithm as in the R `glasso` package.

**Examples:**
- *Sparse inverse covariance estimation*: example on synthetic data showing some recovery of a structure, and comparing to other covariance estimators.
- *Visualizing the stock market structure*: example on real stock market data, finding which symbols are most linked.

Robust Covariance Estimation

Real data sets are often subject to measurement or recording errors. Regular but uncommon observations may also appear for a variety of reasons. Observations which are very uncommon are called outliers. The empirical covariance estimator and the shrunk covariance estimators presented above are very sensitive to the presence of outliers in the data. Therefore, one should use robust covariance estimators to estimate the covariance of its real data sets. Alternatively, robust covariance estimators can be used to perform outlier detection and discard/downweight some observations according to further processing of the data.

The `sklearn.covariance` package implements a robust estimator of covariance, the Minimum Covariance Determinant\(^3\).

Minimum Covariance Determinant

The Minimum Covariance Determinant estimator is a robust estimator of a data set’s covariance introduced by P.J. Rousseeuw in\(^3\). The idea is to find a given proportion (h) of “good” observations which are not outliers and compute their empirical covariance matrix. This empirical covariance matrix is then rescaled to compensate the performed selection of observations (“consistency step”). Having computed the Minimum Covariance Determinant estimator, one can give weights to observations according to their Mahalanobis distance, leading to a reweighted estimate of the covariance matrix of the data set (“reweighting step”).

Rousseeuw and Van Driessen\(^4\) developed the FastMCD algorithm in order to compute the Minimum Covariance Determinant. This algorithm is used in scikit-learn when fitting an MCD object to data. The FastMCD algorithm also computes a robust estimate of the data set location at the same time.

Raw estimates can be accessed as `raw_location_` and `raw_covariance_` attributes of a `MinCovDet` robust covariance estimator object.

References:

Examples:

- See *Robust vs Empirical covariance estimate* for an example on how to fit a `MinCovDet` object to data and see how the estimate remains accurate despite the presence of outliers.
- See *Robust covariance estimation and Mahalanobis distances relevance* to visualize the difference between `EmpiricalCovariance` and `MinCovDet` covariance estimators in terms of Mahalanobis distance (so we get a better estimate of the precision matrix too).

\(^4\) A Fast Algorithm for the Minimum Covariance Determinant Estimator, 1999, American Statistical Association and the American Society for Quality, TECHNOMETRICS.
4.2.7 Novelty and Outlier Detection

Many applications require being able to decide whether a new observation belongs to the same distribution as existing observations (it is an inlier), or should be considered as different (it is an outlier). Often, this ability is used to clean real data sets. Two important distinctions must be made:

- **outlier detection** The training data contains outliers which are defined as observations that are far from the others. Outlier detection estimators thus try to fit the regions where the training data is the most concentrated, ignoring the deviant observations.

- **novelty detection** The training data is not polluted by outliers and we are interested in detecting whether a new observation is an outlier. In this context an outlier is also called a novelty.

Outlier detection and novelty detection are both used for anomaly detection, where one is interested in detecting abnormal or unusual observations. Outlier detection is then also known as unsupervised anomaly detection and novelty detection as semi-supervised anomaly detection. In the context of outlier detection, the outliers/anomalies cannot form a dense cluster as available estimators assume that the outliers/anomalies are located in low density regions. On the contrary, in the context of novelty detection, novelties/anomalies can form a dense cluster as long as they are in a low density region of the training data, considered as normal in this context.

The scikit-learn project provides a set of machine learning tools that can be used both for novelty or outlier detection. This strategy is implemented with objects learning in an unsupervised way from the data:

```
estimator.fit(X_train)
```

new observations can then be sorted as inliers or outliers with a `predict` method:

```
estimator.predict(X_test)
```

Inliers are labeled 1, while outliers are labeled -1. The predict method makes use of a threshold on the raw scoring function computed by the estimator. This scoring function is accessible through the `score_samples` method, while the threshold can be controlled by the `contamination` parameter.

The `decision_function` method is also defined from the scoring function, in such a way that negative values are outliers and non-negative ones are inliers:

```
estimator.decision_function(X_test)
```

Note that `neighbors.LocalOutlierFactor` does not support `predict`, `decision_function` and `score_samples` methods by default but only a `fit_predict` method, as this estimator was originally meant
to be applied for outlier detection. The scores of abnormality of the training samples are accessible through the `negative_outlier_factor_` attribute.

If you really want to use `neighbors.LocalOutlierFactor` for novelty detection, i.e. predict labels or compute the score of abnormality of new unseen data, you can instantiate the estimator with the `novelty` parameter set to `True` before fitting the estimator. In this case, `fit_predict` is not available.

**Warning: Novelty detection with Local Outlier Factor**

When `novelty` is set to `True` be aware that you must only use `predict`, `decision_function` and `score_samples` on new unseen data and not on the training samples as this would lead to wrong results. The scores of abnormality of the training samples are always accessible through the `negative_outlier_factor_` attribute.

The behavior of `neighbors.LocalOutlierFactor` is summarized in the following table.

Overview of outlier detection methods

A comparison of the outlier detection algorithms in scikit-learn. Local Outlier Factor (LOF) does not show a decision boundary in black as it has no predict method to be applied on new data when it is used for outlier detection.

`ensemble.IsolationForest` and `neighbors.LocalOutlierFactor` perform reasonably well on the data sets considered here. The `svm.OneClassSVM` is known to be sensitive to outliers and thus does not perform very well for outlier detection. That being said, outlier detection in high-dimension, or without any assumptions on the distribution of the inlying data is very challenging. `svm.OneClassSVM` may still be used with outlier detection but requires fine-tuning of its hyperparameter `nu` to handle outliers and prevent overfitting. Finally, `covariance.EllipticEnvelope` assumes the data is Gaussian and learns an ellipse. For more details on the different estimators refer to the example *Comparing anomaly detection algorithms for outlier detection on toy datasets* and the sections hereunder.

Examples:

- See *Comparing anomaly detection algorithms for outlier detection on toy datasets* for a comparison of the `svm.OneClassSVM`, the `ensemble.IsolationForest`, the `neighbors.LocalOutlierFactor` and `covariance.EllipticEnvelope`. 
Novelty Detection

Consider a data set of $n$ observations from the same distribution described by $p$ features. Consider now that we add one more observation to that data set. Is the new observation so different from the others that we can doubt it is regular? (i.e. does it come from the same distribution?) Or on the contrary, is it so similar to the other that we cannot distinguish it from the original observations? This is the question addressed by the novelty detection tools and methods.

In general, it is about to learn a rough, close frontier delimiting the contour of the initial observations distribution, plotted in embedding $p$-dimensional space. Then, if further observations lay within the frontier-delimited subspace, they are considered as coming from the same population than the initial observations. Otherwise, if they lay outside the frontier, we can say that they are abnormal with a given confidence in our assessment.

The One-Class SVM has been introduced by Schölkopf et al. for that purpose and implemented in the Support Vector Machines module in the `svm.OneClassSVM` object. It requires the choice of a kernel and a scalar parameter to define a frontier. The RBF kernel is usually chosen although there exists no exact formula or algorithm to set its bandwidth parameter. This is the default in the scikit-learn implementation. The $\nu$ parameter, also known as the margin of the One-Class SVM, corresponds to the probability of finding a new, but regular, observation outside the frontier.

References:

Examples:

- See One-class SVM with non-linear kernel (RBF) for visualizing the frontier learned around some data by a `svm.OneClassSVM` object.
- Species distribution modeling
Outlier Detection

Outlier detection is similar to novelty detection in the sense that the goal is to separate a core of regular observations from some polluting ones, called outliers. Yet, in the case of outlier detection, we don’t have a clean data set representing the population of regular observations that can be used to train any tool.

Fitting an elliptic envelope

One common way of performing outlier detection is to assume that the regular data come from a known distribution (e.g. data are Gaussian distributed). From this assumption, we generally try to define the “shape” of the data, and can define outlying observations as observations which stand far enough from the fit shape.

The scikit-learn provides an object `covariance.EllipticEnvelope` that fits a robust covariance estimate to the data, and thus fits an ellipse to the central data points, ignoring points outside the central mode.

For instance, assuming that the inlier data are Gaussian distributed, it will estimate the inlier location and covariance in a robust way (i.e. without being influenced by outliers). The Mahalanobis distances obtained from this estimate is used to derive a measure of outlyingness. This strategy is illustrated below.

![Mahalanobis distances of a contaminated data set](image)

Examples:

- See Robust covariance estimation and Mahalanobis distances relevance for an illustration of the difference between using a standard (`covariance.EmpiricalCovariance`) or a robust estimate (`covariance.MinCovDet`) of location and covariance to assess the degree of outlyingness of an observation.

References:

Isolation Forest

One efficient way of performing outlier detection in high-dimensional datasets is to use random forests. The `ensemble.IsolationForest` “isolates” observations by randomly selecting a feature and then randomly selecting a split value between the maximum and minimum values of the selected feature.

Since recursive partitioning can be represented by a tree structure, the number of splittings required to isolate a sample is equivalent to the path length from the root node to the terminating node.

This path length, averaged over a forest of such random trees, is a measure of normality and our decision function.

Random partitioning produces noticeably shorter paths for anomalies. Hence, when a forest of random trees collectively produce shorter path lengths for particular samples, they are highly likely to be anomalies.

The implementation of `ensemble.IsolationForest` is based on an ensemble of `tree.ExtraTreeRegressor`. Following Isolation Forest original paper, the maximum depth of each tree is set to $\lceil \log_2(n) \rceil$ where $n$ is the number of samples used to build the tree (see (Liu et al., 2008) for more details). This algorithm is illustrated below.

The `ensemble.IsolationForest` supports `warm_start=True` which allows you to add more trees to an already fitted model:

```python
>>> from sklearn.ensemble import IsolationForest
>>> import numpy as np

>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [0, 0], [-20, 50], [3, 5]])

>>> clf = IsolationForest(n_estimators=10, warm_start=True)
>>> clf.fit(X)  # fit 10 trees
>>> clf.set_params(n_estimators=20)  # add 10 more trees
>>> clf.fit(X)  # fit the added trees
```
Examples:

- See *IsolationForest example* for an illustration of the use of IsolationForest.
- See *Comparing anomaly detection algorithms for outlier detection on toy datasets* for a comparison of ensemble.IsolationForest with neighbors.LocalOutlierFactor, svm.OneClassSVM (tuned to perform like an outlier detection method) and a covariance-based outlier detection with covariance.EllipticEnvelope.

References:

Local Outlier Factor

Another efficient way to perform outlier detection on moderately high dimensional datasets is to use the Local Outlier Factor (LOF) algorithm.

The `neighbors.LocalOutlierFactor` (LOF) algorithm computes a score (called local outlier factor) reflecting the degree of abnormality of the observations. It measures the local density deviation of a given data point with respect to its neighbors. The idea is to detect the samples that have a substantially lower density than their neighbors.

In practice the local density is obtained from the k-nearest neighbors. The LOF score of an observation is equal to the ratio of the average local density of his k-nearest neighbors, and its own local density: a normal instance is expected to have a local density similar to that of its neighbors, while abnormal data are expected to have much smaller local density.

The number k of neighbors considered, (alias parameter n_neighbors) is typically chosen 1) greater than the minimum number of objects a cluster has to contain, so that other objects can be local outliers relative to this cluster, and 2) smaller than the maximum number of close by objects that can potentially be local outliers. In practice, such informations are generally not available, and taking n_neighbors=20 appears to work well in general. When the proportion of outliers is high (i.e. greater than 10 %, as in the example below), n_neighbors should be greater (n_neighbors=35 in the example below).

The strength of the LOF algorithm is that it takes both local and global properties of datasets into consideration: it can perform well even in datasets where abnormal samples have different underlying densities. The question is not, how isolated the sample is, but how isolated it is with respect to the surrounding neighborhood.

When applying LOF for outlier detection, there are no `predict`, `decision_function` and `score_samples` methods but only a `fit_predict` method. The scores of abnormality of the training samples are accessible through the `negative_outlier_factor_` attribute. Note that `predict`, `decision_function` and `score_samples` can be used on new unseen data when LOF is applied for novelty detection, i.e. when the `novelty` parameter is set to `True`. See *Novelty detection with Local Outlier Factor*.

This strategy is illustrated below.

Examples:

- See *Outlier detection with Local Outlier Factor (LOF)* for an illustration of the use of `neighbors.LocalOutlierFactor`. 
• See *Comparing anomaly detection algorithms for outlier detection on toy datasets* for a comparison with other anomaly detection methods.

**References:**

**Novelty detection with Local Outlier Factor**

To use `neighbors.LocalOutlierFactor` for novelty detection, i.e. predict labels or compute the score of abnormality of new unseen data, you need to instantiate the estimator with the `novelty` parameter set to `True` before fitting the estimator:

```python
lof = LocalOutlierFactor(novelty=True)
lof.fit(X_train)
```

Note that `fit_predict` is not available in this case.

**Warning: Novelty detection with Local Outlier Factor**

When `novelty` is set to `True` be aware that you must only use `predict`, `decision_function` and `score_samples` on new unseen data and not on the training samples as this would lead to wrong results. The scores of abnormality of the training samples are always accessible through the `negative_outlier_factor_` attribute.

Novelty detection with Local Outlier Factor is illustrated below.
Density Estimation walks the line between unsupervised learning, feature engineering, and data modeling. Some of the most popular and useful density estimation techniques are mixture models such as Gaussian Mixtures (`GaussianMixture`), and neighbor-based approaches such as the kernel density estimate (`KernelDensity`). Gaussian Mixtures are discussed more fully in the context of clustering, because the technique is also useful as an unsupervised clustering scheme.

Density estimation is a very simple concept, and most people are already familiar with one common density estimation technique: the histogram.

### Density Estimation: Histograms

A histogram is a simple visualization of data where bins are defined, and the number of data points within each bin is tallied. An example of a histogram can be seen in the upper-left panel of the following figure:
A major problem with histograms, however, is that the choice of binning can have a disproportionate effect on the resulting visualization. Consider the upper-right panel of the above figure. It shows a histogram over the same data, with the bins shifted right. The results of the two visualizations look entirely different, and might lead to different interpretations of the data.

Intuitively, one can also think of a histogram as a stack of blocks, one block per point. By stacking the blocks in the appropriate grid space, we recover the histogram. But what if, instead of stacking the blocks on a regular grid, we center each block on the point it represents, and sum the total height at each location? This idea leads to the lower-left visualization. It is perhaps not as clean as a histogram, but the fact that the data drive the block locations mean that it is a much better representation of the underlying data.

This visualization is an example of a kernel density estimation, in this case with a top-hat kernel (i.e. a square block at each point). We can recover a smoother distribution by using a smoother kernel. The bottom-right plot shows a Gaussian kernel density estimate, in which each point contributes a Gaussian curve to the total. The result is a smooth density estimate which is derived from the data, and functions as a powerful non-parametric model of the distribution of points.

**Kernel Density Estimation**

Kernel density estimation in scikit-learn is implemented in the `KernelDensity` estimator, which uses the Ball Tree or KD Tree for efficient queries (see Nearest Neighbors for a discussion of these). Though the above example uses a 1D data set for simplicity, kernel density estimation can be performed in any number of dimensions, though in practice the curse of dimensionality causes its performance to degrade in high dimensions.

In the following figure, 100 points are drawn from a bimodal distribution, and the kernel density estimates are shown for three choices of kernels:
It's clear how the kernel shape affects the smoothness of the resulting distribution. The scikit-learn kernel density estimator can be used as follows:

```python
>>> from sklearn.neighbors import KernelDensity
>>> import numpy as np
>>> X = np.array([-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2])
>>> kde = KernelDensity(kernel='gaussian', bandwidth=0.2).fit(X)
>>> kde.score_samples(X)
array([-0.41075698, -0.41075698, -0.41076071, -0.41075698, -0.41075698,
       -0.41076071])
```

Here we have used `kernel='gaussian'`, as seen above. Mathematically, a kernel is a positive function \( K(x; h) \) which is controlled by the bandwidth parameter \( h \). Given this kernel form, the density estimate at a point \( y \) within a group of points \( x_i; i = 1 \cdots N \) is given by:

\[
\rho_K(y) = \sum_{i=1}^{N} K(y - x_i; h)
\]

The bandwidth here acts as a smoothing parameter, controlling the tradeoff between bias and variance in the result. A large bandwidth leads to a very smooth (i.e. high-bias) density distribution. A small bandwidth leads to an unsmooth (i.e. high-variance) density distribution.

`KernelDensity` implements several common kernel forms, which are shown in the following figure:
The form of these kernels is as follows:

- **Gaussian kernel** (kernel = 'gaussian')
  \[ K(x; h) \propto \exp\left(-\frac{x^2}{2h^2}\right) \]

- **Tophat kernel** (kernel = 'tophat')
  \[ K(x; h) \propto 1 \text{ if } x < h \]

- **Epanechnikov kernel** (kernel = 'epanechnikov')
  \[ K(x; h) \propto 1 - \frac{x^2}{h^2} \]

- **Exponential kernel** (kernel = 'exponential')
  \[ K(x; h) \propto \exp(-x/h) \]

- **Linear kernel** (kernel = 'linear')
  \[ K(x; h) \propto 1 - x/h \text{ if } x < h \]

- **Cosine kernel** (kernel = 'cosine')
  \[ K(x; h) \propto \cos\left(\frac{\pi x}{2h}\right) \text{ if } x < h \]

The kernel density estimator can be used with any of the valid distance metrics (see `DistanceMetric` for a list of available metrics), though the results are properly normalized only for the Euclidean metric. One particularly useful metric is the Haversine distance which measures the angular distance between points on a sphere. Here is an example of using a kernel density estimate for a visualization of geospatial data, in this case the distribution of observations of two different species on the South American continent:
One other useful application of kernel density estimation is to learn a non-parametric generative model of a dataset in order to efficiently draw new samples from this generative model. Here is an example of using this process to create a new set of hand-written digits, using a Gaussian kernel learned on a PCA projection of the data:

The “new” data consists of linear combinations of the input data, with weights probabilistically drawn given the KDE model.
Examples:

- **Simple 1D Kernel Density Estimation**: computation of simple kernel density estimates in one dimension.
- **Kernel Density Estimation**: an example of using Kernel Density estimation to learn a generative model of the hand-written digits data, and drawing new samples from this model.
- **Kernel Density Estimate of Species Distributions**: an example of Kernel Density estimation using the Haversine distance metric to visualize geospatial data

### 4.2.9 Neural network models (unsupervised)

**Restricted Boltzmann machines**

Restricted Boltzmann machines (RBM) are unsupervised nonlinear feature learners based on a probabilistic model. The features extracted by an RBM or a hierarchy of RBMs often give good results when fed into a linear classifier such as a linear SVM or a perceptron.

The model makes assumptions regarding the distribution of inputs. At the moment, scikit-learn only provides `BernoulliRBM`, which assumes the inputs are either binary values or values between 0 and 1, each encoding the probability that the specific feature would be turned on.

The RBM tries to maximize the likelihood of the data using a particular graphical model. The parameter learning algorithm used (Stochastic Maximum Likelihood) prevents the representations from straying far from the input data, which makes them capture interesting regularities, but makes the model less useful for small datasets, and usually not useful for density estimation.

The method gained popularity for initializing deep neural networks with the weights of independent RBMs. This method is known as unsupervised pre-training.

Examples:

- **Restricted Boltzmann Machine features for digit classification**
Graphical model and parametrization

The graphical model of an RBM is a fully-connected bipartite graph.

The nodes are random variables whose states depend on the state of the other nodes they are connected to. The model is therefore parameterized by the weights of the connections, as well as one intercept (bias) term for each visible and hidden unit, omitted from the image for simplicity.
The energy function measures the quality of a joint assignment:

\[ E(v, h) = -\sum_i \sum_j w_{ij}v_ih_j - \sum_i b_i v_i - \sum_j c_j h_j \]

In the formula above, \( b \) and \( c \) are the intercept vectors for the visible and hidden layers, respectively. The joint probability of the model is defined in terms of the energy:

\[ P(v, h) = \frac{e^{-E(v, h)}}{Z} \]

The word restricted refers to the bipartite structure of the model, which prohibits direct interaction between hidden units, or between visible units. This means that the following conditional independencies are assumed:

\[ h_i \perp h_j | v \]
\[ v_i \perp v_j | h \]

The bipartite structure allows for the use of efficient block Gibbs sampling for inference.

### Bernoulli Restricted Boltzmann machines

In the `BernoulliRBM`, all units are binary stochastic units. This means that the input data should either be binary, or real-valued between 0 and 1 signifying the probability that the visible unit would turn on or off. This is a good model for character recognition, where the interest is on which pixels are active and which aren’t. For images of natural scenes it no longer fits because of background, depth and the tendency of neighbouring pixels to take the same values.

The conditional probability distribution of each unit is given by the logistic sigmoid activation function of the input it receives:

\[ P(v_i = 1 | h) = \sigma(\sum_j w_{ij}h_j + b_i) \]
\[ P(h_i = 1 | v) = \sigma(\sum_i w_{ij}v_i + c_j) \]

where \( \sigma \) is the logistic sigmoid function:

\[ \sigma(x) = \frac{1}{1 + e^{-x}} \]

### Stochastic Maximum Likelihood learning

The training algorithm implemented in `BernoulliRBM` is known as Stochastic Maximum Likelihood (SML) or Persistent Contrastive Divergence (PCD). Optimizing maximum likelihood directly is infeasible because of the form of the data likelihood:

\[ \log P(v) = \log \sum_h e^{-E(v, h)} - \log \sum_{x,y} e^{-E(x,y)} \]

For simplicity the equation above is written for a single training example. The gradient with respect to the weights is formed of two terms corresponding to the ones above. They are usually known as the positive gradient and the negative gradient, because of their respective signs. In this implementation, the gradients are estimated over mini-batches of samples.

In maximizing the log-likelihood, the positive gradient makes the model prefer hidden states that are compatible with the observed training data. Because of the bipartite structure of RBMs, it can be computed efficiently. The negative gradient, however, is intractable. Its goal is to lower the energy of joint states that the model prefers, therefore making
it stay true to the data. It can be approximated by Markov chain Monte Carlo using block Gibbs sampling by iteratively sampling each of \( v \) and \( h \) given the other, until the chain mixes. Samples generated in this way are sometimes referred as fantasy particles. This is inefficient and it is difficult to determine whether the Markov chain mixes.

The Contrastive Divergence method suggests to stop the chain after a small number of iterations, \( k \), usually even 1. This method is fast and has low variance, but the samples are far from the model distribution.

Persistent Contrastive Divergence addresses this. Instead of starting a new chain each time the gradient is needed, and performing only one Gibbs sampling step, in PCD we keep a number of chains (fantasy particles) that are updated \( k \) Gibbs steps after each weight update. This allows the particles to explore the space more thoroughly.

4.3 Model selection and evaluation

4.3.1 Cross-validation: evaluating estimator performance

Learning the parameters of a prediction function and testing it on the same data is a methodological mistake: a model that would just repeat the labels of the samples that it has just seen would have a perfect score but would fail to predict anything useful on yet-unseen data. This situation is called overfitting. To avoid it, it is common practice when performing a (supervised) machine learning experiment to hold out part of the available data as a test set \( X_{\text{test}}, y_{\text{test}} \). Note that the word “experiment” is not intended to denote academic use only, because even in commercial settings machine learning usually starts out experimentally. Here is a flowchart of typical cross validation workflow in model training. The best parameters can be determined by grid search techniques.

In scikit-learn a random split into training and test sets can be quickly computed with the `train_test_split` helper function. Let’s load the iris data set to fit a linear support vector machine on it:

```python
>>> import numpy as np
>>> from sklearn.model_selection import train_test_split
>>> from sklearn import datasets
>>> from sklearn import svm
```

(continues on next page)
>>> X, y = datasets.load_iris(return_X_y=True)
>>> X.shape, y.shape
((150, 4), (150,))

We can now quickly sample a training set while holding out 40% of the data for testing (evaluating) our classifier:

```python
>>> X_train, X_test, y_train, y_test = train_test_split(
    ...     X, y, test_size=0.4, random_state=0)
```

```python
>>> X_train.shape, y_train.shape
((90, 4), (90,))
>>> X_test.shape, y_test.shape
((60, 4), (60,))
```

```python
>>> clf = svm.SVC(kernel='linear', C=1).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.96...
```

When evaluating different settings (“hyperparameters”) for estimators, such as the $C$ setting that must be manually set for an SVM, there is still a risk of overfitting on the test set because the parameters can be tweaked until the estimator performs optimally. This way, knowledge about the test set can “leak” into the model and evaluation metrics no longer report on generalization performance. To solve this problem, yet another part of the dataset can be held out as a so-called “validation set”: training proceeds on the training set, after which evaluation is done on the validation set, and when the experiment seems to be successful, final evaluation can be done on the test set.

However, by partitioning the available data into three sets, we drastically reduce the number of samples which can be used for learning the model, and the results can depend on a particular random choice for the pair of (train, validation) sets.

A solution to this problem is a procedure called cross-validation (CV for short). A test set should still be held out for final evaluation, but the validation set is no longer needed when doing CV. In the basic approach, called $k$-fold CV, the training set is split into $k$ smaller sets (other approaches are described below, but generally follow the same principles). The following procedure is followed for each of the $k$ “folds”:

- A model is trained using $k-1$ of the folds as training data;
- the resulting model is validated on the remaining part of the data (i.e., it is used as a test set to compute a performance measure such as accuracy).

The performance measure reported by $k$-fold cross-validation is then the average of the values computed in the loop. This approach can be computationally expensive, but does not waste too much data (as is the case when fixing an arbitrary validation set), which is a major advantage in problems such as inverse inference where the number of samples is very small.
Computing cross-validated metrics

The simplest way to use cross-validation is to call the `cross_val_score` helper function on the estimator and the dataset.

The following example demonstrates how to estimate the accuracy of a linear kernel support vector machine on the iris dataset by splitting the data, fitting a model and computing the score 5 consecutive times (with different splits each time):

```python
>>> from sklearn.model_selection import cross_val_score

>>> clf = svm.SVC(kernel='linear', C=1, random_state=42)

>>> scores = cross_val_score(clf, X, y, cv=5)

>>> scores
array([0.96..., 1., 0.96..., 0.96..., 1.])
```

The mean score and the standard deviation are hence given by:

```python
>>> print("%0.2f accuracy with a standard deviation of %0.2f" % (scores.mean(), scores.std()))

0.98 accuracy with a standard deviation of 0.02
```

By default, the score computed at each CV iteration is the `score` method of the estimator. It is possible to change this by using the scoring parameter:

```python
>>> from sklearn import metrics

>>> scores = cross_val_score(clf, X, y, cv=5, scoring='f1_macro')

>>> scores
array([0.96..., 1., ..., 0.96..., 0.96..., 1.])
```

See *The scoring parameter: defining model evaluation rules* for details. In the case of the Iris dataset, the samples are balanced across target classes hence the accuracy and the F1-score are almost equal.

When the `cv` argument is an integer, `cross_val_score` uses the `KFold` or `StratifiedKFold` strategies by default, the latter being used if the estimator derives from `ClassifierMixin`.

It is also possible to use other cross validation strategies by passing a cross validation iterator instead, for instance:
```python
>>> from sklearn.model_selection import ShuffleSplit

>>> n_samples = X.shape[0]

>>> cv = ShuffleSplit(n_splits=5, test_size=0.3, random_state=0)

>>> cross_val_score(clf, X, y, cv=cv)
array([0.977..., 0.977..., 1. ..., 0.955..., 1.])
```

Another option is to use an iterable yielding (train, test) splits as arrays of indices, for example:

```python
>>> def custom_cv_2folds(X):
...     n = X.shape[0]
...     i = 1
...     while i <= 2:
...         idx = np.arange(n * (i - 1) / 2, n * i / 2, dtype=int)
...         yield idx, idx
...         i += 1
...

>>> custom_cv = custom_cv_2folds(X)

>>> cross_val_score(clf, X, y, cv=custom_cv)
array([1. , 0.973...])
```

### Data transformation with held out data

Just as it is important to test a predictor on data held-out from training, preprocessing (such as standardization, feature selection, etc.) and similar data transformations similarly should be learnt from a training set and applied to held-out data for prediction:

```python
>>> from sklearn import preprocessing

>>> X_train, X_test, y_train, y_test = train_test_split(
...     X, y, test_size=0.4, random_state=0)

>>> scaler = preprocessing.StandardScaler().fit(X_train)

>>> X_train_transformed = scaler.transform(X_train)

>>> clf = svm.SVC(C=1).fit(X_train_transformed, y_train)

>>> X_test_transformed = scaler.transform(X_test)

>>> clf.score(X_test_transformed, y_test)
0.9333...
```

A **Pipeline** makes it easier to compose estimators, providing this behavior under cross-validation:

```python
>>> from sklearn.pipeline import make_pipeline

>>> clf = make_pipeline(preprocessing.StandardScaler(), svm.SVC(C=1))

>>> cross_val_score(clf, X, y, cv=cv)
array([0.977..., 0.933..., 0.955..., 0.933..., 0.977...])
```

### The `cross_validate` function and multiple metric evaluation

The `cross_validate` function differs from `cross_val_score` in two ways:

- It allows specifying multiple metrics for evaluation.
- It returns a dict containing fit-times, score-times (and optionally training scores as well as fitted estimators) in addition to the test score.

For single metric evaluation, where the scoring parameter is a string, callable or None, the keys will be `['test_score', 'fit_time', 'score_time']`. For multiple metrics, the keys will be `['test_score', 'fit_time', 'score_time', 'data_time', 'memory_usage']`.
And for multiple metric evaluation, the return value is a dict with the following keys -
['test_<scorer1_name>', 'test_<scorer2_name>', 'test_<scorer3_name>', 'fit_time', 'score_time']

return_train_score is set to False by default to save computation time. To evaluate the scores on the training set as well you need to be set to True.

You may also retain the estimator fitted on each training set by setting return_estimator=True.

The multiple metrics can be specified either as a list, tuple or set of predefined scorer names:

```python
>>> from sklearn.model_selection import cross_validate
>>> from sklearn.metrics import recall_score

>>> scoring = ['precision_macro', 'recall_macro']
>>> clf = svm.SVC(kernel='linear', C=1, random_state=0)
>>> scores = cross_validate(clf, X, y, scoring=scoring)

>>> sorted(scores.keys())
['fit_time', 'score_time', 'test_precision_macro', 'test_recall_macro']

>>> scores['test_recall_macro']
array([0.96..., 1. ..., 0.96..., 0.96..., 1. ...])
```

Or as a dict mapping scorer name to a predefined or custom scoring function:

```python
>>> from sklearn.metrics import make_scorer

>>> scoring = {'prec_macro': 'precision_macro',
...             'rec_macro': make_scorer(recall_score, average='macro')}

>>> scores = cross_validate(clf, X, y, scoring=scoring,
...                          cv=5, return_train_score=True)

>>> sorted(scores.keys())
['fit_time', 'score_time', 'test_prec_macro', 'test_rec_macro',
 'train_prec_macro', 'train_rec_macro']

>>> scores['train_rec_macro']
array([0.97..., 0.97..., 0.99..., 0.98..., 0.98...])
```

Or as a dict mapping scorer name to a predefined or custom scoring function:

```python
>>> scoring = {'prec_macro': 'precision_macro',
...             'rec_macro': make_scorer(recall_score, average='macro')}

>>> scores = cross_validate(clf, X, y, scoring=scoring,
...                          cv=5, return_train_score=True)

>>> sorted(scores.keys())
['fit_time', 'score_time', 'test_prec_macro', 'test_rec_macro',
 'train_prec_macro', 'train_rec_macro']

>>> scores['train_rec_macro']
array([0.97..., 0.97..., 0.99..., 0.98..., 0.98...])
```

Here is an example of cross_validate using a single metric:

```python
>>> scores = cross_validate(clf, X, y,
...                          scoring='precision_macro', cv=5,
...                          return_estimator=True)

>>> sorted(scores.keys())
['estimator', 'fit_time', 'score_time', 'test_score']
```

**Obtaining predictions by cross-validation**

The function `cross_val_predict` has a similar interface to `cross_val_score`, but returns, for each element in the input, the prediction that was obtained for that element when it was in the test set. Only cross-validation strategies that assign all elements to a test set exactly once can be used (otherwise, an exception is raised).

**Warning:** Note on inappropriate usage of cross_val_predict

The result of `cross_val_predict` may be different from those obtained using `cross_val_score` as the elements are grouped in different ways. The function `cross_val_score` takes an average over cross-validation folds, whereas `cross_val_predict` simply returns the labels (or probabilities) from several distinct models undistinguished. Thus, `cross_val_predict` is not an appropriate measure of generalisation error.

The function `cross_val_predict` is appropriate for:

4.3. Model selection and evaluation 511
• Visualization of predictions obtained from different models.
• Model blending: When predictions of one supervised estimator are used to train another estimator in
ensemble methods.

The available cross validation iterators are introduced in the following section.

### Examples

- *Receiver Operating Characteristic (ROC) with cross validation*,
- *Recursive feature elimination with cross-validation*,
- *Parameter estimation using grid search with cross-validation*,
- *Sample pipeline for text feature extraction and evaluation*,
- *Plotting Cross-Validated Predictions*,
- *Nested versus non-nested cross-validation*.

### Cross validation iterators

The following sections list utilities to generate indices that can be used to generate dataset splits according to different
cross validation strategies.

#### Cross-validation iterators for i.i.d. data

Assuming that some data is Independent and Identically Distributed (i.i.d.) is making the assumption that all samples
stem from the same generative process and that the generative process is assumed to have no memory of past generated
samples.

The following cross-validators can be used in such cases.

**Note:** While i.i.d. data is a common assumption in machine learning theory, it rarely holds in practice. If one knows
that the samples have been generated using a time-dependent process, it is safer to use a *time-series aware cross-
validation scheme*. Similarly, if we know that the generative process has a group structure (samples collected from
different subjects, experiments, measurement devices), it is safer to use *group-wise cross-validation*.

#### K-fold

*KFold* divides all the samples in *k* groups of samples, called folds (if *k* = *n*, this is equivalent to the *Leave One Out*
strategy), of equal sizes (if possible). The prediction function is learned using *k* − 1 folds, and the fold left out is used for test.

Example of 2-fold cross-validation on a dataset with 4 samples:

```python
>>> import numpy as np
>>> from sklearn.model_selection import KFold

>>> X = ["a", "b", "c", "d"]
>>> kf = KFold(n_splits=2)
>>> for train, test in kf.split(X):
```

(continues on next page)
...    print("%s %s" % (train, test))
[2 3] [0 1]
[0 1] [2 3]

Here is a visualization of the cross-validation behavior. Note that KFold is not affected by classes or groups.

![KFold visualization](image)

Each fold is constituted by two arrays: the first one is related to the training set, and the second one to the test set. Thus, one can create the training/test sets using numpy indexing:

```python
>>> X = np.array([[0., 0.], [1., 1.], [-1., -1.], [2., 2.]])
>>> y = np.array([0, 1, 0, 1])
>>> X_train, X_test, y_train, y_test = X[train], X[test], y[train], y[test]
```

### Repeated K-Fold

RepeatedKFold repeats K-Fold n times. It can be used when one requires to run KFold n times, producing different splits in each repetition.

Example of 2-fold K-Fold repeated 2 times:

```python
>>> import numpy as np
>>> from sklearn.model_selection import RepeatedKFold
>>> X = np.array([[1, 2], [3, 4], [1, 2], [3, 4]])
>>> random_state = 12883823
>>> rf = RepeatedKFold(n_splits=2, n_repeats=2, random_state=random_state)
>>> for train, test in rf.split(X):
...    print("%s %s" % (train, test))
...
[2 3] [0 1]
[0 1] [2 3]
[0 2] [1 3]
[1 3] [0 2]
```

Similarly, RepeatedStratifiedKFold repeats Stratified K-Fold n times with different randomization in each repetition.

---

4.3. Model selection and evaluation 513
Leave One Out (LOO)

LeaveOneOut (or LOO) is a simple cross-validation. Each learning set is created by taking all the samples except one, the test set being the sample left out. Thus, for \( n \) samples, we have \( n \) different training sets and \( n \) different tests set. This cross-validation procedure does not waste much data as only one sample is removed from the training set:

```python
>>> from sklearn.model_selection import LeaveOneOut
>>> X = [1, 2, 3, 4]
>>> loo = LeaveOneOut()
>>> for train, test in loo.split(X):
...     print("%s %s" % (train, test))
[1 2 3] [0]
[0 2 3] [1]
[0 1 3] [2]
[0 1 2] [3]
```

Potential users of LOO for model selection should weigh a few known caveats. When compared with \( k \)-fold cross validation, one builds \( n \) models from \( n \) samples instead of \( k \) models, where \( n > k \). Moreover, each is trained on \( n - 1 \) samples rather than \( (k - 1)n/k \). In both ways, assuming \( k \) is not too large and \( k < n \), LOO is more computationally expensive than \( k \)-fold cross validation.

In terms of accuracy, LOO often results in high variance as an estimator for the test error. Intuitively, since \( n - 1 \) of the \( n \) samples are used to build each model, models constructed from folds are virtually identical to each other and to the model built from the entire training set.

However, if the learning curve is steep for the training size in question, then 5- or 10- fold cross validation can overestimate the generalization error.

As a general rule, most authors, and empirical evidence, suggest that 5- or 10- fold cross validation should be preferred to LOO.

Leave P Out (LPO)

LeavePOut is very similar to LeaveOneOut as it creates all the possible training/test sets by removing $p$ samples from the complete set. For $n$ samples, this produces $\binom{n}{p}$ train-test pairs. Unlike LeaveOneOut and KFold, the test sets will overlap for $p > 1$.

Example of Leave-2-Out on a dataset with 4 samples:

```python
>>> from sklearn.model_selection import LeavePOut
...
X = np.ones(4)
...
lpo = LeavePOut(p=2)
... for train, test in lpo.split(X):
...     print("%s %s" % (train, test))
[2 3] [0 1]
[1 3] [0 2]
[1 2] [0 3]
[0 3] [1 2]
[0 2] [1 3]
[0 1] [2 3]
```

Random permutations cross-validation a.k.a. Shuffle & Split

The ShuffleSplit iterator will generate a user defined number of independent train/test dataset splits. Samples are first shuffled and then split into a pair of train and test sets.

It is possible to control the randomness for reproducibility of the results by explicitly seeding the random_state pseudo random number generator.

Here is a usage example:

```python
>>> from sklearn.model_selection import ShuffleSplit
...
X = np.arange(10)
...
ss = ShuffleSplit(n_splits=5, test_size=0.25, random_state=0)
... for train_index, test_index in ss.split(X):
...     print("%s %s" % (train_index, test_index))
[9 1 6 7 3 0 5] [2 8 4]
[2 9 8 0 6 7 4] [3 5 1]
[4 5 1 0 6 9 7] [2 3 8]
[2 7 5 8 0 3 4] [6 1 9]
[4 1 0 6 8 9 3] [5 2 7]
```

Here is a visualization of the cross-validation behavior. Note that ShuffleSplit is not affected by classes or groups.

ShuffleSplit is thus a good alternative to KFold cross validation that allows a finer control on the number of iterations and the proportion of samples on each side of the train/test split.

4.3. Model selection and evaluation 515
Cross-validation iterators with stratification based on class labels.

Some classification problems can exhibit a large imbalance in the distribution of the target classes: for instance there could be several times more negative samples than positive samples. In such cases it is recommended to use stratified sampling as implemented in `StratifiedKFold` and `StratifiedShuffleSplit` to ensure that relative class frequencies is approximately preserved in each train and validation fold.

**Stratified k-fold**

`StratifiedKFold` is a variation of `k-fold` which returns *stratified* folds: each set contains approximately the same percentage of samples of each target class as the complete set.

Here is an example of stratified 3-fold cross-validation on a dataset with 50 samples from two unbalanced classes. We show the number of samples in each class and compare with `KFold`.

```python
>>> from sklearn.model_selection import StratifiedKFold, KFold
>>> import numpy as np

>>> X, y = np.ones((50, 1)), np.hstack(([0] * 45, [1] * 5))

>>> skf = StratifiedKFold(n_splits=3)
>>> for train, test in skf.split(X, y):
...     print('train - {} | test - {}'.format(np.bincount(y[train]), np.bincount(y[test])))
...     train - [30 3] | test - [15 2]
...     train - [30 3] | test - [15 2]
...     train - [30 4] | test - [15 1]

>>> kf = KFold(n_splits=3)
>>> for train, test in kf.split(X, y):
...     print('train - {} | test - {}'.format(np.bincount(y[train]), np.bincount(y[test])))
...     train - [28 5] | test - [17]
...     train - [28 5] | test - [17]
...     train - [34] | test - [11 5]
```

We can see that `StratifiedKFold` preserves the class ratios (approximately 1 / 10) in both train and test dataset. Here is a visualization of the cross-validation behavior.

`RepeatedStratifiedKFold` can be used to repeat Stratified K-Fold n times with different randomization in each repetition.
Stratified Shuffle Split

*StratifiedShuffleSplit* is a variation of *ShuffleSplit*, which returns stratified splits, *i.e.* which creates splits by preserving the same percentage for each target class as in the complete set.

Here is a visualization of the cross-validation behavior.

**Cross-validation iterators for grouped data.**

The i.i.d. assumption is broken if the underlying generative process yield groups of dependent samples.

Such a grouping of data is domain specific. An example would be when there is medical data collected from multiple patients, with multiple samples taken from each patient. And such data is likely to be dependent on the individual group. In our example, the patient id for each sample will be its group identifier.

In this case we would like to know if a model trained on a particular set of groups generalizes well to the unseen groups. To measure this, we need to ensure that all the samples in the validation fold come from groups that are not represented at all in the paired training fold.

The following cross-validation splitters can be used to do that. The grouping identifier for the samples is specified via the *groups* parameter.
Group k-fold

*GroupKFold* is a variation of k-fold which ensures that the same group is not represented in both testing and training sets. For example if the data is obtained from different subjects with several samples per-subject and if the model is flexible enough to learn from highly person specific features it could fail to generalize to new subjects. *GroupKFold* makes it possible to detect this kind of overfitting situations.

Imagine you have three subjects, each with an associated number from 1 to 3:

```python
>>> from sklearn.model_selection import GroupKFold

>>> X = [0.1, 0.2, 2.2, 2.4, 2.3, 4.55, 5.8, 8.8, 9, 10]
>>> y = ["a", "b", "b", "b", "c", "c", "c", "d", "d", "d"]
>>> groups = [1, 1, 1, 2, 2, 2, 3, 3, 3, 3]

>>> gkf = GroupKFold(n_splits=3)
>>> for train, test in gkf.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
[0 1 2 3 4 5] [6 7 8 9]
[0 1 2 6 7 8 9] [3 4 5]
[3 4 5 6 7 8 9] [0 1 2]
```

Each subject is in a different testing fold, and the same subject is never in both testing and training. Notice that the folds do not have exactly the same size due to the imbalance in the data.

Here is a visualization of the cross-validation behavior.

![GroupKFold Visualization](image)

**Leave One Group Out**

*LeaveOneGroupOut* is a cross-validation scheme which holds out the samples according to a third-party provided array of integer groups. This group information can be used to encode arbitrary domain specific pre-defined cross-validation folds.

Each training set is thus constituted by all the samples except the ones related to a specific group.

For example, in the cases of multiple experiments, *LeaveOneGroupOut* can be used to create a cross-validation based on the different experiments: we create a training set using the samples of all the experiments except one:

```python
>>> from sklearn.model_selection import LeaveOneGroupOut
```

(continues on next page)
Another common application is to use time information: for instance the groups could be the year of collection of the samples and thus allow for cross-validation against time-based splits.

**Leave P Groups Out**

`LeavePGroupsOut` is similar as `LeaveOneGroupOut`, but removes samples related to \( P \) groups for each training/test set.

Example of Leave-2-Group Out:

```python
>>> from sklearn.model_selection import LeavePGroupsOut
>>> X = np.arange(6)
>>> y = [1, 1, 1, 2, 2, 2]
>>> groups = [1, 1, 2, 2, 3, 3]
>>> lpg = LeavePGroupsOut(n_groups=2)
>>> for train, test in lpg.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
  [4 5] [0 1 2 3]
  [2 3] [0 1 4 5]
  [0 1] [2 3 4 5]
```

**Group Shuffle Split**

The `GroupShuffleSplit` iterator behaves as a combination of `ShuffleSplit` and `LeavePGroupsOut`, and generates a sequence of randomized partitions in which a subset of groups are held out for each split.

Here is a usage example:

```python
>>> from sklearn.model_selection import GroupShuffleSplit
>>> X = [0.1, 0.2, 2.2, 2.4, 2.3, 4.55, 5.8, 0.001]
>>> y = ["a", "b", "b", "b", "c", "c", "c", "a"]
>>> groups = [1, 1, 2, 2, 3, 3, 4, 4]
>>> gss = GroupShuffleSplit(n_splits=4, test_size=0.5, random_state=0)
>>> for train, test in gss.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
...  [0 1 2 3] [4 5 6 7]
  [2 3 6 7] [0 1 4 5]
  [2 3 4 5] [0 1 6 7]
  [4 5 6 7] [0 1 2 3]
```

Here is a visualization of the cross-validation behavior.
This class is useful when the behavior of LeavePGroupsOut is desired, but the number of groups is large enough that generating all possible partitions with $P$ groups withheld would be prohibitively expensive. In such a scenario, GroupShuffleSplit provides a random sample (with replacement) of the train / test splits generated by LeavePGroupsOut.

Predefined Fold-Splits / Validation-Sets

For some datasets, a pre-defined split of the data into training- and validation fold or into several cross-validation folds already exists. Using PredefinedSplit it is possible to use these folds e.g. when searching for hyperparameters.

For example, when using a validation set, set the test_fold to 0 for all samples that are part of the validation set, and to -1 for all other samples.

Using cross-validation iterators to split train and test

The above group cross-validation functions may also be useful for splitting a dataset into training and testing subsets. Note that the convenience function train_test_split is a wrapper around ShuffleSplit and thus only allows for stratified splitting (using the class labels) and cannot account for groups.

To perform the train and test split, use the indices for the train and test subsets yielded by the generator output by the split() method of the cross-validation splitter. For example:

```python
>>> from sklearn.model_selection import GroupShuffleSplit
>>> X = np.array([0.1, 0.2, 2.2, 2.4, 2.3, 4.55, 5.8, 0.001])
>>> y = np.array(['a', 'b', 'b', 'b', 'c', 'c', 'c', 'a'])
>>> groups = np.array([1, 1, 2, 2, 3, 3, 4, 4])
>>> train_indx, test_indx = next...
...  GroupShuffleSplit(random_state=7).split(X, y, groups)
...
>>> X_train, X_test, y_train, y_test = ...
...  X[train_indx], X[test_indx], y[train_indx], y[test_indx]
>>> X_train.shape, X_test.shape
((6,), (2,))
>>> np.unique(groups[train_indx]), np.unique(groups[test_indx])
(array([1, 2, 4]), array([3]))
```
Cross validation of time series data

Time series data is characterised by the correlation between observations that are near in time (autocorrelation). However, classical cross-validation techniques such as KFold and ShuffleSplit assume the samples are independent and identically distributed, and would result in unreasonable correlation between training and testing instances (yielding poor estimates of generalisation error) on time series data. Therefore, it is very important to evaluate our model for time series data on the “future” observations least like those that are used to train the model. To achieve this, one solution is provided by TimeSeriesSplit.

**Time Series Split**

TimeSeriesSplit is a variation of k-fold which returns first k folds as train set and the (k + 1) th fold as test set. Note that unlike standard cross-validation methods, successive training sets are supersets of those that come before them. Also, it adds all surplus data to the first training partition, which is always used to train the model.

This class can be used to cross-validate time series data samples that are observed at fixed time intervals.

Example of 3-split time series cross-validation on a dataset with 6 samples:

```python
>>> from sklearn.model_selection import TimeSeriesSplit

>>> X = np.array([[1, 2], [3, 4], [1, 2], [3, 4], [1, 2], [3, 4]])

>>> y = np.array([1, 2, 3, 4, 5, 6])

>>> tscv = TimeSeriesSplit(n_splits=3)

>>> print(tscv)
TimeSeriesSplit(gap=0, max_train_size=None, n_splits=3, test_size=None)

>>> for train, test in tscv.split(X):
...     print("%s %s" % (train, test))
[0 1 2] [3]
[0 1 2 3] [4]
[0 1 2 3 4] [5]
```

Here is a visualization of the cross-validation behavior.
A note on shuffling

If the data ordering is not arbitrary (e.g., samples with the same class label are contiguous), shuffling it first may be essential to get a meaningful cross-validation result. However, the opposite may be true if the samples are not independently and identically distributed. For example, if samples correspond to news articles, and are ordered by their time of publication, then shuffling the data will likely lead to a model that is overfit and an inflated validation score: it will be tested on samples that are artificially similar (close in time) to training samples.

Some cross validation iterators, such as `KFold`, have an inbuilt option to shuffle the data indices before splitting them. Note that:

- This consumes less memory than shuffling the data directly.
- By default no shuffling occurs, including for the (stratified) K fold cross-validation performed by specifying `cv=some_integer` to `cross_val_score`, grid search, etc. Keep in mind that `train_test_split` still returns a random split.
- The `random_state` parameter defaults to `None`, meaning that the shuffling will be different every time `KFold(..., shuffle=True)` is iterated. However, `GridSearchCV` will use the same shuffling for each set of parameters validated by a single call to its `fit` method.
- To get identical results for each split, set `random_state` to an integer.

Cross validation and model selection

Cross validation iterators can also be used to directly perform model selection using Grid Search for the optimal hyperparameters of the model. This is the topic of the next section: Tuning the hyper-parameters of an estimator.

Permutation test score

`permutation_test_score` offers another way to evaluate the performance of classifiers. It provides a permutation-based p-value, which represents how likely an observed performance of the classifier would be obtained by chance. The null hypothesis in this test is that the classifier fails to leverage any statistical dependency between the features and the labels to make correct predictions on left out data. `permutation_test_score` generates a null distribution by calculating `n_permutations` different permutations of the data. In each permutation the labels are randomly shuffled, thereby removing any dependency between the features and the labels. The p-value output is the fraction of permutations for which the average cross-validation score obtained by the model is better than the cross-validation score obtained by the model using the original data. For reliable results `n_permutations` should typically be larger than 100 and `cv` between 3-10 folds.

A low p-value provides evidence that the dataset contains real dependency between features and labels and the classifier was able to utilize this to obtain good results. A high p-value could be due to a lack of dependency between features and labels (there is no difference in feature values between the classes) or because the classifier was not able to use the dependency in the data. In the latter case, using a more appropriate classifier that is able to utilize the structure in the data, would result in a low p-value.

Cross-validation provides information about how well a classifier generalizes, specifically the range of expected errors of the classifier. However, a classifier trained on a high dimensional dataset with no structure may still perform better than expected on cross-validation, just by chance. This can typically happen with small datasets with less than a few hundred samples. `permutation_test_score` provides information on whether the classifier has found a real class structure and can help in evaluating the performance of the classifier.

It is important to note that this test has been shown to produce low p-values even if there is only weak structure in the data because in the corresponding permuted datasets there is absolutely no structure. This test is therefore only able to show when the model reliably outperforms random guessing.
Finally, `permutation_test_score` is computed using brute force and internally fits \((n_{\text{permutations}} + 1) \times n_{\text{cv}}\) models. It is therefore only tractable with small datasets for which fitting an individual model is very fast.

### Examples

- *Test with permutations the significance of a classification score*

#### 4.3.2 Tuning the hyper-parameters of an estimator

Hyper-parameters are parameters that are not directly learnt within estimators. In scikit-learn they are passed as arguments to the constructor of the estimator classes. Typical examples include `C`, `kernel` and `gamma` for Support Vector Classifier, `alpha` for Lasso, etc.

It is possible and recommended to search the hyper-parameter space for the best *cross validation* score.

Any parameter provided when constructing an estimator may be optimized in this manner. Specifically, to find the names and current values for all parameters for a given estimator, use:

```python
estimator.get_params()
```

A search consists of:

- an estimator (regressor or classifier such as `sklearn.svm.SVC()`);
- a parameter space;
- a method for searching or sampling candidates;
- a cross-validation scheme; and
- a *score function*.

Two generic approaches to parameter search are provided in scikit-learn: for given values, `GridSearchCV` exhaustively considers all parameter combinations, while `RandomizedSearchCV` can sample a given number of candidates from a parameter space with a specified distribution. Both these tools have successive halving counterparts `HalvingGridSearchCV` and `HalvingRandomSearchCV`, which can be much faster at finding a good parameter combination.

After describing these tools we detail *best practices* applicable to these approaches. Some models allow for specialized, efficient parameter search strategies, outlined in *Alternatives to brute force parameter search*.

Note that it is common that a small subset of those parameters can have a large impact on the predictive or computation performance of the model while others can be left to their default values. It is recommended to read the docstring of the estimator class to get a finer understanding of their expected behavior, possibly by reading the enclosed reference to the literature.
Exhaustive Grid Search

The grid search provided by `GridSearchCV` exhaustively generates candidates from a grid of parameter values specified with the `param_grid` parameter. For instance, the following `param_grid`:

```
param_grid = [
    {'C': [1, 10, 100, 1000], 'kernel': ['linear']},
    {'C': [1, 10, 100, 1000], 'gamma': [0.001, 0.0001], 'kernel': ['rbf']},
]
```

specifies that two grids should be explored: one with a linear kernel and C values in [1, 10, 100, 1000], and the second one with an RBF kernel, and the cross-product of C values ranging in [1, 10, 100, 1000] and gamma values in [0.001, 0.0001].

The `GridSearchCV` instance implements the usual estimator API: when “fitting” it on a dataset all the possible combinations of parameter values are evaluated and the best combination is retained.

Examples:

- See [Parameter estimation using grid search with cross-validation](#) for an example of Grid Search computation on the digits dataset.
- See [Sample pipeline for text feature extraction and evaluation](#) for an example of Grid Search coupling parameters from a text documents feature extractor (n-gram count vectorizer and TF-IDF transformer) with a classifier (here a linear SVM trained with SGD with either elastic net or L2 penalty) using a pipeline. Pipeline instance.
- See [Nested versus non-nested cross-validation](#) for an example of Grid Search within a cross validation loop on the iris dataset. This is the best practice for evaluating the performance of a model with grid search.
- See [Demonstration of multi-metric evaluation on cross_val_score and GridSearchCV](#) for an example of `GridSearchCV` being used to evaluate multiple metrics simultaneously.
- See [Balance model complexity and cross-validated score](#) for an example of using `refit=callable` interface in `GridSearchCV`. The example shows how this interface adds certain amount of flexibility in identifying the “best” estimator. This interface can also be used in multiple metrics evaluation.

Randomized Parameter Optimization

While using a grid of parameter settings is currently the most widely used method for parameter optimization, other search methods have more favourable properties. `RandomizedSearchCV` implements a randomized search over parameters, where each setting is sampled from a distribution over possible parameter values. This has two main benefits over an exhaustive search:

- A budget can be chosen independent of the number of parameters and possible values.
- Adding parameters that do not influence the performance does not decrease efficiency.

Specifying how parameters should be sampled is done using a dictionary, very similar to specifying parameters for `GridSearchCV`. Additionally, a computation budget, being the number of sampled candidates or sampling iterations, is specified using the `n_iter` parameter. For each parameter, either a distribution over possible values or a list of discrete choices (which will be sampled uniformly) can be specified:

```
{'C': scipy.stats.expon(scale=100), 'gamma': scipy.stats.expon(scale=1),
 'kernel': ['rbf'], 'class_weight': ['balanced', None]}
```
This example uses the `scipy.stats` module, which contains many useful distributions for sampling parameters, such as `expon`, `gamma`, `uniform` or `randint`.

In principle, any function can be passed that provides a `rvs` (random variate sample) method to sample a value. A call to the `rvs` function should provide independent random samples from possible parameter values on consecutive calls.

```python
from sklearn.utils.fixes import loguniform

{'C': loguniform(1e0, 1e3),
 'gamma': loguniform(1e-4, 1e-3),
 'kernel': ['rbf'],
 'class_weight': ['balanced', None]}
```

For continuous parameters, such as `C` above, it is important to specify a continuous distribution to take full advantage of the randomization. This way, increasing `n_iter` will always lead to a finer search.

A continuous log-uniform random variable is available through `loguniform`. This is a continuous version of log-spaced parameters. For example to specify `C` above, `loguniform(1, 100)` can be used instead of `[1, 10, 100]` or `np.logspace(0, 2, num=1000)`. This is an alias to SciPy's `stats.reciprocal`.

Mirroring the example above in grid search, we can specify a continuous random variable that is log-uniformly distributed between `1e0` and `1e3`:

### Examples:

- Comparing randomized search and grid search for hyperparameter estimation compares the usage and efficiency of randomized search and grid search.

### References:

### Searching for optimal parameters with successive halving

Scikit-learn also provides the `HalvingGridSearchCV` and `HalvingRandomSearchCV` estimators that can be used to search a parameter space using successive halving\(^1\). Successive halving (SH) is like a tournament among candidate parameter combinations. SH is an iterative selection process where all candidates (the parameter combinations) are evaluated with a small amount of resources at the first iteration. Only some of these candidates are selected for the next iteration, which will be allocated more resources. For parameter tuning, the resource is typically the number of training samples, but it can also be an arbitrary numeric parameter such as `n_estimators` in a random forest.

---

As illustrated in the figure below, only a subset of candidates ‘survive’ until the last iteration. These are the candidates that have consistently ranked among the top-scoring candidates across all iterations. Each iteration is allocated an increasing amount of resources per candidate, here the number of samples.

![Scores of candidates over iterations](image)

We here briefly describe the main parameters, but each parameter and their interactions are described in more details in the sections below. The \texttt{factor} (> 1) parameter controls the rate at which the resources grow, and the rate at which the number of candidates decreases. In each iteration, the number of resources per candidate is multiplied by factor and the number of candidates is divided by the same factor. Along with \texttt{resource} and \texttt{min\_resources}, \texttt{factor} is the most important parameter to control the search in our implementation, though a value of 3 usually works well. \texttt{factor} effectively controls the number of iterations in \texttt{HalvingGridSearchCV} and the number of candidates (by default) and iterations in \texttt{HalvingRandomSearchCV}. \texttt{aggressive\_elimination=True} can also be used if the number of available resources is small. More control is available through tuning the \texttt{min\_resources} parameter.

These estimators are still \texttt{experimental}: their predictions and their API might change without any deprecation cycle. To use them, you need to explicitly import \texttt{enable_halving_search_cv}:

```python
>>> # explicitly require this experimental feature
>>> from sklearn.experimental import enable_halving_search_cv # noqa
>>> # now you can import normally from model_selection
>>> from sklearn.model_selection import HalvingGridSearchCV
>>> from sklearn.model_selection import HalvingRandomSearchCV
```
Examples:

- Comparison between grid search and successive halving
- Successive Halving Iterations

Choosing min_resources and the number of candidates

Beside factor, the two main parameters that influence the behaviour of a successive halving search are the min_resources parameter, and the number of candidates (or parameter combinations) that are evaluated. min_resources is the amount of resources allocated at the first iteration for each candidate. The number of candidates is specified directly in HalvingRandomSearchCV, and is determined from the param_grid parameter of HalvingGridSearchCV.

Consider a case where the resource is the number of samples, and where we have 1000 samples. In theory, with min_resources=10 and factor=2, we are able to run at most 7 iterations with the following number of samples: [10, 20, 40, 80, 160, 320, 640].

But depending on the number of candidates, we might run less than 7 iterations: if we start with a small number of candidates, the last iteration might use less than 640 samples, which means not using all the available resources (samples). For example if we start with 5 candidates, we only need 2 iterations: 5 candidates for the first iteration, then 5 // 2 = 2 candidates at the second iteration, after which we know which candidate performs the best (so we don’t need a third one). We would only be using at most 20 samples which is a waste since we have 1000 samples at our disposal. On the other hand, if we start with a high number of candidates, we might end up with a lot of candidates at the last iteration, which may not always be ideal: it means that many candidates will run with the full resources, basically reducing the procedure to standard search.

In the case of HalvingRandomSearchCV, the number of candidates is set by default such that the last iteration uses as much of the available resources as possible. For HalvingGridSearchCV, the number of candidates is determined by the param_grid parameter. Changing the value of min_resources will impact the number of possible iterations, and as a result will also have an effect on the ideal number of candidates.

Another consideration when choosing min_resources is whether or not it is easy to discriminate between good and bad candidates with a small amount of resources. For example, if you need a lot of samples to distinguish between good and bad parameters, a high min_resources is recommended. On the other hand if the distinction is clear even with a small amount of samples, then a small min_resources may be preferable since it would speed up the computation.

Notice in the example above that the last iteration does not use the maximum amount of resources available: 1000 samples are available, yet only 640 are used, at most. By default, both HalvingRandomSearchCV and HalvingGridSearchCV try to use as many resources as possible in the last iteration, with the constraint that this amount of resources must be a multiple of both min_resources and factor (this constraint will be clear in the next section). HalvingRandomSearchCV achieves this by sampling the right amount of candidates, while HalvingGridSearchCV achieves this by properly setting min_resources. Please see Exhausting the available resources for details.
Amount of resource and number of candidates at each iteration

At any iteration \( i \), each candidate is allocated a given amount of resources which we denote \( n_{\text{resources}_i} \). This quantity is controlled by the parameters \( \text{factor} \) and \( \text{min\_resources} \) as follows (\( \text{factor} \) is strictly greater than 1):

\[
n_{\text{resources}_i} = \text{factor}^i \times \text{min\_resources},
\]

or equivalently:

\[
n_{\text{resources}_{i+1}} = n_{\text{resources}_i} \times \text{factor}
\]

where \( \text{min\_resources} = n_{\text{resources}_0} \) is the amount of resources used at the first iteration. \( \text{factor} \) also defines the proportions of candidates that will be selected for the next iteration:

\[
n_{\text{candidates}_i} = \frac{n_{\text{candidates}}}{(\text{factor}^i)}
\]

or equivalently:

\[
n_{\text{candidates}_0} = n_{\text{candidates}}
n_{\text{candidates}_{i+1}} = \frac{n_{\text{candidates}_i}}{\text{factor}}
\]

So in the first iteration, we use \( \text{min\_resources} \) resources \( n_{\text{candidates}} \) times. In the second iteration, we use \( \text{min\_resources} \times \text{factor} \) resources \( n_{\text{candidates}} \) times. The third again multiplies the resources per candidate and divides the number of candidates. This process stops when the maximum amount of resource per candidate is reached, or when we have identified the best candidate. The best candidate is identified at the iteration that is evaluating \( \text{factor} \) or less candidates (see just below for an explanation).

Here is an example with \( \text{min\_resources}=3 \) and \( \text{factor}=2 \), starting with 70 candidates:

<table>
<thead>
<tr>
<th>( n_{\text{resources}_i} )</th>
<th>( n_{\text{candidates}_i} )</th>
</tr>
</thead>
<tbody>
<tr>
<td>3 (=min_resources)</td>
<td>70 (=n_candidates)</td>
</tr>
<tr>
<td>3 \times 2 = 6</td>
<td>70 \div 2 = 35</td>
</tr>
<tr>
<td>6 \times 2 = 12</td>
<td>35 \div 2 = 17</td>
</tr>
<tr>
<td>12 \times 2 = 24</td>
<td>17 \div 2 = 8</td>
</tr>
<tr>
<td>24 \times 2 = 48</td>
<td>8 \div 2 = 4</td>
</tr>
<tr>
<td>48 \times 2 = 96</td>
<td>4 \div 2 = 2</td>
</tr>
</tbody>
</table>

We can note that:

- the process stops at the first iteration which evaluates \( \text{factor}=2 \) candidates: the best candidate is the best out of these 2 candidates. It is not necessary to run an additional iteration, since it would only evaluate one candidate (namely the best one, which we have already identified). For this reason, in general, we want the last iteration to run at most \( \text{factor} \) candidates. If the last iteration evaluates more than \( \text{factor} \) candidates, then this last iteration reduces to a regular search (as in \text{RandomizedSearchCV} or \text{GridSearchCV}).
- each \( n_{\text{resources}_i} \) is a multiple of both \( \text{factor} \) and \( \text{min\_resources} \) (which is confirmed by its definition above).

The amount of resources that is used at each iteration can be found in the \( n_{\text{resources}_i} \) attribute.
Choosing a resource

By default, the resource is defined in terms of number of samples. That is, each iteration will use an increasing amount of samples to train on. You can however manually specify a parameter to use as the resource with the `resource` parameter. Here is an example where the resource is defined in terms of the number of estimators of a random forest:

```python
>>> from sklearn.datasets import make_classification
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.experimental import enable_halving_search_cv  # noqa
>>> from sklearn.model_selection import HalvingGridSearchCV
>>> import pandas as pd

>>> param_grid = {'max_depth': [3, 5, 10],
    ...     'min_samples_split': [2, 5, 10]}
>>> base_estimator = RandomForestClassifier(random_state=0)
>>> X, y = make_classification(n_samples=1000, random_state=0)
>>> sh = HalvingGridSearchCV(base_estimator, param_grid, cv=5,
    ...     factor=2, resource='n_estimators',
    ...     max_resources=30).fit(X, y)
>>> sh.best_estimator_
RandomForestClassifier(max_depth=5, n_estimators=24, random_state=0)
```

Note that it is not possible to budget on a parameter that is part of the parameter grid.

Exhausting the available resources

As mentioned above, the number of resources that is used at each iteration depends on the `min_resources` parameter. If you have a lot of resources available but start with a low number of resources, some of them might be wasted (i.e. not used):

```python
>>> from sklearn.datasets import make_classification
>>> from sklearn.svm import SVC
>>> from sklearn.experimental import enable_halving_search_cv  # noqa
>>> from sklearn.model_selection import HalvingGridSearchCV
>>> import pandas as pd

>>> param_grid = {'kernel': ('linear', 'rbf'),
    ...     'C': [1, 10, 100]}
>>> base_estimator = SVC(gamma='scale')
>>> X, y = make_classification(n_samples=1000)
>>> sh = HalvingGridSearchCV(base_estimator, param_grid, cv=5,
    ...     factor=2, min_resources=20).fit(X, y)
>>> sh.n_resources_
[20, 40, 80]
```

The search process will only use 80 resources at most, while our maximum amount of available resources is `n_samples=1000`. Here, we have `min_resources = r_0 = 20`.

For `HalvingGridSearchCV`, by default, the `min_resources` parameter is set to ‘exhaust’. This means that `min_resources` is automatically set such that the last iteration can use as many resources as possible, within the `max_resources` limit:

```python
>>> sh = HalvingGridSearchCV(base_estimator, param_grid, cv=5,
    ...     factor=2, min_resources='exhaust').fit(X, y)
>>> sh.n_resources_
[250, 500, 1000]
```
min_resources was here automatically set to 250, which results in the last iteration using all the resources. The exact value that is used depends on the number of candidate parameter, on max_resources and on factor.

For HalvingRandomSearchCV, exhausting the resources can be done in 2 ways:

- by setting min_resources='exhaust', just like for HalvingGridSearchCV;
- by setting n_candidates='exhaust'.

Both options are mutually exclusive: using min_resources='exhaust' requires knowing the number of candidates, and symmetrically n_candidates='exhaust' requires knowing min_resources.

In general, exhausting the total number of resources leads to a better final candidate parameter, and is slightly more time-intensive.

**Aggressive elimination of candidates**

Ideally, we want the last iteration to evaluate factor candidates (see Amount of resource and number of candidates at each iteration). We then just have to pick the best one. When the number of available resources is small with respect to the number of candidates, the last iteration may have to evaluate more than factor candidates:

```python
>>> from sklearn.datasets import make_classification
>>> from sklearn.svm import SVC
>>> from sklearn.experimental import enable_halving_search_cv  # noqa
>>> from sklearn.model_selection import HalvingGridSearchCV
>>> import pandas as pd

>>> param_grid = {'kernel': ('linear', 'rbf'), 'C': [1, 10, 100]}
>>> base_estimator = SVC(gamma='scale')
>>> X, y = make_classification(n_samples=1000)
>>> sh = HalvingGridSearchCV(base_estimator, param_grid, cv=5, factor=2, max_resources=40, aggressive_elimination=False).fit(X, y)
>>> sh.n_resources_
[20, 40]
>>> sh.n_candidates_
[6, 3]
```

Since we cannot use more than max_resources=40 resources, the process has to stop at the second iteration which evaluates more than factor=2 candidates.

Using the aggressive_elimination parameter, you can force the search process to end up with less than factor candidates at the last iteration. To do this, the process will eliminate as many candidates as necessary using min_resources resources:

```python
>>> sh = HalvingGridSearchCV(base_estimator, param_grid, cv=5, factor=2, max_resources=40, aggressive_elimination=True).fit(X, y)
>>> sh.n_resources_
[20, 20, 40]
>>> sh.n_candidates_
[6, 3, 2]
```

Notice that we end with 2 candidates at the last iteration since we have eliminated enough candidates during the first iterations, using n_resources = min_resources = 20.
Analysing results with the cv_results_ attribute

The cv_results_ attribute contains useful information for analysing the results of a search. It can be converted to a pandas dataframe with df = pd.DataFrame(est.cv_results_). The cv_results_ attribute of HalvingGridSearchCV and HalvingRandomSearchCV is similar to that of GridSearchCV and RandomizedSearchCV, with additional information related to the successive halving process.

Here is an example with some of the columns of a (truncated) dataframe:

<table>
<thead>
<tr>
<th>iter</th>
<th>n_resources</th>
<th>mean_test_score</th>
<th>params</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>0.983667</td>
<td>{'criterion': 'entropy', 'max_depth': None, 'max_features': 9, 'min_samples_split': 5}</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
<td>0.983667</td>
<td>{'criterion': 'gini', 'max_depth': None, 'max_features': 8, 'min_samples_split': 7}</td>
</tr>
<tr>
<td>2</td>
<td>0</td>
<td>0.983667</td>
<td>{'criterion': 'gini', 'max_depth': None, 'max_features': 10, 'min_samples_split': 10}</td>
</tr>
<tr>
<td>3</td>
<td>0</td>
<td>0.983667</td>
<td>{'criterion': 'entropy', 'max_depth': None, 'max_features': 6, 'min_samples_split': 6}</td>
</tr>
<tr>
<td>...</td>
<td>...</td>
<td>...</td>
<td>...</td>
</tr>
<tr>
<td>15</td>
<td>2</td>
<td>0.951958</td>
<td>{'criterion': 'entropy', 'max_depth': None, 'max_features': 9, 'min_samples_split': 10}</td>
</tr>
<tr>
<td>16</td>
<td>2</td>
<td>0.947958</td>
<td>{'criterion': 'gini', 'max_depth': None, 'max_features': 10, 'min_samples_split': 10}</td>
</tr>
<tr>
<td>17</td>
<td>2</td>
<td>0.951958</td>
<td>{'criterion': 'gini', 'max_depth': None, 'max_features': 10, 'min_samples_split': 4}</td>
</tr>
<tr>
<td>18</td>
<td>3</td>
<td>0.961009</td>
<td>{'criterion': 'entropy', 'max_depth': None, 'max_features': 9, 'min_samples_split': 10}</td>
</tr>
<tr>
<td>19</td>
<td>3</td>
<td>0.955989</td>
<td>{'criterion': 'gini', 'max_depth': None, 'max_features': 10, 'min_samples_split': 4}</td>
</tr>
</tbody>
</table>

Each row corresponds to a given parameter combination (a candidate) and a given iteration. The iteration is given by the iter column. The n_resources column tells you how many resources were used.

In the example above, the best parameter combination is {'criterion': 'entropy', 'max_depth': None, 'max_features': 9, 'min_samples_split': 10} since it has reached the last iteration (3) with the highest score: 0.96.

Tips for parameter search

Specifying an objective metric

By default, parameter search uses the score function of the estimator to evaluate a parameter setting. These are the sklearn.metrics.accuracy_score for classification and sklearn.metrics.r2_score for regression. For some applications, other scoring functions are better suited (for example in unbalanced classification, the accuracy score is often uninformative). An alternative scoring function can be specified via the scoring parameter of most parameter search tools. See The scoring parameter: defining model evaluation rules for more details.
Specifying multiple metrics for evaluation

`GridSearchCV` and `RandomizedSearchCV` allow specifying multiple metrics for the `scoring` parameter.

Multimetric scoring can either be specified as a list of strings of predefined scores names or a dict mapping the scorer name to the scorer function and/or the predefined scorer name(s). See `Using multiple metric evaluation` for more details.

When specifying multiple metrics, the `refit` parameter must be set to the metric (string) for which the `best_params_` will be found and used to build the `best_estimator_` on the whole dataset. If the search should not be refit, set `refit=False`. Leaving refit to the default value `None` will result in an error when using multiple metrics.

See `Demonstration of multi-metric evaluation on cross_val_score and GridSearchCV` for an example usage.

`HalvingRandomSearchCV` and `HalvingGridSearchCV` do not support multimetric scoring.

Composite estimators and parameter spaces

`GridSearchCV` and `RandomizedSearchCV` allow searching over parameters of composite or nested estimators such as `Pipeline`, `ColumnTransformer`, `VotingClassifier` or `CalibratedClassifierCV` using a dedicated `<estimator>__<parameter>` syntax:

```python
>>> from sklearn.model_selection import GridSearchCV
>>> from sklearn.calibration import CalibratedClassifierCV
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.datasets import make_moons

>>> X, y = make_moons()

>>> calibrated_forest = CalibratedClassifierCV(
...    base_estimator=RandomForestClassifier(n_estimators=10))

>>> param_grid = {
...    'base_estimator__max_depth': [2, 4, 6, 8]
...}

>>> search = GridSearchCV(calibrated_forest, param_grid, cv=5)

>>> search.fit(X, y)

GridSearchCV(cv=5,
            estimator=CalibratedClassifierCV(...),
            param_grid={'base_estimator__max_depth': [2, 4, 6, 8]})
```

Here, `<estimator>` is the parameter name of the nested estimator, in this case `base_estimator`. If the meta-estimator is constructed as a collection of estimators as in `pipeline.Pipeline`, then `<estimator>` refers to the name of the estimator, see `Nested parameters`. In practice, there can be several levels of nesting:

```python
>>> from sklearn.pipeline import Pipeline
>>> from sklearn.feature_selection import SelectKBest

>>> pipe = Pipeline([
...    ('select', SelectKBest()),
...    ('model', calibrated_forest)])

>>> param_grid = {
...    'select__k': [1, 2],
...    'model__base_estimator__max_depth': [2, 4, 6, 8]}

>>> search = GridSearchCV(pipe, param_grid, cv=5).fit(X, y)
```

Please refer to `Pipeline: chaining estimators` for performing parameter searches over pipelines.
Model selection: development and evaluation

Model selection by evaluating various parameter settings can be seen as a way to use the labeled data to “train” the parameters of the grid.

When evaluating the resulting model it is important to do it on held-out samples that were not seen during the grid search process: it is recommended to split the data into a development set (to be fed to the `GridSearchCV` instance) and an evaluation set to compute performance metrics.

This can be done by using the `train_test_split` utility function.

Parallelism

The parameter search tools evaluate each parameter combination on each data fold independently. Computations can be run in parallel by using the keyword `n_jobs=-1`. See function signature for more details, and also the Glossary entry for `n_jobs`.

Robustness to failure

Some parameter settings may result in a failure to fit one or more folds of the data. By default, this will cause the entire search to fail, even if some parameter settings could be fully evaluated. Setting `error_score=0` (or `=np.NaN`) will make the procedure robust to such failure, issuing a warning and setting the score for that fold to 0 (or `NaN`), but completing the search.

Alternatives to brute force parameter search

Model specific cross-validation

Some models can fit data for a range of values of some parameter almost as efficiently as fitting the estimator for a single value of the parameter. This feature can be leveraged to perform a more efficient cross-validation used for model selection of this parameter.

The most common parameter amenable to this strategy is the parameter encoding the strength of the regularizer. In this case we say that we compute the regularization path of the estimator.

Here is the list of such models:

- `linear_model.LarsCV(**kwargs)` Cross-validated Least Angle Regression model.
- `linear_model.LassoCV(**kwargs)` Lasso linear model with iterative fitting along a regularization path.
- `linear_model.LassoLarsCV(**kwargs)` Cross-validated Lasso, using the LARS algorithm.
- `linear_model.LogisticRegressionCV(**kwargs)` Logistic Regression CV (aka logit, MaxEnt) classifier.
- `linear_model.MultiTaskLassoCV(**kwargs)` Multi-task Lasso model trained with L1/L2 mixed-norm as regularizer.

continues on next page
Information Criterion

Some models can offer an information-theoretic closed-form formula of the optimal estimate of the regularization parameter by computing a single regularization path (instead of several when using cross-validation).

Here is the list of models benefiting from the Akaike Information Criterion (AIC) or the Bayesian Information Criterion (BIC) for automated model selection:

<table>
<thead>
<tr>
<th>Model Class</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>linear_model.LassoLarsIC(**kwargs)</code></td>
<td>Lasso model fit with Lars using BIC or AIC for model selection</td>
</tr>
</tbody>
</table>

Out of Bag Estimates

When using ensemble methods base upon bagging, i.e. generating new training sets using sampling with replacement, part of the training set remains unused. For each classifier in the ensemble, a different part of the training set is left out.

This left out portion can be used to estimate the generalization error without having to rely on a separate validation set. This estimate comes “for free” as no additional data is needed and can be used for model selection.

This is currently implemented in the following classes:

<table>
<thead>
<tr>
<th>Model Class</th>

<td>Gradient Boosting for regression.</td>
</tr>
</tbody>
</table>

4.3.3 Metrics and scoring: quantifying the quality of predictions

There are 3 different APIs for evaluating the quality of a model’s predictions:

- **Estimator score method**: Estimators have a `score` method providing a default evaluation criterion for the problem they are designed to solve. This is not discussed on this page, but in each estimator’s documentation.

- **Scoring parameter**: Model-evaluation tools using `cross-validation` (such as `model_selection.cross_val_score` and `model_selection.GridSearchCV`) rely on an internal `scoring` strategy. This is discussed in the section *The scoring parameter: defining model evaluation rules*.

- **Metric functions**: The `sklearn.metrics` module implements functions assessing prediction error for specific purposes. These metrics are detailed in sections on *Classification metrics*, *Multilabel ranking metrics*, *Regression metrics* and *Clustering metrics*.

Finally, *Dummy estimators* are useful to get a baseline value of those metrics for random predictions.

See also:

For “pairwise” metrics, between *samples* and not estimators or predictions, see the *Pairwise metrics, Affinities and Kernels* section.
The **scoring** parameter: defining model evaluation rules

Model selection and evaluation using tools, such as `model_selection.GridSearchCV` and `model_selection.cross_val_score`, take a `scoring` parameter that controls what metric they apply to the estimators evaluated.

**Common cases: predefined values**

For the most common use cases, you can designate a scorer object with the `scoring` parameter; the table below shows all possible values. All scorer objects follow the convention that **higher return values are better than lower return values**. Thus metrics which measure the distance between the model and the data, like `metrics.mean_squared_error`, are available as `neg_mean_squared_error` which return the negated value of the metric.

Usage examples:

```python
tests = from sklearn import svm, datasets
tests from sklearn.model_selection import cross_val_score
tests X, y = datasets.load_iris(return_X_y=True)
tests clf = svm.SVC(random_state=0)
tests cross_val_score(clf, X, y, cv=5, scoring='recall_macro')
array([0.96..., 0.96..., 0.96..., 0.93..., 1.])
tests model = svm.SVC()
tests cross_val_score(model, X, y, cv=5, scoring='wrong_choice')
Traceback (most recent call last):
ValueError: 'wrong_choice' is not a valid scoring value. Use sorted(sklearn.metrics._SCORERS.keys()) to get valid options.
```

Note: The values listed by the ValueError exception correspond to the functions measuring prediction accuracy described in the following sections. The scorer objects for those functions are stored in the dictionary sklearn.metrics.SCORERS.

Defining your scoring strategy from metric functions

The module sklearn.metrics also exposes a set of simple functions measuring a prediction error given ground truth and prediction:

- functions ending with _score return a value to maximize, the higher the better.
- functions ending with _error or _loss return a value to minimize, the lower the better. When converting into a scorer object using make_scorer, set the greater_is_better parameter to False (True by default; see the parameter description below).

Metrics available for various machine learning tasks are detailed in sections below.

Many metrics are not given names to be used as scoring values, sometimes because they require additional parameters, such as fbeta_score. In such cases, you need to generate an appropriate scoring object. The simplest way to generate a callable object for scoring is by using make_scorer. That function converts metrics into callables that can be used for model evaluation.

One typical use case is to wrap an existing metric function from the library with non-default values for its parameters, such as the beta parameter for the fbeta_score function:

```python
tests from sklearn.metrics import fbeta_score, make_scorer
tests ftwo_scorer = make_scorer(fbeta_score, beta=2)
tests from sklearn.model_selection import GridSearchCV
tests from sklearn.svm import LinearSVC
tests grid = GridSearchCV(LinearSVC(), param_grid={'C': [1, 10]},...
                          scoring=ftwo_scorer, cv=5)
```
• the python function you want to use (my_custom_loss_func in the example below)

• whether the python function returns a score (greater_is_better=True, the default) or a loss (greater_is_better=False). If a loss, the output of the python function is negated by the scorer object, conforming to the cross validation convention that scorers return higher values for better models.

• for classification metrics only: whether the python function you provided requires continuous decision certain-
ties (needs_threshold=True). The default value is False.

• any additional parameters, such as beta or labels in f1_score.

Here is an example of building custom scorers, and of using the greater_is_better parameter:

```python
>>> import numpy as np
>>> def my_custom_loss_func(y_true, y_pred):
...     diff = np.abs(y_true - y_pred).max()
...     return np.log1p(diff)
... # score will negate the return value of my_custom_loss_func,
# which will be np.log(2), 0.693, given the values for X
# and y defined below.
>>> score = make_scorer(my_custom_loss_func, greater_is_better=False)
>>> X = [[1], [1]]
>>> y = [0, 1]
>>> from sklearn.dummy import DummyClassifier
>>> clf = DummyClassifier(strategy='most_frequent', random_state=0)
>>> clf = clf.fit(X, y)
>>> my_custom_loss_func(y, clf.predict(X))
0.69...
>>> score(clf, X, y)
-0.69...
```

**Implementing your own scoring object**

You can generate even more flexible model scorers by constructing your own scoring object from scratch, without using the make_scorer factory. For a callable to be a scorer, it needs to meet the protocol specified by the following two rules:

• It can be called with parameters (estimator, X, y), where estimator is the model that should be evaluated, X is validation data, and y is the ground truth target for X (in the supervised case) or None (in the unsupervised case).

• It returns a floating point number that quantifies the estimator prediction quality on X, with reference to y. Again, by convention higher numbers are better, so if your scorer returns loss, that value should be negated.

**Note: Using custom scorers in functions where n_jobs > 1**

While defining the custom scoring function alongside the calling function should work out of the box with the default joblib backend (loky), importing it from another module will be a more robust approach and work independently of the joblib backend.

For example, to use n_jobs greater than 1 in the example below, custom_scoring_function function is saved in a user-created module (custom_scorer_module.py) and imported:

```python
>>> from custom_scorer_module import custom_scoring_function
>>> cross_val_score(model,
...                 X_train,
...                 ...)
... y_train,
... scoring=make_scorer(custom_scoring_function, greater_is_better=False),
... cv=5,
... n_jobs=-1)

Using multiple metric evaluation

Scikit-learn also permits evaluation of multiple metrics in GridSearchCV, RandomizedSearchCV and cross_validate.

There are three ways to specify multiple scoring metrics for the scoring parameter:

- As an iterable of string metrics:

  ```python
  >>> scoring = ['accuracy', 'precision']
  ```

- As a dict mapping the scorer name to the scoring function:

  ```python
  >>> from sklearn.metrics import accuracy_score
  >>> from sklearn.metrics import make_scorer
  >>> scoring = {'accuracy': make_scorer(accuracy_score),
  ...            'prec': 'precision'}
  ```

  Note that the dict values can either be scorer functions or one of the predefined metric strings.

- As a callable that returns a dictionary of scores:

  ```python
  >>> from sklearn.model_selection import cross_validate
  >>> from sklearn.metrics import confusion_matrix
  >>> # A sample toy binary classification dataset
  >>> X, y = datasets.make_classification(n_classes=2, random_state=0)
  >>> svm = LinearSVC(random_state=0)
  >>> def confusion_matrix_scorer(clf, X, y):
  ...     y_pred = clf.predict(X)
  ...     cm = confusion_matrix(y, y_pred)
  ...     return {'tn': cm[0, 0], 'fp': cm[0, 1],
  ...             'fn': cm[1, 0], 'tp': cm[1, 1]}
  >>> cv_results = cross_validate(svm, X, y, cv=5,
  ...                              scoring=confusion_matrix_scorer)
  >>> # Getting the test set true positive scores
  >>> print(cv_results['test_tp'])
  [10  9  8  7  8]
  >>> # Getting the test set false negative scores
  >>> print(cv_results['test_fn'])
  [0  1  2  3  2]
Classification metrics

The `sklearn.metrics` module implements several loss, score, and utility functions to measure classification performance. Some metrics might require probability estimates of the positive class, confidence values, or binary decisions values. Most implementations allow each sample to provide a weighted contribution to the overall score, through the `sample_weight` parameter.

Some of these are restricted to the binary classification case:

- `precision_recall_curve(y_true, probas_pred, *args)`
  - Compute precision-recall pairs for different probability thresholds.
- `roc_curve(y_true, y_score, *[, pos_label, ...])`
  - Compute Receiver operating characteristic (ROC).
- `det_curve(y_true, y_score, *[, pos_label, ...])`
  - Compute error rates for different probability thresholds.

Others also work in the multiclass case:

- `balanced_accuracy_score(y_true, y_pred, *[, ...])`
  - Compute the balanced accuracy.
- `cohen_kappa_score(y1, y2, *[, labels, ...])`
  - Cohen's kappa: a statistic that measures inter-annotator agreement.
- `confusion_matrix(y_true, y_pred, *[, ...])`
  - Compute confusion matrix to evaluate the accuracy of a classification.
- `hinge_loss(y_true, pred_decision, *[, ...])`
  - Average hinge loss (non-regularized).
- `matthews_corrcoef(y_true, y_pred, *[, ...])`
  - Compute the Matthews correlation coefficient (MCC).
- `roc_auc_score(y_true, y_score, *[, average, ...])`
  - Compute Area Under the Receiver Operating Characteristic Curve (ROC AUC) from prediction scores.

Some also work in the multilabel case:

- `accuracy_score(y_true, y_pred, *[, ...])`
  - Accuracy classification score.
- `classification_report(y_true, y_pred, *[, ...])`
  - Build a text report showing the main classification metrics.
- `f1_score(y_true, y_pred, *[, labels, ...])`
  - Compute the F1 score, also known as balanced F-score or F-measure.
- `fbeta_score(y_true, y_pred, *, beta[, ...])`
  - Compute the F-beta score.
- `hamming_loss(y_true, y_pred, *[, sample_weight])`
  - Compute the average Hamming loss.
- `jaccard_score(y_true, y_pred, *[, labels, ...])`
  - Jaccard similarity coefficient score.
- `log_loss(y_true, y_pred, *[, eps, ...])`
  - Log loss, aka logistic loss or cross-entropy loss.
- `multilabel_confusion_matrix(y_true, y_pred, *[, ...])`
  - Compute a confusion matrix for each class or sample.
- `precision_recall_fscore_support(y_true, ...)`
  - Compute precision, recall, F-measure and support for each class.
- `precision_score(y_true, y_pred, *[, labels, ...])`
  - Compute the precision.
- `recall_score(y_true, y_pred, *[, labels, ...])`
  - Compute the recall.
- `roc_auc_score(y_true, y_score, *[, average, ...])`
  - Compute Area Under the Receiver Operating Characteristic Curve (ROC AUC) from prediction scores.
- `zero_one_loss(y_true, y_pred, *[, ...])`
  - Zero-one classification loss.

And some work with binary and multilabel (but not multiclass) problems:
average_precision_score(y_true, y_score, *) Compute average precision (AP) from prediction scores.

In the following sub-sections, we will describe each of those functions, preceded by some notes on common API and metric definition.

From binary to multiclass and multilabel

Some metrics are essentially defined for binary classification tasks (e.g. f1_score, roc_auc_score). In these cases, by default only the positive label is evaluated, assuming by default that the positive class is labelled 1 (though this may be configurable through the pos_label parameter).

In extending a binary metric to multiclass or multilabel problems, the data is treated as a collection of binary problems, one for each class. There are then a number of ways to average binary metric calculations across the set of classes, each of which may be useful in some scenario. Where available, you should select among these using the average parameter.

- "macro" simply calculates the mean of the binary metrics, giving equal weight to each class. In problems where infrequent classes are nonetheless important, macro-averaging may be a means of highlighting their performance. On the other hand, the assumption that all classes are equally important is often untrue, such that macro-averaging will over-emphasize the typically low performance on an infrequent class.
- "weighted" accounts for class imbalance by computing the average of binary metrics in which each class's score is weighted by its presence in the true data sample.
- "micro" gives each sample-class pair an equal contribution to the overall metric (except as a result of sample-weight). Rather than summing the metric per class, this sums the dividends and divisors that make up the per-class metrics to calculate an overall quotient. Micro-averaging may be preferred in multilabel settings, including multiclass classification where a majority class is to be ignored.
- "samples" applies only to multilabel problems. It does not calculate a per-class measure, instead calculating the metric over the true and predicted classes for each sample in the evaluation data, and returning their (sample_weight-weighted) average.
- Selecting average=None will return an array with the score for each class.

While multiclass data is provided to the metric, like binary targets, as an array of class labels, multilabel data is specified as an indicator matrix, in which cell \[i, j\] has value 1 if sample \(i\) has label \(j\) and value 0 otherwise.

Accuracy score

The accuracy_score function computes the accuracy, either the fraction (default) or the count (normalize=False) of correct predictions.

In multilabel classification, the function returns the subset accuracy. If the entire set of predicted labels for a sample strictly match with the true set of labels, then the subset accuracy is 1.0; otherwise it is 0.0.

If \(\hat{y}_i\) is the predicted value of the \(i\)-th sample and \(y_i\) is the corresponding true value, then the fraction of correct predictions over \(n_{\text{samples}}\), is defined as

\[
\text{accuracy}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} 1(\hat{y}_i = y_i)
\]

where \(1(x)\) is the indicator function.
In the multilabel case with binary label indicators:

```python
>>> accuracy_score(np.array([[0, 1], [1, 1]]), np.ones((2, 2)))
0.5
```

Example:

- See *Test with permutations the significance of a classification score* for an example of accuracy score usage using permutations of the dataset.

**Balanced accuracy score**

The `balanced_accuracy_score` function computes the balanced accuracy, which avoids inflated performance estimates on imbalanced datasets. It is the macro-average of recall scores per class or, equivalently, raw accuracy where each sample is weighted according to the inverse prevalence of its true class. Thus for balanced datasets, the score is equal to accuracy.

In the binary case, balanced accuracy is equal to the arithmetic mean of sensitivity (true positive rate) and specificity (true negative rate), or the area under the ROC curve with binary predictions rather than scores:

\[
\text{balanced-accuracy} = \frac{1}{2} \left( \frac{TP}{TP + FN} + \frac{TN}{TN + FP} \right)
\]

If the classifier performs equally well on either class, this term reduces to the conventional accuracy (i.e., the number of correct predictions divided by the total number of predictions).

In contrast, if the conventional accuracy is above chance only because the classifier takes advantage of an imbalanced test set, then the balanced accuracy, as appropriate, will drop to \( \frac{1}{n_{\text{classes}}} \).

The score ranges from 0 to 1, or when `adjusted=True` is used, it rescaled to the range \( \frac{1}{1-n_{\text{classes}}} \) to 1, inclusive, with performance at random scoring 0.

If \( y_i \) is the true value of the \( i \)-th sample, and \( w_i \) is the corresponding sample weight, then we adjust the sample weight to:

\[
\hat{w}_i = \frac{w_i}{\sum_j 1(y_j = y_i)w_j}
\]

where \( 1(x) \) is the indicator function. Given predicted \( \hat{y}_i \) for sample \( i \), balanced accuracy is defined as:

\[
\text{balanced-accuracy}(y, \hat{y}, w) = \frac{1}{\hat{w}_i} \sum_i 1(\hat{y}_i = y_i)\hat{w}_i
\]

With `adjusted=True`, balanced accuracy reports the relative increase from \( \text{balanced-accuracy}(y, 0, w) = \frac{1}{n_{\text{classes}}} \). In the binary case, this is also known as *Youden’s J statistic*, or *informedness*.  

4.3. Model selection and evaluation
Note: The multiclass definition here seems the most reasonable extension of the metric used in binary classification, though there is no certain consensus in the literature:

- Our definition: [Mosley2013], [Kelleher2015] and [Guyon2015], where [Guyon2015] adopt the adjusted version to ensure that random predictions have a score of 0 and perfect predictions have a score of 1.

- Class balanced accuracy as described in [Mosley2013]: the minimum between the precision and the recall for each class is computed. Those values are then averaged over the total number of classes to get the balanced accuracy.

- Balanced Accuracy as described in [Urbanowicz2015]: the average of sensitivity and specificity is computed for each class and then averaged over total number of classes.

References:

Cohen’s kappa

The function `cohen_kappa_score` computes Cohen’s kappa statistic. This measure is intended to compare labelings by different human annotators, not a classifier versus a ground truth.

The kappa score (see docstring) is a number between -1 and 1. Scores above .8 are generally considered good agreement; zero or lower means no agreement (practically random labels).

Kappa scores can be computed for binary or multiclass problems, but not for multilabel problems (except by manually computing a per-label score) and not for more than two annotators.

```python
>>> from sklearn.metrics import cohen_kappa_score
>>> y_true = [2, 0, 2, 2, 0, 1]
>>> y_pred = [0, 0, 2, 2, 0, 2]
>>> cohen_kappa_score(y_true, y_pred)
0.4285714285714286
```

Confusion matrix

The `confusion_matrix` function evaluates classification accuracy by computing the confusion matrix with each row corresponding to the true class (Wikipedia and other references may use different convention for axes).

By definition, entry $i,j$ in a confusion matrix is the number of observations actually in group $i$, but predicted to be in group $j$. Here is an example:

```python
>>> from sklearn.metrics import confusion_matrix
>>> y_true = [2, 0, 2, 2, 0, 1]
>>> y_pred = [0, 0, 2, 2, 0, 2]
>>> confusion_matrix(y_true, y_pred)
array([[2, 0, 0],
       [0, 0, 1],
       [1, 0, 2]])
```

`plot_confusion_matrix` can be used to visually represent a confusion matrix as shown in the Confusion matrix example, which creates the following figure:
The parameter `normalize` allows to report ratios instead of counts. The confusion matrix can be normalized in 3 different ways: 'pred', 'true', and 'all' which will divide the counts by the sum of each columns, rows, or the entire matrix, respectively.

```python
>>> y_true = [0, 0, 0, 1, 1, 1, 1, 1]
>>> y_pred = [0, 1, 0, 1, 0, 1, 0, 1]
>>> confusion_matrix(y_true, y_pred, normalize='all')
array([[0.25 , 0.125],
       [0.25 , 0.375]])
```

For binary problems, we can get counts of true negatives, false positives, false negatives and true positives as follows:

```python
>>> y_true = [0, 0, 0, 1, 1, 1, 1, 1]
>>> y_pred = [0, 1, 0, 1, 0, 1, 0, 1]
>>> tn, fp, fn, tp = confusion_matrix(y_true, y_pred).ravel()
>>> tn, fp, fn, tp
(2, 1, 2, 3)
```

**Example:**

- See [Confusion matrix](#) for an example of using a confusion matrix to evaluate classifier output quality.
- See [Recognizing hand-written digits](#) for an example of using a confusion matrix to classify hand-written digits.
- See [Classification of text documents using sparse features](#) for an example of using a confusion matrix to classify text documents.
Classification report

The `classification_report` function builds a text report showing the main classification metrics. Here is a small example with custom `target_names` and inferred labels:

```python
>>> from sklearn.metrics import classification_report

>>> y_true = [0, 1, 2, 2, 0]
>>> y_pred = [0, 0, 2, 1, 0]
>>> target_names = ['class 0', 'class 1', 'class 2']
>>> print(classification_report(y_true, y_pred, target_names=target_names))

<table>
<thead>
<tr>
<th>class</th>
<th>precision</th>
<th>recall</th>
<th>f1-score</th>
<th>support</th>
</tr>
</thead>
<tbody>
<tr>
<td>class 0</td>
<td>0.67</td>
<td>1.00</td>
<td>0.80</td>
<td>2</td>
</tr>
<tr>
<td>class 1</td>
<td>0.00</td>
<td>0.00</td>
<td>0.00</td>
<td>1</td>
</tr>
<tr>
<td>class 2</td>
<td>1.00</td>
<td>0.50</td>
<td>0.67</td>
<td>2</td>
</tr>
</tbody>
</table>

accuracy 0.60 | 5

macro avg 0.56 | 0.50 | 0.49 | 5

weighted avg 0.67 | 0.60 | 0.59 | 5
```

Example:

- See [Recognizing hand-written digits](#) for an example of classification report usage for hand-written digits.
- See [Classification of text documents using sparse features](#) for an example of classification report usage for text documents.
- See [Parameter estimation using grid search with cross-validation](#) for an example of classification report usage for grid search with nested cross-validation.

Hamming loss

The `hamming_loss` computes the average Hamming loss or Hamming distance between two sets of samples. If $\hat{y}_j$ is the predicted value for the $j$-th label of a given sample, $y_j$ is the corresponding true value, and $n\text{labels}$ is the number of classes or labels, then the Hamming loss $L_{Hamming}$ between two samples is defined as:

$$L_{Hamming}(y, \hat{y}) = \frac{1}{n\text{labels}} \sum_{j=0}^{n\text{labels}-1} 1(\hat{y}_j \neq y_j)$$

where $1(x)$ is the indicator function.

```python
>>> from sklearn.metrics import hamming_loss

>>> y_pred = [1, 2, 3, 4]
>>> y_true = [2, 2, 3, 4]
>>> hamming_loss(y_true, y_pred)
0.25
```

In the multilabel case with binary label indicators:

```python
>>> hamming_loss(np.array([[0, 1], [1, 1]]), np.zeros((2, 2)))
0.75
```
Note: In multiclass classification, the Hamming loss corresponds to the Hamming distance between \( y_{true} \) and \( y_{pred} \) which is similar to the Zero one loss function. However, while zero-one loss penalizes prediction sets that do not strictly match true sets, the Hamming loss penalizes individual labels. Thus the Hamming loss, upper bounded by the zero-one loss, is always between zero and one, inclusive; and predicting a proper subset or superset of the true labels will give a Hamming loss between zero and one, exclusive.

Precision, recall and F-measures

Intuitively, precision is the ability of the classifier not to label as positive a sample that is negative, and recall is the ability of the classifier to find all the positive samples.

The F-measure \((F_\beta \text{ and } F_1 \text{ measures})\) can be interpreted as a weighted harmonic mean of the precision and recall. A \( F_\beta \) measure reaches its best value at 1 and its worst score at 0. With \( \beta = 1 \), \( F_\beta \) and \( F_1 \) are equivalent, and the recall and the precision are equally important.

The \texttt{precision\_recall\_curve} computes a precision-recall curve from the ground truth label and a score given by the classifier by varying a decision threshold.

The \texttt{average\_precision\_score} function computes the average precision (AP) from prediction scores. The value is between 0 and 1 and higher is better. AP is defined as

\[
AP = \sum_n (R_n - R_{n-1}) P_n
\]

where \( P_n \) and \( R_n \) are the precision and recall at the nth threshold. With random predictions, the AP is the fraction of positive samples.

 References [Manning2008] and [Everingham2010] present alternative variants of AP that interpolate the precision-recall curve. Currently, \texttt{average\_precision\_score} does not implement any interpolated variant. References [Davis2006] and [Flach2015] describe why a linear interpolation of points on the precision-recall curve provides an overly-optimistic measure of classifier performance. This linear interpolation is used when computing area under the curve with the trapezoidal rule in \texttt{auc}.

Several functions allow you to analyze the precision, recall and F-measures score:

<table>
<thead>
<tr>
<th>Function Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{average_precision_score(y, y_score, *)}</td>
<td>Compute average precision (AP) from prediction scores.</td>
</tr>
<tr>
<td>\texttt{f1_score(y, y_pred, *[, labels, ...])}</td>
<td>Compute the F1 score, also known as balanced F-score or F-measure.</td>
</tr>
<tr>
<td>\texttt{fbeta_score(y, y_pred, *[, beta[, ...])}</td>
<td>Compute the F-beta score.</td>
</tr>
<tr>
<td>\texttt{precision_recall_curve(y, probas_pred, *[, alpha, ...])}</td>
<td>Compute precision-recall pairs for different probability thresholds.</td>
</tr>
<tr>
<td>\texttt{precision_recall_f_score_support(y, probas_pred, *[, alpha, ...])}</td>
<td>Compute precision, recall, F-measure and support for each class.</td>
</tr>
<tr>
<td>\texttt{precision_score(y, y_pred, *[, labels, ...])}</td>
<td>Compute the precision.</td>
</tr>
<tr>
<td>\texttt{recall_score(y, y_pred, *[, labels, ...])}</td>
<td>Compute the recall.</td>
</tr>
</tbody>
</table>

Note that the \texttt{precision\_recall\_curve} function is restricted to the binary case. The \texttt{average\_precision\_score} function works only in binary classification and multilabel indicator format. The \texttt{plot\_precision\_recall\_curve} function plots the precision recall as follows.
Examples:

- See Classification of text documents using sparse features for an example of f1_score usage to classify text documents.
- See Parameter estimation using grid search with cross-validation for an example of precision_score and recall_score usage to estimate parameters using grid search with nested cross-validation.
- See Precision-Recall for an example of precision_recall_curve usage to evaluate classifier output quality.

References:

Binary classification

In a binary classification task, the terms “positive” and “negative” refer to the classifier’s prediction, and the terms “true” and “false” refer to whether that prediction corresponds to the external judgment (sometimes known as the “observation”). Given these definitions, we can formulate the following table:

<table>
<thead>
<tr>
<th>Predicted class (expectation)</th>
<th>Actual class (observation)</th>
</tr>
</thead>
<tbody>
<tr>
<td>tp (true positive) Correct result</td>
<td>tp (false positive) Unexpected result</td>
</tr>
<tr>
<td>fn (false negative) Missing result</td>
<td>tn (true negative) Correct absence of result</td>
</tr>
</tbody>
</table>

In this context, we can define the notions of precision, recall and F-measure:

\[
\text{precision} = \frac{tp}{tp + fp},
\]

\[
\text{recall} = \frac{tp}{tp + fn},
\]

\[
\text{F-measure} = \frac{2 \times \text{precision} \times \text{recall}}{\text{precision} + \text{recall}}.
\]
\[
\text{recall} = \frac{tp}{tp + fn},
\]

\[
F_\beta = \left(1 + \beta^2\right) \frac{\text{precision} \times \text{recall}}{\beta^2 \text{precision} + \text{recall}}.
\]

Here are some small examples in binary classification:

```python
>>> from sklearn import metrics
>>> y_pred = [0, 1, 0, 0]
>>> y_true = [0, 1, 0, 1]
>>> metrics.precision_score(y_true, y_pred)
1.0
>>> metrics.recall_score(y_true, y_pred)
0.5
>>> metrics.f1_score(y_true, y_pred)
0.66...
>>> metrics.fbeta_score(y_true, y_pred, beta=0.5)
0.83...
>>> metrics.fbeta_score(y_true, y_pred, beta=1)
0.66...
>>> metrics.fbeta_score(y_true, y_pred, beta=2)
0.55...
>>> metrics.precision_recall_fscore_support(y_true, y_pred, beta=0.5)
(array([0.66..., 1.]), array([1. , 0.5]), array([0.71..., 0.83...]), array([2, ˓→2]))
```

```python
>>> import numpy as np
>>> from sklearn.metrics import precision_recall_curve
>>> from sklearn.metrics import average_precision_score

>>> y_true = np.array([0, 0, 1, 1])
>>> y_scores = np.array([0.1, 0.4, 0.35, 0.8])

>>> precision, recall, threshold = precision_recall_curve(y_true, y_scores)
>>> precision
array([0.66..., 0.5 , 1. , 1. , 1. , 1. , 1. ])
>>> recall
array([1. , 0.5, 0.5, 0. , 0. , 0. , 0. ])
>>> threshold
array([0.35, 0.4 , 0.8 ])
>>> average_precision_score(y_true, y_scores)
0.83...
```

### Multiclass and multilabel classification

In multiclass and multilabel classification task, the notions of precision, recall, and F-measures can be applied to each label independently. There are a few ways to combine results across labels, specified by the `average` argument to the `average_precision_score` (multilabel only), `f1_score`, `fbeta_score`, `precision_recall_fscore_support`, `precision_score` and `recall_score` functions, as described above. Note that if all labels are included, “micro”-averaging in a multiclass setting will produce precision, recall and $F$ that are all identical to accuracy. Also note that “weighted” averaging may produce an $F$-score that is not between precision and recall.

To make this more explicit, consider the following notation:

- $y$ the set of predicted $(sample, label)$ pairs
- $\hat{y}$ the set of true $(sample, label)$ pairs

4.3. Model selection and evaluation
• $L$ the set of labels
• $S$ the set of samples
• $y_s$ the subset of $y$ with sample $s$, i.e. $y_s := \{(s', l) \in y | s' = s\}$
• $y_l$ the subset of $y$ with label $l$
• similarly, $\hat{y}_s$ and $\hat{y}_l$ are subsets of $\hat{y}$
• $P(A, B) := \frac{|A \cap B|}{|A|}$ for some sets $A$ and $B$
• $R(A, B) := \frac{|A \cap B|}{|B|}$ (Conventions vary on handling $B = \emptyset$; this implementation uses $R(A, B) := 0$, and similar for $P$.)
• $F_\beta(A, B) := \left(1 + \beta^2\right) \frac{P(A, B) \times R(A, B)}{P(A, B) + \beta^2 R(A, B)}$

Then the metrics are defined as:

<table>
<thead>
<tr>
<th>average</th>
<th>Precision</th>
<th>Recall</th>
<th>$F_\beta$</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;micro&quot;</td>
<td>$P(y, \hat{y})$</td>
<td>$R(y, \hat{y})$</td>

</table>

>>> from sklearn import metrics
>>> y_true = [0, 1, 2, 0, 1, 2]
>>> y_pred = [0, 2, 1, 0, 0, 1]
>>> metrics.precision_score(y_true, y_pred, average='macro')
0.22...
>>> metrics.recall_score(y_true, y_pred, average='micro')
0.33...
>>> metrics.f1_score(y_true, y_pred, average='weighted')
0.26...
>>> metrics.fbeta_score(y_true, y_pred, average='macro', beta=0.5)
0.23...
>>> metrics.precision_recall_fscore_support(y_true, y_pred, beta=0.5, average=None)
(array([0.66..., 0., 0., 0.]), array([1., 0., 0.]), array([0.71..., 0., 0., 0.]), array([2, 2, 2, 2]))

For multiclass classification with a “negative class”, it is possible to exclude some labels:

>>> metrics.recall_score(y_true, y_pred, labels=[1, 2], average='micro')
... # excluding 0, no labels were correctly recalled
0.0

Similarly, labels not present in the data sample may be accounted for in macro-averaging.

>>> metrics.recall_score(y_true, y_pred, labels=[0, 1, 2, 3], average='macro')
0.166...
Jaccard similarity coefficient score

The `jaccard_score` function computes the average of Jaccard similarity coefficients, also called the Jaccard index, between pairs of label sets.

The Jaccard similarity coefficient of the $i$-th samples, with a ground truth label set $y_i$ and predicted label set $\hat{y}_i$, is defined as

$$J(y_i, \hat{y}_i) = \frac{|y_i \cap \hat{y}_i|}{|y_i \cup \hat{y}_i|}.$$ 

`jaccard_score` works like `precision_recall_fscore_support` as a naively set-wise measure applying natively to binary targets, and extended to apply to multilabel and multiclass through the use of `average` (see above).

In the binary case:

```python
>>> import numpy as np
>>> from sklearn.metrics import jaccard_score
>>> y_true = np.array([[0, 1, 1], ...
... [1, 1, 0]])
>>> y_pred = np.array([[1, 1, 1], ...
... [1, 0, 0]])
>>> jaccard_score(y_true[0], y_pred[0])
0.6666...
```

In the multilabel case with binary label indicators:

```python
>>> jaccard_score(y_true, y_pred, average='samples')
0.5833...
>>> jaccard_score(y_true, y_pred, average='macro')
0.6666...
>>> jaccard_score(y_true, y_pred, average=None)
array([0.5, 0.5, 1. ])
```

Multiclass problems are binarized and treated like the corresponding multilabel problem:

```python
>>> y_pred = [0, 2, 1, 2]
>>> y_true = [0, 1, 2, 2]
>>> jaccard_score(y_true, y_pred, average=None)
array([1. , 0. , 0.33...])
>>> jaccard_score(y_true, y_pred, average='macro')
0.44...
>>> jaccard_score(y_true, y_pred, average='micro')
0.33...
```

Hinge loss

The `hinge_loss` function computes the average distance between the model and the data using hinge loss, a one-sided metric that considers only prediction errors. (Hinge loss is used in maximal margin classifiers such as support vector machines.)

If the labels are encoded with +1 and -1, $y$: is the true value, and $w$ is the predicted decisions as output by `decision_function`, then the hinge loss is defined as:

$$L_{Hinge}(y, w) = \max \{1 - wy, 0\} = |1 - wy|_+$$

If there are more than two labels, `hinge_loss` uses a multiclass variant due to Crammer & Singer. Here is the paper describing it.
If $y_0$ is the predicted decision for true label and $y_t$ is the maximum of the predicted decisions for all other labels, where predicted decisions are output by decision function, then multiclass hinge loss is defined by:

$$L_{\text{Hinge}}(y_0, y_t) = \max \{1 + y_t - y_0, 0\}$$

Here a small example demonstrating the use of the `hinge_loss` function with a svm classifier in a binary class problem:

```python
>>> from sklearn import svm
>>> from sklearn.metrics import hinge_loss
>>> X = [[0], [1]]
>>> y = [-1, 1]
>>> est = svm.LinearSVC(random_state=0)
>>> est.fit(X, y)
LinearSVC(random_state=0)
>>> pred_decision = est.decision_function([[-2], [3], [0.5]])
>>> pred_decision
array([-2.18..., 2.36..., 0.09...])
>>> hinge_loss([-1, 1, 1], pred_decision)
0.3...
```

Here is an example demonstrating the use of the `hinge_loss` function with a svm classifier in a multiclass problem:

```python
>>> X = np.array([[0], [1], [2], [3]])
>>> Y = np.array([0, 1, 2, 3])
>>> labels = np.array([0, 1, 2, 3])
>>> est = svm.LinearSVC()
>>> est.fit(X, Y)
LinearSVC()
>>> pred_decision = est.decision_function([[-1], [2], [3]])
>>> y_true = [0, 2, 3]
>>> hinge_loss(y_true, pred_decision, labels)
0.56...
```

**Log loss**

Log loss, also called logistic regression loss or cross-entropy loss, is defined on probability estimates. It is commonly used in (multinomial) logistic regression and neural networks, as well as in some variants of expectation-maximization, and can be used to evaluate the probability outputs (`predict_proba`) of a classifier instead of its discrete predictions.

For binary classification with a true label $y \in \{0, 1\}$ and a probability estimate $p = \Pr(y = 1)$, the log loss per sample is the negative log-likelihood of the classifier given the true label:

$$L_{\text{log}}(y, p) = -\log \Pr(y \mid p) = -(y \log(p) + (1 - y) \log(1 - p))$$

This extends to the multiclass case as follows. Let the true labels for a set of samples be encoded as a 1-of-K binary indicator matrix $Y$, i.e., $y_{i,k} = 1$ if sample $i$ has label $k$ taken from a set of $K$ labels. Let $P$ be a matrix of probability estimates, with $p_{i,k} = \Pr(y_{i,k} = 1)$. Then the log loss of the whole set is

$$L_{\text{log}}(Y, P) = -\log \Pr(Y \mid P) = -\frac{1}{N} \sum_{i=0}^{N-1} \sum_{k=0}^{K-1} y_{i,k} \log p_{i,k}$$

To see how this generalizes the binary log loss given above, note that in the binary case, $p_{i,0} = 1 - p_{i,1}$ and $y_{i,0} = 1 - y_{i,1}$, so expanding the inner sum over $y_{i,k} \in \{0, 1\}$ gives the binary log loss.

The `log_loss` function computes log loss given a list of ground-truth labels and a probability matrix, as returned by an estimator’s `predict_proba` method.
>>> from sklearn.metrics import log_loss
>>> y_true = [0, 0, 1, 1]
>>> y_pred = [[.9, .1], [.8, .2], [.3, .7], [.01, .99]]
>>> log_loss(y_true, y_pred)
0.1738...

The first [.9, .1] in y_pred denotes 90% probability that the first sample has label 0. The log loss is non-negative.

Matthews correlation coefficient

The `matthews_corrcoef` function computes the Matthew’s correlation coefficient (MCC) for binary classes. Quoting Wikipedia:

“The Matthews correlation coefficient is used in machine learning as a measure of the quality of binary (two-class) classifications. It takes into account true and false positives and negatives and is generally regarded as a balanced measure which can be used even if the classes are of very different sizes. The MCC is in essence a correlation coefficient value between -1 and +1. A coefficient of +1 represents a perfect prediction, 0 an average random prediction and -1 an inverse prediction. The statistic is also known as the phi coefficient.”

In the binary (two-class) case, \(tp, tn, fp\) and \(fn\) are respectively the number of true positives, true negatives, false positives and false negatives, the MCC is defined as:

\[
MCC = \frac{tp \times tn - fp \times fn}{\sqrt{(tp + fp)(tp + fn)(tn + fp)(tn + fn)}}
\]

In the multiclass case, the Matthews correlation coefficient can be defined in terms of a confusion_matrix \(C\) for \(K\) classes. To simplify the definition consider the following intermediate variables:

- \(t_k = \sum_i^K C_{ik}\) the number of times class \(k\) truly occurred,
- \(p_k = \sum_i^K C_{ki}\) the number of times class \(k\) was predicted,
- \(c = \sum_k^K C_{kk}\) the total number of samples correctly predicted,
- \(s = \sum_i^K \sum_j^K C_{ij}\) the total number of samples.

Then the multiclass MCC is defined as:

\[
MCC = \frac{c \times s - \sum_k^K p_k \times t_k}{\sqrt{(s^2 - \sum_k^K p_k^2) \times (s^2 - \sum_k^K t_k^2)}}
\]

When there are more than two labels, the value of the MCC will no longer range between -1 and +1. Instead the minimum value will be somewhere between -1 and 0 depending on the number and distribution of ground true labels. The maximum value is always +1.

Here is a small example illustrating the usage of the `matthews_corrcoef` function:

```python
>>> from sklearn.metrics import matthews_corrcoef
>>> y_true = [+1, +1, +1, -1]
>>> y_pred = [+1, -1, +1, +1]
>>> matthews_corrcoef(y_true, y_pred)
-0.33...
```
Multi-label confusion matrix

The `multilabel_confusion_matrix` function computes class-wise (default) or sample-wise (sample-wise=True) multilabel confusion matrix to evaluate the accuracy of a classification. `multilabel_confusion_matrix` also treats multiclass data as if it were multilabel, as this is a transformation commonly applied to evaluate multiclass problems with binary classification metrics (such as precision, recall, etc.).

When calculating class-wise multilabel confusion matrix \( C \), the count of true negatives for class \( i \) is \( C_{i,0,0} \), false negatives is \( C_{i,1,0} \), true positives is \( C_{i,1,1} \) and false positives is \( C_{i,0,1} \).

Here is an example demonstrating the use of the `multilabel_confusion_matrix` function with multilabel indicator matrix input:

```python
>>> import numpy as np
>>> from sklearn.metrics import multilabel_confusion_matrix

>>> y_true = np.array([[1, 0, 1],
                    [0, 1, 0]])
>>> y_pred = np.array([[1, 0, 0],
                    [0, 1, 1]])

>>> multilabel_confusion_matrix(y_true, y_pred)
array([[1, 0],
       [0, 1]])
```

Or a confusion matrix can be constructed for each sample’s labels:

```python
>>> multilabel_confusion_matrix(y_true, y_pred, samplewise=True)
array([[1, 1],
       [1, 0]])
```

Here is an example demonstrating the use of the `multilabel_confusion_matrix` function with multiclass input:

```python
>>> y_true = ["cat", "ant", "cat", "ant", "bird"]
>>> y_pred = ["ant", "ant", "cat", "cat", "ant"]

>>> multilabel_confusion_matrix(y_true, y_pred,
                                  labels=["ant", "bird", "cat"])
array([[3, 1],
       [0, 2]],
       [[5, 0],
        [1, 0]],
       [[2, 1],
        [1, 2]])
```

Here are some examples demonstrating the use of the `multilabel_confusion_matrix` function to calculate recall (or sensitivity), specificity, fall out and miss rate for each class in a problem with multilabel indicator matrix input.

Calculating recall (also called the true positive rate or the sensitivity) for each class:
Calculating specificity (also called the true negative rate) for each class:

```python
>>> tn / (tn + fp)
array([1. , 0. , 0.5])
```

Calculating fall out (also called the false positive rate) for each class:

```python
>>> fp / (fp + tn)
array([0. , 1. , 0.5])
```

Calculating miss rate (also called the false negative rate) for each class:

```python
>>> fn / (fn + tp)
array([0. , 0.5, 1.])
```

**Receiver operating characteristic (ROC)**

The function `roc_curve` computes the receiver operating characteristic curve, or ROC curve. Quoting Wikipedia:

“A receiver operating characteristic (ROC), or simply ROC curve, is a graphical plot which illustrates the performance of a binary classifier system as its discrimination threshold is varied. It is created by plotting the fraction of true positives out of the positives (TPR = true positive rate) vs. the fraction of false positives out of the negatives (FPR = false positive rate), at various threshold settings. TPR is also known as sensitivity, and FPR is one minus the specificity or true negative rate.”

This function requires the true binary value and the target scores, which can either be probability estimates of the positive class, confidence values, or binary decisions. Here is a small example of how to use the `roc_curve` function:

```python
>>> import numpy as np
>>> from sklearn.metrics import roc_curve
>>> y = np.array([1, 1, 2, 2])
>>> scores = np.array([0.1, 0.4, 0.35, 0.8])
>>> fpr, tpr, thresholds = roc_curve(y, scores, pos_label=2)
>>> fpr
array([0. , 0. , 0.5, 0.5, 1.])
>>> tpr
array([0. , 0.5, 0.5, 1. , 1.])
>>> thresholds
array([1.8 , 0.8 , 0.4 , 0.35, 0.1])
```

This figure shows an example of such an ROC curve:
The `roc_auc_score` function computes the area under the receiver operating characteristic (ROC) curve, which is also denoted by AUC or AUROC. By computing the area under the roc curve, the curve information is summarized in one number. For more information see the Wikipedia article on AUC.

Compared to metrics such as the subset accuracy, the Hamming loss, or the F1 score, ROC doesn’t require optimizing a threshold for each label.

**Binary case**

In the binary case, you can either provide the probability estimates, using the `classifier.predict_proba()` method, or the non-thresholded decision values given by the `classifier.decision_function()` method. In the case of providing the probability estimates, the probability of the class with the “greater label” should be provided. The “greater label” corresponds to `classifier.classes_[1]` and thus `classifier.predict_proba(X)[:, 1]`. Therefore, the `y_score` parameter is of size `(n_samples,)`.

```python
>>> from sklearn.datasets import load_breast_cancer
>>> from sklearn.linear_model import LogisticRegression
>>> from sklearn.metrics import roc_auc_score

>>> X, y = load_breast_cancer(return_X_y=True)
>>> clf = LogisticRegression(solver="liblinear").fit(X, y)
>>> clf.classes_
array([0, 1])

We can use the probability estimates corresponding to `clf.classes_[1]`.

```python
>>> y_score = clf.predict_proba(X)[:, 1]
>>> roc_auc_score(y, y_score)
0.99...
```
Multi-class case

The `roc_auc_score` function can also be used in multi-class classification. Two averaging strategies are currently supported: the one-vs-one algorithm computes the average of the pairwise ROC AUC scores, and the one-vs-rest algorithm computes the average of the ROC AUC scores for each class against all other classes. In both cases, the predicted labels are provided in an array with values from 0 to `n_classes`, and the scores correspond to the probability estimates that a sample belongs to a particular class. The OvO and OvR algorithms support weighting uniformly (average='macro') and by prevalence (average='weighted').

One-vs-one Algorithm: Computes the average AUC of all possible pairwise combinations of classes. [HT2001] defines a multiclass AUC metric weighted uniformly:

\[
2 \sum_{j=1}^{c-1} \sum_{k>j}^{c} (\text{AUC}(j|k) + \text{AUC}(k|j)) / c(c-1)
\]

where `c` is the number of classes and AUC(j|k) is the AUC with class `j` as the positive class and class `k` as the negative class. In general, AUC(j|k) \neq AUC(k|j) in the multiclass case. This algorithm is used by setting the keyword argument `multiclass` to 'ovo' and average to 'macro'.

The [HT2001] multiclass AUC metric can be extended to be weighted by the prevalence:

\[
2 \sum_{j=1}^{c-1} \sum_{k>j}^{c} p(j \cup k) (\text{AUC}(j|k) + \text{AUC}(k|j)) / c(c-1)
\]

where `c` is the number of classes. This algorithm is used by setting the keyword argument `multiclass` to 'ovo' and average to 'weighted'. The 'weighted' option returns a prevalence-weighted average as described in [FC2009].

One-vs-rest Algorithm: Computes the AUC of each class against the rest [PD2000]. The algorithm is functionally the same as the multilabel case. To enable this algorithm set the keyword argument `multiclass` to 'ovr'. Like OvO, OvR supports two types of averaging: 'macro' [F2006] and 'weighted' [F2001].

In applications where a high false positive rate is not tolerable the parameter `max_fpr` of `roc_auc_score` can be used to summarize the ROC curve up to the given limit.
Multi-label case

In multi-label classification, the `roc_auc_score` function is extended by averaging over the labels as above. In this case, you should provide a `y_score` of shape `(n_samples, n_classes)`. Thus, when using the probability estimates, one needs to select the probability of the class with the greater label for each output.

```python
>>> from sklearn.datasets import make_multilabel_classification
>>> from sklearn.multioutput import MultiOutputClassifier

>>> X, y = make_multilabel_classification(random_state=0)

>>> inner_clf = LogisticRegression(solver="liblinear", random_state=0)

>>> clf = MultiOutputClassifier(inner_clf).fit(X, y)

>>> y_score = np.transpose([y_pred[:, 1] for y_pred in clf.predict_proba(X)])

>>> roc_auc_score(y, y_score, average=None)
array([0.82..., 0.86..., 0.94..., 0.85..., 0.94...])
```

And the decision values do not require such processing.

```python
>>> from sklearn.linear_model import RidgeClassifierCV

>>> clf = RidgeClassifierCV().fit(X, y)

>>> y_score = clf.decision_function(X)

>>> roc_auc_score(y, y_score, average=None)
array([0.81..., 0.84..., 0.93..., 0.87..., 0.94...])
```

Examples:

- See *Receiver Operating Characteristic (ROC)* for an example of using ROC to evaluate the quality of the output of a classifier.
- See *Receiver Operating Characteristic (ROC) with cross validation* for an example of using ROC to evaluate classifier output quality, using cross-validation.
Detection error tradeoff (DET)

The function `det_curve` computes the detection error tradeoff curve (DET) curve [WikipediaDET2017]. Quoting Wikipedia:

“A detection error tradeoff (DET) graph is a graphical plot of error rates for binary classification systems, plotting false reject rate vs. false accept rate. The x- and y-axes are scaled non-linearly by their standard normal deviates (or just by logarithmic transformation), yielding tradeoff curves that are more linear than ROC curves, and use most of the image area to highlight the differences of importance in the critical operating region.”

DET curves are a variation of receiver operating characteristic (ROC) curves where False Negative Rate is plotted on the y-axis instead of True Positive Rate. DET curves are commonly plotted in normal deviate scale by transformation with $\phi^{-1}$ (with $\phi$ being the cumulative distribution function). The resulting performance curves explicitly visualize the tradeoff of error types for given classification algorithms. See [Martin1997] for examples and further motivation.

This figure compares the ROC and DET curves of two example classifiers on the same classification task:

Properties:

- DET curves form a linear curve in normal deviate scale if the detection scores are normally (or close-to normally) distributed. It was shown by [Navratil2007] that the reverse it not necessarily true and even more general distributions are able produce linear DET curves.
- The normal deviate scale transformation spreads out the points such that a comparatively larger space of plot is occupied. Therefore curves with similar classification performance might be easier to distinguish on a DET plot.
- With False Negative Rate being “inverse” to True Positive Rate the point of perfection for DET curves is the origin (in contrast to the top left corner for ROC curves).
Applications and limitations:

DET curves are intuitive to read and hence allow quick visual assessment of a classifier’s performance. Additionally, DET curves can be consulted for threshold analysis and operating point selection. This is particularly helpful if a comparison of error types is required.

One the other hand DET curves do not provide their metric as a single number. Therefore for either automated evaluation or comparison to other classification tasks metrics like the derived area under ROC curve might be better suited.

Examples:

- See Detection error tradeoff (DET) curve for an example comparison between receiver operating characteristic (ROC) curves and Detection error tradeoff (DET) curves.

References:

Zero one loss

The zero_one_loss function computes the sum or the average of the 0-1 classification loss ($L_{0-1}$) over $n_{samples}$. By default, the function normalizes over the sample. To get the sum of the $L_{0-1}$, set normalize to False.

In multilabel classification, the zero_one_loss scores a subset as one if its labels strictly match the predictions, and as a zero if there are any errors. By default, the function returns the percentage of imperfectly predicted subsets. To get the count of such subsets instead, set normalize to False.

If $\hat{y}_i$ is the predicted value of the $i$-th sample and $y_i$ is the corresponding true value, then the 0-1 loss $L_{0-1}$ is defined as:

$$L_{0-1}(y_i, \hat{y}_i) = 1(\hat{y}_i \neq y_i)$$

where $1(x)$ is the indicator function.

```python
>>> from sklearn.metrics import zero_one_loss
>>> y_pred = [1, 2, 3, 4]
>>> y_true = [2, 2, 3, 4]
>>> zero_one_loss(y_true, y_pred)
0.25
>>> zero_one_loss(y_true, y_pred, normalize=False)
1
```

In the multilabel case with binary label indicators, where the first label set [0,1] has an error:

```python
>>> zero_one_loss(np.array([[0, 1], [1, 1]]), np.ones((2, 2)))
0.5
>>> zero_one_loss(np.array([[0, 1], [1, 1]]), np.ones((2, 2)), normalize=False)
1
```
Brier score loss

The `brier_score_loss` function computes the Brier score for binary classes [Brier1950]. Quoting Wikipedia:

“The Brier score is a proper score function that measures the accuracy of probabilistic predictions. It is applicable to tasks in which predictions must assign probabilities to a set of mutually exclusive discrete outcomes.”

This function returns the mean squared error of the actual outcome \( y \in \{0, 1\} \) and the predicted probability estimate \( p = \Pr(y = 1) \) (\textit{predict\_proba}) as outputted by:

\[
BS = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} (y_i - p_i)^2
\]

The Brier score loss is also between 0 to 1 and the lower the value (the mean square difference is smaller), the more accurate the prediction is.

Here is a small example of usage of this function:

```python
>>> import numpy as np
>>> from sklearn.metrics import brier_score_loss
>>> y_true = np.array([0, 1, 1, 0])
>>> y_true_categorical = np.array(['spam', 'ham', 'ham', 'spam'])
>>> y_prob = np.array([0.1, 0.9, 0.8, 0.4])
>>> y_pred = np.array([0, 1, 1, 0])
>>> brier_score_loss(y_true, y_prob)
0.055
>>> brier_score_loss(y_true, 1 - y_prob, pos_label=0)
0.055
>>> brier_score_loss(y_true_categorical, y_prob, pos_label='ham')
0.055
>>> brier_score_loss(y_true, y_prob > 0.5)
0.0
```

The Brier score can be used to assess how well a classifier is calibrated. However, a lower Brier score loss does not always mean a better calibration. This is because, by analogy with the bias-variance decomposition of the mean squared error, the Brier score loss can be decomposed as the sum of calibration loss and refinement loss [Bella2012]. Calibration loss is defined as the mean squared deviation from empirical probabilities derived from the slope of ROC segments. Refinement loss can be defined as the expected optimal loss as measured by the area under the optimal cost curve. Refinement loss can change independently from calibration loss, thus a lower Brier score loss does not necessarily mean a better calibrated model. “Only when refinement loss remains the same does a lower Brier score loss always mean better calibration” [Bella2012], [Flach2008].
Multilabel ranking metrics

In multilabel learning, each sample can have any number of ground truth labels associated with it. The goal is to give high scores and better rank to the ground truth labels.

Coverage error

The `coverage_error` function computes the average number of labels that have to be included in the final prediction such that all true labels are predicted. This is useful if you want to know how many top-scored-labels you have to predict in average without missing any true one. The best value of this metrics is thus the average number of true labels.

Note: Our implementation’s score is 1 greater than the one given in Tsoumakas et al., 2010. This extends it to handle the degenerate case in which an instance has 0 true labels.

Formally, given a binary indicator matrix of the ground truth labels $y \in \{0, 1\}^{n_{\text{samples}} \times n_{\text{labels}}}$ and the score associated with each label $\hat{f} \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$, the coverage is defined as

$$\text{coverage}(y, \hat{f}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \max_{j : y_{ij} = 1} \text{rank}_{ij}$$

with $\text{rank}_{ij} = \left| \left\{ k : \hat{f}_{ik} \geq \hat{f}_{ij} \right\} \right|$. Given the rank definition, ties in $y_{\text{scores}}$ are broken by giving the maximal rank that would have been assigned to all tied values.

Here is a small example of usage of this function:

```python
>>> import numpy as np
>>> from sklearn.metrics import coverage_error
>>> y_true = np.array([[1, 0, 0], [0, 0, 1]])
>>> y_score = np.array([[0.75, 0.5, 1], [1, 0.2, 0.1]])
>>> coverage_error(y_true, y_score)
2.5
```

Label ranking average precision

The `label_ranking_average_precision_score` function implements label ranking average precision (LRAP). This metric is linked to the `average_precision_score` function, but is based on the notion of label ranking instead of precision and recall.

Label ranking average precision (LRAP) averages over the samples the answer to the following question: for each ground truth label, what fraction of higher-ranked labels were true labels? This performance measure will be higher if you are able to give better rank to the labels associated with each sample. The obtained score is always strictly greater than 0, and the best value is 1. If there is exactly one relevant label per sample, label ranking average precision is equivalent to the mean reciprocal rank.
Formally, given a binary indicator matrix of the ground truth labels $y \in \{0, 1\}^{n_{\text{samples}} \times n_{\text{labels}}}$ and the score associated with each label $\hat{f} \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$, the average precision is defined as

$$L_{RAP}(y, \hat{f}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \frac{1}{\|y_i\|_0} \sum_{j:y_{ij}=1} \frac{|L_{ij}|}{\text{rank}_{ij}}$$

where $L_{ij} = \{k: y_{ik} = 1, \hat{f}_{ik} \geq \hat{f}_{ij}\}$, $\text{rank}_{ij} = \{k: \hat{f}_{ik} \geq \hat{f}_{ij}, y_{ik} = 1, y_{il} = 0\}$, $\|\cdot\|$ computes the cardinality of the set (i.e., the number of elements in the set), and $\|\cdot\|_0$ is the $\ell_0$ “norm” (which computes the number of nonzero elements in a vector).

Here is a small example of usage of this function:

```python
>>> import numpy as np
>>> from sklearn.metrics import label_ranking_average_precision_score
>>> y_true = np.array([[1, 0, 0], [0, 0, 1]])
>>> y_score = np.array([[0.75, 0.5, 1], [1, 0.2, 0.1]])
>>> label_ranking_average_precision_score(y_true, y_score)
0.416...
```

**Ranking loss**

The `label_ranking_loss` function computes the ranking loss which averages over the samples the number of label pairs that are incorrectly ordered, i.e. true labels have a lower score than false labels, weighted by the inverse of the number of ordered pairs of false and true labels. The lowest achievable ranking loss is zero.

Formally, given a binary indicator matrix of the ground truth labels $y \in \{0, 1\}^{n_{\text{samples}} \times n_{\text{labels}}}$ and the score associated with each label $\hat{f} \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$, the ranking loss is defined as

$$\text{ranking_loss}(y, \hat{f}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \frac{1}{\|y_i\|_0 (n_{\text{labels}} - \|y_i\|_0)} \left| \left\{ (k, l): \hat{f}_{ik} \leq \hat{f}_{il}, y_{ik} = 1, y_{il} = 0 \right\} \right|$$

where $\|\cdot\|$ computes the cardinality of the set (i.e., the number of elements in the set) and $\|\cdot\|_0$ is the $\ell_0$ “norm” (which computes the number of nonzero elements in a vector).

Here is a small example of usage of this function:

```python
>>> import numpy as np
>>> from sklearn.metrics import label_ranking_loss
>>> y_true = np.array([[1, 0, 0], [0, 0, 1]])
>>> y_score = np.array([[0.75, 0.5, 1], [1, 0.2, 0.1]])
>>> label_ranking_loss(y_true, y_score)
0.75...
>>> # With the following prediction, we have perfect and minimal loss
>>> y_score = np.array([[1.0, 0.1, 0.2], [0.1, 0.2, 0.9]])
>>> label_ranking_loss(y_true, y_score)
0.0
```

Normalized Discounted Cumulative Gain

Discounted Cumulative Gain (DCG) and Normalized Discounted Cumulative Gain (NDCG) are ranking metrics implemented in `dcg_score` and `ndcg_score`; they compare a predicted order to ground-truth scores, such as the relevance of answers to a query.

From the Wikipedia page for Discounted Cumulative Gain:

“Discounted cumulative gain (DCG) is a measure of ranking quality. In information retrieval, it is often used to measure effectiveness of web search engine algorithms or related applications. Using a graded relevance scale of documents in a search-engine result set, DCG measures the usefulness, or gain, of a document based on its position in the result list. The gain is accumulated from the top of the result list to the bottom, with the gain of each result discounted at lower ranks.”

DCG orders the true targets (e.g. relevance of query answers) in the predicted order, then multiplies them by a logarithmic decay and sums the result. The sum can be truncated after the first $K$ results, in which case we call it DCG@K. NDCG, or NDCG@K is DCG divided by the DCG obtained by a perfect prediction, so that it is always between 0 and 1. Usually, NDCG is preferred to DCG.

Compared with the ranking loss, NDCG can take into account relevance scores, rather than a ground-truth ranking. So if the ground-truth consists only of an ordering, the ranking loss should be preferred; if the ground-truth consists of actual usefulness scores (e.g. 0 for irrelevant, 1 for relevant, 2 for very relevant), NDCG can be used.

For one sample, given the vector of continuous ground-truth values for each target $y \in \mathbb{R}^M$, where $M$ is the number of outputs, and the prediction $\hat{y}$, which induces the ranking function $f$, the DCG score is

$$\sum_{r=1}^{\min(K,M)} \frac{y_f(r)}{\log(1+r)}$$

and the NDCG score is the DCG score divided by the DCG score obtained for $y$.

- Wikipedia entry for Discounted Cumulative Gain

Regression metrics

The `sklearn.metrics` module implements several loss, score, and utility functions to measure regression performance. Some of those have been enhanced to handle the multioutput case: `mean_squared_error`, `mean_absolute_error`, `explained_variance_score` and `r2_score`.

These functions have an `multioutput` keyword argument which specifies the way the scores or losses for each individual target should be averaged. The default is 'uniform_average', which specifies a uniformly weighted mean over outputs. If an `ndarray` of shape `(n_outputs,)` is passed, then its entries are interpreted as weights and an according weighted average is returned. If `multioutput` is 'raw_values' is specified, then all unaltered individual scores or losses will be returned in an array of shape `(n_outputs,)`.
The `r2_score` and `explained_variance_score` accept an additional value `'variance_weighted'` for the `multioutput` parameter. This option leads to a weighting of each individual score by the variance of the corresponding target variable. This setting quantifies the globally captured unscaled variance. If the target variables are of different scale, then this score puts more importance on well explaining the higher variance variables. `multioutput='variance_weighted'` is the default value for `r2_score` for backward compatibility. This will be changed to `uniform_average` in the future.

**Explained variance score**

The `explained_variance_score` computes the explained variance regression score.

If $\hat{y}$ is the estimated target output, $y$ the corresponding (correct) target output, and $Var$ is Variance, the square of the standard deviation, then the explained variance is estimated as follow:

$$explained\_variance(y, \hat{y}) = 1 - \frac{Var\{y - \hat{y}\}}{Var\{y\}}$$

The best possible score is 1.0, lower values are worse.

Here is a small example of usage of the `explained_variance_score` function:

```python
>>> from sklearn.metrics import explained_variance_score
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> explained_variance_score(y_true, y_pred)
0.957...

>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> explained_variance_score(y_true, y_pred, multioutput='raw_values')
array([0.967..., 1.])
>>> explained_variance_score(y_true, y_pred, multioutput=[0.3, 0.7])
0.990...
```

**Max error**

The `max_error` function computes the maximum residual error, a metric that captures the worst case error between the predicted value and the true value. In a perfectly fitted single output regression model, `max_error` would be 0 on the training set and though this would be highly unlikely in the real world, this metric shows the extent of error that the model had when it was fitted.

If $\hat{y}_i$ is the predicted value of the $i$-th sample, and $y_i$ is the corresponding true value, then the max error is defined as

$$\text{Max Error}(y, \hat{y}) = \max(||y_i - \hat{y}_i||)$$

Here is a small example of usage of the `max_error` function:

```python
>>> from sklearn.metrics import max_error
>>> y_true = [3, 2, 7, 1]
>>> y_pred = [9, 2, 7, 1]
>>> max_error(y_true, y_pred)
6
```

The `max_error` does not support multioutput.
Mean absolute error

The `mean_absolute_error` function computes mean absolute error, a risk metric corresponding to the expected value of the absolute error loss or $l_1$-norm loss.

If $\hat{y}_i$ is the predicted value of the $i$-th sample, and $y_i$ is the corresponding true value, then the mean absolute error (MAE) estimated over $n_{\text{samples}}$ is defined as

$$\text{MAE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} |y_i - \hat{y}_i|.$$  

Here is a small example of usage of the `mean_absolute_error` function:

```python
>>> from sklearn.metrics import mean_absolute_error
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> mean_absolute_error(y_true, y_pred)
0.5
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> mean_absolute_error(y_true, y_pred)
0.75
>>> mean_absolute_error(y_true, y_pred, multioutput='raw_values')
array([0.5, 1.])
>>> mean_absolute_error(y_true, y_pred, multioutput=[0.3, 0.7])
0.85...
```

Mean squared error

The `mean_squared_error` function computes mean square error, a risk metric corresponding to the expected value of the squared (quadratic) error or loss.

If $\hat{y}_i$ is the predicted value of the $i$-th sample, and $y_i$ is the corresponding true value, then the mean squared error (MSE) estimated over $n_{\text{samples}}$ is defined as

$$\text{MSE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} (y_i - \hat{y}_i)^2.$$  

Here is a small example of usage of the `mean_squared_error` function:

```python
>>> from sklearn.metrics import mean_squared_error
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> mean_squared_error(y_true, y_pred)
0.375
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> mean_squared_error(y_true, y_pred)
0.7083...
```

Examples:

- See Gradient Boosting regression for an example of mean squared error usage to evaluate gradient boosting regression.
Mean squared logarithmic error

The `mean_squared_log_error` function computes a risk metric corresponding to the expected value of the squared logarithmic (quadratic) error or loss.

If \( \hat{y}_i \) is the predicted value of the \( i \)-th sample, and \( y_i \) is the corresponding true value, then the mean squared logarithmic error (MSLE) estimated over \( n_{\text{samples}} \) samples is defined as

\[
\text{MSLE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} (\log_e(1 + y_i) - \log_e(1 + \hat{y}_i))^2.
\]

Where \( \log_e(x) \) means the natural logarithm of \( x \). This metric is best to use when targets having exponential growth, such as population counts, average sales of a commodity over a span of years etc. Note that this metric penalizes an under-predicted estimate greater than an over-predicted estimate.

Here is a small example of usage of the `mean_squared_log_error` function:

```python
from sklearn.metrics import mean_squared_log_error

y_true = [3, 5, 2.5, 7]
y_pred = [2.5, 5, 4, 8]
mean_squared_log_error(y_true, y_pred)
0.039...

y_true = [[0.5, 1], [1, 2], [7, 6]]
y_pred = [[0.5, 2], [1, 2.5], [8, 8]]
mean_squared_log_error(y_true, y_pred)
0.044...
```

Mean absolute percentage error

The `mean_absolute_percentage_error` (MAPE), also known as mean absolute percentage deviation (MAPD), is an evaluation metric for regression problems. The idea of this metric is to be sensitive to relative errors. It is for example not changed by a global scaling of the target variable.

If \( \hat{y}_i \) is the predicted value of the \( i \)-th sample and \( y_i \) is the corresponding true value, then the mean absolute percentage error (MAPE) estimated over \( n_{\text{samples}} \) samples is defined as

\[
\text{MAPE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \frac{|y_i - \hat{y}_i|}{\max(\epsilon, |y_i|)}
\]

where \( \epsilon \) is an arbitrary small yet strictly positive number to avoid undefined results when \( y \) is zero.

The `mean_absolute_percentage_error` function supports multioutput.

Here is a small example of usage of the `mean_absolute_percentage_error` function:

```python
from sklearn.metrics import mean_absolute_percentage_error

y_true = [1, 10, 1e6]
y_pred = [0.9, 15, 1.2e6]
mean_absolute_percentage_error(y_true, y_pred)
0.2666...
```

In above example, if we had used `mean_absolute_error`, it would have ignored the small magnitude values and only reflected the error in prediction of highest magnitude value. But that problem is resolved in case of MAPE because it calculates relative percentage error with respect to actual output.
Median absolute error

The `median_absolute_error` is particularly interesting because it is robust to outliers. The loss is calculated by taking the median of all absolute differences between the target and the prediction.

If \( \hat{y}_i \) is the predicted value of the \( i \)-th sample and \( y_i \) is the corresponding true value, then the median absolute error (MedAE) estimated over \( n \) samples is defined as

\[
\text{MedAE}(y, \hat{y}) = \text{median}(|y_1 - \hat{y}_1|, \ldots, |y_n - \hat{y}_n|).
\]

The `median_absolute_error` does not support multioutput.

Here is a small example of usage of the `median_absolute_error` function:

```python
>>> from sklearn.metrics import median_absolute_error
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> median_absolute_error(y_true, y_pred)
0.5
```

R² score, the coefficient of determination

The `r2_score` function computes the coefficient of determination, usually denoted as \( R^2 \).

It represents the proportion of variance (of \( y \)) that has been explained by the independent variables in the model. It provides an indication of goodness of fit and therefore a measure of how well unseen samples are likely to be predicted by the model, through the proportion of explained variance.

As such variance is dataset dependent, \( R^2 \) may not be meaningfully comparable across different datasets. Best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of \( y \), disregarding the input features, would get a \( R^2 \) score of 0.0.

If \( \hat{y}_i \) is the predicted value of the \( i \)-th sample and \( y_i \) is the corresponding true value for total \( n \) samples, the estimated \( R^2 \) is defined as:

\[
R^2(y, \hat{y}) = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2}
\]

where \( \bar{y} = \frac{1}{n} \sum_{i=1}^{n} y_i \) and \( \sum_{i=1}^{n}(y_i - \hat{y}_i)^2 = \sum_{i=1}^{n} \epsilon_i^2 \).

Note that `r2_score` calculates unadjusted \( R^2 \) without correcting for bias in sample variance of \( y \).

Here is a small example of usage of the `r2_score` function:

```python
>>> from sklearn.metrics import r2_score
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> r2_score(y_true, y_pred)
0.948...
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> r2_score(y_true, y_pred, multioutput='variance_weighted')
0.938...
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> r2_score(y_true, y_pred, multioutput='uniform_average')
0.936...
>>> r2_score(y_true, y_pred, multioutput='raw_values')
```

(continues on next page)
Example:

- See *Lasso and Elastic Net for Sparse Signals* for an example of $R^2$ score usage to evaluate Lasso and Elastic Net on sparse signals.

### Mean Poisson, Gamma, and Tweedie deviances

The `mean_tweedie_deviance` function computes the mean Tweedie deviance error with a `power` parameter ($p$). This is a metric that elicits predicted expectation values of regression targets.

Following special cases exist,

- when $power=0$ it is equivalent to `mean_squared_error`.
- when $power=1$ it is equivalent to `mean_poisson_deviance`.
- when $power=2$ it is equivalent to `mean_gamma_deviance`.

If $\hat{y}_i$ is the predicted value of the $i$-th sample, and $y_i$ is the corresponding true value, then the mean Tweedie deviance error ($D$) for power $p$, estimated over $n_{\text{samples}}$ is defined as:

$$
D(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} 
\begin{cases} 
(y_i - \hat{y}_i)^2, & \text{for } p = 0 \text{ (Normal)} \\
2(y_i \log(y_i/\hat{y}_i) + \hat{y}_i - y_i), & \text{for } p = 1 \text{ (Poisson)} \\
2(\log(\hat{y}_i/y_i) + y_i/\hat{y}_i - 1), & \text{for } p = 2 \text{ (Gamma)} \\
2\left(\frac{\max(y_i,0)^{2-p} + y_i^{2-p}}{1-p} + \frac{\hat{y}_i^{2-p}}{2-p}\right), & \text{otherwise}
\end{cases}
$$

Tweedie deviance is a homogeneous function of degree $2-power$. Thus, Gamma distribution with $power=2$ means that simultaneously scaling $y_{\text{true}}$ and $y_{\text{pred}}$ has no effect on the deviance. For Poisson distribution $power=1$ the deviance scales linearly, and for Normal distribution ($power=0$), quadratically. In general, the higher $power$ the less weight is given to extreme deviations between true and predicted targets.

For instance, let’s compare the two predictions 1.0 and 100 that are both 50% of their corresponding true value.

The mean squared error ($power=0$) is very sensitive to the prediction difference of the second point:

```python
>>> from sklearn.metrics import mean_tweedie_deviance
>>> mean_tweedie_deviance([1.0], [1.5], power=0)
0.25
>>> mean_tweedie_deviance([100.], [150.], power=0)
2500.0
```

If we increase $power$ to 1:

```python
>>> mean_tweedie_deviance([1.0], [1.5], power=1)
0.18...
>>> mean_tweedie_deviance([100.], [150.], power=1)
18.9...
```

the difference in errors decreases. Finally, by setting $power=2$:
we would get identical errors. The deviance when `power=2` is thus only sensitive to relative errors.

**Clustering metrics**

The `sklearn.metrics` module implements several loss, score, and utility functions. For more information see the *Clustering performance evaluation* section for instance clustering, and *Biclustering evaluation* for biclustering.

**Dummy estimators**

When doing supervised learning, a simple sanity check consists of comparing one’s estimator against simple rules of thumb. `DummyClassifier` implements several such simple strategies for classification:

- `stratified` generates random predictions by respecting the training set class distribution.
- `most_frequent` always predicts the most frequent label in the training set.
- `prior` always predicts the class that maximizes the class prior (like `most_frequent`) and `predict_proba` returns the class prior.
- `uniform` generates predictions uniformly at random.
- `constant` always predicts a constant label that is provided by the user. A major motivation of this method is F1-scoring, when the positive class is in the minority.

Note that with all these strategies, the `predict` method completely ignores the input data!

To illustrate `DummyClassifier`, first let’s create an imbalanced dataset:

```python
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split

>>> X, y = load_iris(return_X_y=True)
>>> y[y != 1] = -1
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
```

Next, let’s compare the accuracy of `SVC` and `most_frequent`:

```python
>>> from sklearn.dummy import DummyClassifier
>>> from sklearn.svm import SVC

>>> clf = SVC(kernel='linear', C=1).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.63...

>>> clf = DummyClassifier(strategy='most_frequent', random_state=0)
>>> clf.fit(X_train, y_train)
DummyClassifier(random_state=0, strategy='most_frequent')

>>> clf.score(X_test, y_test)
0.57...
```

We see that `SVC` doesn’t do much better than a dummy classifier. Now, let’s change the kernel:

```python
>>> clf = SVC(kernel='rbf', C=1).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.94...
```
We see that the accuracy was boosted to almost 100%. A cross validation strategy is recommended for a better estimate of the accuracy, if it is not too CPU costly. For more information see the Cross-validation: evaluating estimator performance section. Moreover if you want to optimize over the parameter space, it is highly recommended to use an appropriate methodology; see the Tuning the hyper-parameters of an estimator section for details.

More generally, when the accuracy of a classifier is too close to random, it probably means that something went wrong: features are not helpful, a hyperparameter is not correctly tuned, the classifier is suffering from class imbalance, etc…

DummyRegressor also implements four simple rules of thumb for regression:

- **mean** always predicts the mean of the training targets.
- **median** always predicts the median of the training targets.
- **quantile** always predicts a user provided quantile of the training targets.
- **constant** always predicts a constant value that is provided by the user.

In all these strategies, the predict method completely ignores the input data.

### 4.3.4 Validation curves: plotting scores to evaluate models

Every estimator has its advantages and drawbacks. Its generalization error can be decomposed in terms of bias, variance and noise. The **bias** of an estimator is its average error for different training sets. The **variance** of an estimator indicates how sensitive it is to varying training sets. Noise is a property of the data.

In the following plot, we see a function \( f(x) = \cos\left(\frac{3}{2} \pi x\right) \) and some noisy samples from that function. We use three different estimators to fit the function: linear regression with polynomial features of degree 1, 4 and 15. We see that the first estimator can at best provide only a poor fit to the samples and the true function because it is too simple (high bias), the second estimator approximates it almost perfectly and the last estimator approximates the training data perfectly but does not fit the true function very well, i.e. it is very sensitive to varying training data (high variance).

![Validation curves](image.png)

Bias and variance are inherent properties of estimators and we usually have to select learning algorithms and hyperparameters so that both bias and variance are as low as possible (see Bias-variance dilemma). Another way to reduce the variance of a model is to use more training data. However, you should only collect more training data if the true function is too complex to be approximated by an estimator with a lower variance.

In the simple one-dimensional problem that we have seen in the example it is easy to see whether the estimator suffers from bias or variance. However, in high-dimensional spaces, models can become very difficult to visualize. For this reason, it is often helpful to use the tools described below.
Examples:

- Underfitting vs. Overfitting
- Plotting Validation Curves
- Plotting Learning Curves

Validation curve

To validate a model we need a scoring function (see `Metrics and scoring: quantifying the quality of predictions`), for example accuracy for classifiers. The proper way of choosing multiple hyperparameters of an estimator are of course grid search or similar methods (see `Tuning the hyper-parameters of an estimator`) that select the hyperparameter with the maximum score on a validation set or multiple validation sets. Note that if we optimized the hyperparameters based on a validation score the validation score is biased and not a good estimate of the generalization any longer. To get a proper estimate of the generalization we have to compute the score on another test set.

However, it is sometimes helpful to plot the influence of a single hyperparameter on the training score and the validation score to find out whether the estimator is overfitting or underfitting for some hyperparameter values.

The function `validation_curve` can help in this case:

```python
>>> import numpy as np
>>> from sklearn.model_selection import validation_curve
>>> from sklearn.datasets import load_iris
>>> from sklearn.linear_model import Ridge

>>> np.random.seed(0)
>>> X, y = load_iris(return_X_y=True)
>>> indices = np.arange(y.shape[0])
>>> np.random.shuffle(indices)
>>> X, y = X[indices], y[indices]

>>> train_scores, valid_scores = validation_curve(Ridge(), X, y, 'alpha',
... np.logspace(-7, 3, 3),
... cv=5)

>>> train_scores
array([[0.93..., 0.94..., 0.92..., 0.91..., 0.92...],
[0.93..., 0.94..., 0.92..., 0.91..., 0.92...],
[0.51..., 0.52..., 0.49..., 0.47..., 0.49...]])

>>> valid_scores
array([[0.90..., 0.84..., 0.94..., 0.96..., 0.93...],
[0.90..., 0.84..., 0.94..., 0.96..., 0.93...],
[0.46..., 0.25..., 0.50..., 0.49..., 0.52...]])
```

If the training score and the validation score are both low, the estimator will be underfitting. If the training score is high and the validation score is low, the estimator is overfitting and otherwise it is working very well. A low training score and a high validation score is usually not possible. All three cases can be found in the plot below where we vary the parameter $\gamma$ of an SVM on the digits dataset.
Learning curve

A learning curve shows the validation and training score of an estimator for varying numbers of training samples. It is a tool to find out how much we benefit from adding more training data and whether the estimator suffers more from a variance error or a bias error. Consider the following example where we plot the learning curve of a naive Bayes classifier and an SVM.

For the naive Bayes, both the validation score and the training score converge to a value that is quite low with increasing size of the training set. Thus, we will probably not benefit much from more training data.

In contrast, for small amounts of data, the training score of the SVM is much greater than the validation score. Adding more training samples will most likely increase generalization.

We can use the function `learning_curve` to generate the values that are required to plot such a learning curve (number of samples that have been used, the average scores on the training sets and the average scores on the validation sets):

```python
>>> from sklearn.model_selection import learning_curve
>>> from sklearn.svm import SVC

>>> train_sizes, train_scores, valid_scores = learning_curve( ...
...     SVC(kernel='linear'), X, y, train_sizes=[50, 80, 110], cv=5)

>>> train_sizes
array([ 50,  80, 110])

>>> train_scores
array([[[0.98..., 0.98 , 0.98..., 0.98..., 0.98...],
        [0.98..., 1. , 0.98..., 0.98..., 0.98...],
        [0.98..., 1. , 0.98..., 0.98..., 0.99...]]])

>>> valid_scores
array([[[1. , 0.93..., 1. , 1. , 0.96...],
        [1. , 0.96..., 1. , 1. , 0.96...],
        [1. , 0.96..., 1. , 1. , 0.96...]]])
```
4.4 Inspection

Predictive performance is often the main goal of developing machine learning models. Yet summarising performance with an evaluation metric is often insufficient: it assumes that the evaluation metric and test dataset perfectly reflect the target domain, which is rarely true. In certain domains, a model needs a certain level of interpretability before it can be deployed. A model that is exhibiting performance issues needs to be debugged for one to understand the model’s underlying issue. The `sklearn.inspection` module provides tools to help understand the predictions from a model and what affects them. This can be used to evaluate assumptions and biases of a model, design a better model, or to diagnose issues with model performance.

Examples:
- Common pitfalls in interpretation of coefficients of linear models

4.4.1 Partial Dependence and Individual Conditional Expectation plots

Partial dependence plots (PDP) and individual conditional expectation (ICE) plots can be used to visualize and analyze interaction between the target response and a set of input features of interest.

Both PDPs and ICEs assume that the input features of interest are independent from the complement features, and this assumption is often violated in practice. Thus, in the case of correlated features, we will create absurd data points to compute the PDP/ICE.

Partial dependence plots

Partial dependence plots (PDP) show the dependence between the target response and a set of input features of interest, marginalizing over the values of all other input features (the ‘complement’ features). Intuitively, we can interpret the partial dependence as the expected target response as a function of the input features of interest.

Due to the limits of human perception the size of the set of input feature of interest must be small (usually, one or two) thus the input features of interest are usually chosen among the most important features.

The figure below shows two one-way and one two-way partial dependence plots for the California housing dataset, with a `HistGradientBoostingRegressor`:

One-way PDPs tell us about the interaction between the target response and an input feature of interest feature (e.g. linear, non-linear). The left plot in the above figure shows the effect of the average occupancy on the median house price; we can clearly see a linear relationship among them when the average occupancy is inferior to 3 persons. Similarly, we could analyze the effect of the house age on the median house price (middle plot). Thus, these interpretations are marginal, considering a feature at a time.

PDPs with two input features of interest show the interactions among the two features. For example, the two-variable PDP in the above figure shows the dependence of median house price on joint values of house age and average occupants per household. We can clearly see an interaction between the two features: for an average occupancy greater than two, the house price is nearly independent of the house age, whereas for values less than 2 there is a strong dependence on age.

The `sklearn.inspection` module provides a convenience function `plot_partial_dependence` to create one-way and two-way partial dependence plots. In the below example we show how to create a grid of partial dependence plots: two one-way PDPs for the features 0 and 1 and a two-way PDP between the two features:
You can access the newly created figure and Axes objects using `plt.gcf()` and `plt.gca()`.

For multi-class classification, you need to set the class label for which the PDPs should be created via the `target` argument:

```python
>>> from sklearn.datasets import load_iris
>>> iris = load_iris()
>>> mc_clf = GradientBoostingClassifier(n_estimators=10,
...    max_depth=1).fit(iris.data, iris.target)
>>> features = [3, 2, (3, 2)]
>>> plot_partial_dependence(mc_clf, X, features, target=0)
```

The same parameter `target` is used to specify the target in multi-output regression settings.

If you need the raw values of the partial dependence function rather than the plots, you can use the `sklearn.inspection.partial_dependence` function:

```python
>>> from sklearn.inspection import partial_dependence
>>> pdp, axes = partial_dependence(clf, X, [0])
>>> pdp
array([[ 2.466...,  2.466..., ...
```
spond to the axis of the plots.

### Individual conditional expectation (ICE) plot

Similar to a PDP, an individual conditional expectation (ICE) plot shows the dependence between the target function and an input feature of interest. However, unlike a PDP, which shows the average effect of the input feature, an ICE plot visualizes the dependence of the prediction on a feature for each sample separately with one line per sample. Due to the limits of human perception, only one input feature of interest is supported for ICE plots.

The figures below show four ICE plots for the California housing dataset, with a HistGradientBoostingRegressor. The second figure plots the corresponding PD line overlaid on ICE lines.

While the PDPs are good at showing the average effect of the target features, they can obscure a heterogeneous relationship created by interactions. When interactions are present the ICE plot will provide many more insights. For example, we could observe a linear relationship between the median income and the house price in the PD line. However, the ICE lines show that there are some exceptions, where the house price remains constant in some ranges of the median income.

The sklearn.inspection module’s `plot_partial_dependence` convenience function can be used to create ICE plots by setting `kind='individual'`. In the example below, we show how to create a grid of ICE plots:

```python
>>> from sklearn.datasets import make_hastie_10_2
>>> from sklearn.ensemble import GradientBoostingClassifier
>>> from sklearn.inspection import plot_partial_dependence

>>> X, y = make_hastie_10_2(random_state=0)
>>> clf = GradientBoostingClassifier(n_estimators=100, learning_rate=1.0,
... max_depth=1, random_state=0).fit(X, y)
>>> features = [0, 1]
>>> plot_partial_dependence(clf, X, features,
... kind='individual')
```
In ICE plots it might not be easy to see the average effect of the input feature of interest. Hence, it is recommended to use ICE plots alongside PDPs. They can be plotted together with kind='both'.

```python
>>> plot_partial_dependence(clf, X, features, ...
...   kind='both')
```

**Mathematical Definition**

Let $X_S$ be the set of input features of interest (i.e. the `features` parameter) and let $X_C$ be its complement.

The partial dependence of the response $f$ at a point $x_S$ is defined as:

$$pd_{X_S}(x_S) \overset{def}{=} E_{X_C} [f(x_S, X_C)] = \int f(x_S, x_C) p(x_C) dx_C,$$

where $f(x_S, x_C)$ is the response function (`predict`, `predict_proba` or `decision_function`) for a given sample whose values are defined by $x_S$ for the features in $X_S$, and by $x_C$ for the features in $X_C$. Note that $x_S$ and $x_C$ may be tuples.

Computing this integral for various values of $x_S$ produces a PDP plot as above. An ICE line is defined as a single $f(x_S, x_C(i))$ evaluated at at $x_S$.

**Computation methods**

There are two main methods to approximate the integral above, namely the ‘brute’ and ‘recursion’ methods. The `method` parameter controls which method to use.

The ‘brute’ method is a generic method that works with any estimator. Note that computing ICE plots is only supported with the ‘brute’ method. It approximates the above integral by computing an average over the data $X$:

$$pd_{X_S}(x_S) \approx \frac{1}{n_{\text{samples}}} \sum_{i=1}^n f(x_S, x_C(i)),$$

where $x_C(i)$ is the value of the $i$-th sample for the features in $X_C$. For each value of $x_S$, this method requires a full pass over the dataset $X$ which is computationally intensive.

Each of the $f(x_S, x_C(i))$ corresponds to one ICE line evaluated at $x_S$. Computing this for multiple values of $x_S$, one obtains a full ICE line. As one can see, the average of the ICE lines correspond to the partial dependence line.

The ‘recursion’ method is faster than the ‘brute’ method, but it is only supported for PDP plots by some tree-based estimators. It is computed as follows. For a given point $x_S$, a weighted tree traversal is performed: if a split node involves an input feature of interest, the corresponding left or right branch is followed; otherwise both branches are followed, each branch being weighted by the fraction of training samples that entered that branch. Finally, the partial dependence is given by a weighted average of all the visited leaves values.

With the ‘brute’ method, the parameter $X$ is used both for generating the grid of values $x_S$ and the complement feature values $x_C$. However with the ‘recursion’ method, $X$ is only used for the grid values: implicitly, the $x_C$ values are those of the training data.

By default, the ‘recursion’ method is used for plotting PDPs on tree-based estimators that support it, and ‘brute’ is used for the rest.

**Note:** While both methods should be close in general, they might differ in some specific settings. The ‘brute’ method assumes the existence of the data points $(x_S, x_C(i))$. When the features are correlated, such artificial samples may have a very low probability mass. The ‘brute’ and ‘recursion’ methods will likely disagree regarding the value of the
partial dependence, because they will treat these unlikely samples differently. Remember, however, that the primary assumption for interpreting PDPs is that the features should be independent.

### 4.4.2 Permutation feature importance

Permutation feature importance is a model inspection technique that can be used for any *fitted estimator* when the data is tabular. This is especially useful for non-linear or opaque *estimators*. The permutation feature importance is defined to be the decrease in a model score when a single feature value is randomly shuffled\(^1\). This procedure breaks the relationship between the feature and the target, thus the drop in the model score is indicative of how much the model depends on the feature. This technique benefits from being model agnostic and can be calculated many times with different permutations of the feature.

The *permutation_importance* function calculates the feature importance of *estimators* for a given dataset. The *n_repeats* parameter sets the number of times a feature is randomly shuffled and returns a sample of feature importances.

Let’s consider the following trained regression model:

```python
>>> from sklearn.datasets import load_diabetes
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.linear_model import Ridge

>>> diabetes = load_diabetes()

>>> X_train, X_val, y_train, y_val = train_test_split(diabetes.data, diabetes.target, random_state=0)

>>> model = Ridge(alpha=1e-2).fit(X_train, y_train)

>>> model.score(X_val, y_val)
0.356...
```

Its validation performance, measured via the \(R^2\) score, is significantly larger than the chance level. This makes it possible to use the *permutation_importance* function to probe which features are most predictive:

```python
>>> from sklearn.inspection import permutation_importance

>>> r = permutation_importance(model, X_val, y_val, n_repeats=30, random_state=0)
```

... for i in r.importances_mean.argsort()[::-1]:
...
... if r.importances_mean[i] - 2 * r.importances_std[i] > 0:
...
...     print(f"{diabetes.feature_names[i]}: <8")
...     print(f"{r.importances_mean[i]:.3f}")
...     print(f" +/- {r.importances_std[i]:.3f}"
...
sg5  0.204 +/- 0.050
bmi  0.176 +/- 0.048
bp   0.088 +/- 0.033
sex  0.056 +/- 0.023

Note that the importance values for the top features represent a large fraction of the reference score of 0.356.

Permutation importances can be computed either on the training set or on a held-out testing or validation set. Using a held-out set makes it possible to highlight which features contribute the most to the generalization power of the inspected model. Features that are important on the training set but not on the held-out set might cause the model to overfit.

**Warning:** Features that are deemed of *low importance for a bad model* (low cross-validation score) could be *very important for a good model*. Therefore it is always important to evaluate the predictive power of a model using a held-out set (or better with cross-validation) prior to computing importances. Permutation importance does not reflect to the intrinsic predictive value of a feature by itself but how important this feature is for a particular model.

**Outline of the permutation importance algorithm**

- Inputs: fitted predictive model $m$, tabular dataset (training or validation) $D$.
- Compute the reference score $s$ of the model $m$ on data $D$ (for instance the accuracy for a classifier or the $R^2$ for a regressor).
- For each feature $j$ (column of $D$):
  - For each repetition $k$ in $1, \ldots, K$:
    - Randomly shuffle column $j$ of dataset $D$ to generate a corrupted version of the data named $\tilde{D}_{k,j}$.
    - Compute the score $s_{k,j}$ of model $m$ on corrupted data $\tilde{D}_{k,j}$.
  - Compute importance $i_j$ for feature $f_j$ defined as:

$$i_j = s - \frac{1}{K} \sum_{k=1}^{K} s_{k,j}$$
Relation to impurity-based importance in trees

Tree-based models provide an alternative measure of feature importances based on the mean decrease in impurity (MDI). Impurity is quantified by the splitting criterion of the decision trees (Gini, Entropy or Mean Squared Error). However, this method can give high importance to features that may not be predictive on unseen data when the model is overfitting. Permutation-based feature importance, on the other hand, avoids this issue, since it can be computed on unseen data.

Furthermore, impurity-based feature importance for trees are strongly biased and favor high cardinality features (typically numerical features) over low cardinality features such as binary features or categorical variables with a small number of possible categories.

Permutation-based feature importances do not exhibit such a bias. Additionally, the permutation feature importance may be computed performance metric on the model predictions predictions and can be used to analyze any model class (not just tree-based models).

The following example highlights the limitations of impurity-based feature importance in contrast to permutation-based feature importance: Permutation Importance vs Random Forest Feature Importance (MDI).

Misleading values on strongly correlated features

When two features are correlated and one of the features is permuted, the model will still have access to the feature through its correlated feature. This will result in a lower importance value for both features, where they might actually be important.

One way to handle this is to cluster features that are correlated and only keep one feature from each cluster. This strategy is explored in the following example: Permutation Importance with Multicollinear or Correlated Features.

Examples:

- Permutation Importance vs Random Forest Feature Importance (MDI)
- Permutation Importance with Multicollinear or Correlated Features

4.5 Visualizations

Scikit-learn defines a simple API for creating visualizations for machine learning. The key feature of this API is to allow for quick plotting and visual adjustments without recalculation. In the following example, we plot a ROC curve for a fitted support vector machine:

```python
from sklearn.model_selection import train_test_split
from sklearn.svm import SVC
from sklearn.metrics import plot_roc_curve
from sklearn.datasets import load_wine

X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=42)
svc = SVC(random_state=42)
svc.fit(X_train, y_train)
```
The returned `svc_disp` object allows us to continue using the already computed ROC curve for SVC in future plots. In this case, the `svc_disp` is a `RocCurveDisplay` that stores the computed values as attributes called `roc_auc`, `fpr`, and `tpr`. Next, we train a random forest classifier and plot the previously computed roc curve again by using the plot method of the `Display` object.

```python
import matplotlib.pyplot as plt
from sklearn.ensemble import RandomForestClassifier

rfc = RandomForestClassifier(random_state=42)
rfc.fit(X_train, y_train)

ax = plt.gca()
rfc_disp = plot_roc_curve(rfc, X_test, y_test, ax=ax, alpha=0.8)
svc_disp.plot(ax=ax, alpha=0.8)
```

Notice that we pass `alpha=0.8` to the plot functions to adjust the alpha values of the curves.

**Examples:**

- *ROC Curve with Visualization API*
- *Advanced Plotting With Partial Dependence*
- *Visualizations with Display Objects*
4.5.1 Available Plotting Utilities

Functions

- `inspection.plot_partial_dependence(...)`, Partial dependence (PD) and individual conditional expectation (ICE) plots.
- `metrics.plot_confusion_matrix(estimator, X, ...)`, Plot Confusion Matrix.
- `metrics.plot_det_curve(estimator, X, y, ...)`, Plot detection error tradeoff (DET) curve.
- `metrics.plot_precision_recall_curve(...)`, Plot Precision Recall Curve for binary classifiers.
- `metrics.plot_roc_curve(estimator, X, y, ...)`, Plot Receiver operating characteristic (ROC) curve.

Display Objects

- `metrics.DetCurveDisplay(*, fpr, fnr, ...)`, DET curve visualization.
- `metrics.PrecisionRecallDisplay(**kwargs)` Precision Recall visualization.
- `metrics.RocCurveDisplay(**kwargs)` ROC Curve visualization.

4.6 Dataset transformations

scikit-learn provides a library of transformers, which may clean (see Preprocessing data), reduce (see Unsupervised dimensionality reduction), expand (see Kernel Approximation) or generate (see Feature extraction) feature representations.

4.6.1 Pipelines and composite estimators

Transformers are usually combined with classifiers, regressors or other estimators to build a composite estimator. The most common tool is a Pipeline. Pipeline is often used in combination with FeatureUnion which concatenates the output of transformers into a composite feature space. TransformedTargetRegressor deals with transforming the target (i.e. log-transform y). In contrast, Pipelines only transform the observed data (X).
Pipeline: chaining estimators

Pipeline can be used to chain multiple estimators into one. This is useful as there is often a fixed sequence of steps in processing the data, for example feature selection, normalization and classification. Pipeline serves multiple purposes here:

Convenience and encapsulation  You only have to call fit and predict once on your data to fit a whole sequence of estimators.

Joint parameter selection  You can grid search over parameters of all estimators in the pipeline at once.

Safety  Pipelines help avoid leaking statistics from your test data into the trained model in cross-validation, by ensuring that the same samples are used to train the transformers and predictors.

All estimators in a pipeline, except the last one, must be transformers (i.e. must have a transform method). The last estimator may be any type (transformer, classifier, etc.).

Usage

Construction

The Pipeline is built using a list of (key, value) pairs, where the key is a string containing the name you want to give this step and value is an estimator object:

>>> from sklearn.pipeline import Pipeline
>>> from sklearn.svm import SVC
>>> from sklearn.decomposition import PCA

>>> estimators = [('reduce_dim', PCA()), ('clf', SVC())]

>>> pipe = Pipeline(estimators)

>>> pipe
Pipeline(steps=[('reduce_dim', PCA()), ('clf', SVC())])

The utility function make_pipeline is a shorthand for constructing pipelines; it takes a variable number of estimators and returns a pipeline, filling in the names automatically:

>>> from sklearn.pipeline import make_pipeline
>>> from sklearn.naive_bayes import MultinomialNB
>>> from sklearn.preprocessing import Binarizer

>>> make_pipeline(Binarizer(), MultinomialNB())
Pipeline(steps=[('binarizer', Binarizer()), ('multinomialnb', MultinomialNB())])

Accessing steps

The estimators of a pipeline are stored as a list in the steps attribute, but can be accessed by index or name by indexing (with [idx]) the Pipeline:

>>> pipe.steps[0]
('reduce_dim', PCA())

>>> pipe[0]
PCA()

>>> pipe['reduce_dim']
PCA()

Pipeline's named_steps attribute allows accessing steps by name with tab completion in interactive environments:
A sub-pipeline can also be extracted using the slicing notation commonly used for Python Sequences such as lists or strings (although only a step of 1 is permitted). This is convenient for performing only some of the transformations (or their inverse):

```
>>> pipe[:1]
Pipeline(steps=[('reduce_dim', PCA())])
>>> pipe[-1:]
Pipeline(steps=[('clf', SVC())])
```

**Nested parameters**

Parameters of the estimators in the pipeline can be accessed using the `<estimator>__<parameter>` syntax:

```
>>> pipe.set_params(clf__C=10)
Pipeline(steps=[('reduce_dim', PCA()), ('clf', SVC(C=10))])
```

This is particularly important for doing grid searches:

```
>>> from sklearn.model_selection import GridSearchCV
>>> param_grid = dict(reduce_dim__n_components=[2, 5, 10],
                    clf__C=[0.1, 10, 100])
>>> grid_search = GridSearchCV(pipe, param_grid=param_grid)
```

Individual steps may also be replaced as parameters, and non-final steps may be ignored by setting them to 'passthrough':

```
>>> from sklearn.linear_model import LogisticRegression
>>> param_grid = dict(reduce_dim=[('passthrough', PCA(5), PCA(10))],
                    clf=[SVC(), LogisticRegression()],
                    clf__C=[0.1, 10, 100])
>>> grid_search = GridSearchCV(pipe, param_grid=param_grid)
```

The estimators of the pipeline can be retrieved by index:

```
>>> pipe[0]
PCA()
```

or by name:

```
>>> pipe['reduce_dim']
PCA()
```

**Examples:**

- **Pipeline Anova SVM**
- **Sample pipeline for text feature extraction and evaluation**
- **Pipelining: chaining a PCA and a logistic regression**
- **Explicit feature map approximation for RBF kernels**
• SVM-Anova: SVM with univariate feature selection
• Selecting dimensionality reduction with Pipeline and GridSearchCV

See Also:

• Composite estimators and parameter spaces

Notes

Calling `fit` on the pipeline is the same as calling `fit` on each estimator in turn, `transform` the input and pass it on to the next step. The pipeline has all the methods that the last estimator in the pipeline has, i.e. if the last estimator is a classifier, the `Pipeline` can be used as a classifier. If the last estimator is a transformer, again, so is the pipeline.

Caching transformers: avoid repeated computation

Fitting transformers may be computationally expensive. With its `memory` parameter set, `Pipeline` will cache each transformer after calling `fit`. This feature is used to avoid computing the fit transformers within a pipeline if the parameters and input data are identical. A typical example is the case of a grid search in which the transformers can be fitted only once and reused for each configuration.

The parameter `memory` is needed in order to cache the transformers. `memory` can be either a string containing the directory where to cache the transformers or a `joblib.Memory` object:

```python
>>> from tempfile import mkdtemp
>>> from sklearn.decomposition import PCA
>>> from sklearn.pipeline import Pipeline

estimators = [('reduce_dim', PCA()), ('clf', SVC())]

cachedir = mkdtemp()

pipe = Pipeline(estimators, memory=cachedir)

# Clear the cache directory when you don't need it anymore
rmtree(cachedir)
```

Warning: Side effect of caching transformers

Using a `Pipeline` without cache enabled, it is possible to inspect the original instance such as:

```python
>>> from sklearn.datasets import load_digits

X_digits, y_digits = load_digits(return_X_y=True)

pca1 = PCA()

svm1 = SVC()

pipe = Pipeline([('reduce_dim', pca1), ('clf', svm1)])

pipe.fit(X_digits, y_digits)

# The pca instance can be inspected directly

print(pca1.components_)
```

[[-1.77484909e-19 ... 4.07058917e-18]]
Enabling caching triggers a clone of the transformers before fitting. Therefore, the transformer instance given to the pipeline cannot be inspected directly. In following example, accessing the PCA instance pca2 will raise an AttributeError since pca2 will be an unfitted transformer. Instead, use the attribute named_steps to inspect estimators within the pipeline:

```python
>>> cachedir = mkdtemp()
>>> pca2 = PCA()
>>> svm2 = SVC()
>>> cached_pipe = Pipeline([('reduce_dim', pca2), ('clf', svm2)],
                        memory=cachedir)
>>> cached_pipe.fit(X_digits, y_digits)
Pipeline(memory=..., steps=[('reduce_dim', PCA()), ('clf', SVC())])
>>> print(cached_pipe.named_steps['reduce_dim'].components_)
[[-1.77484909e-19 ... 4.07058917e-18]]
>>> # Remove the cache directory
>>> rmtree(cachedir)
```

Examples:

- Selecting dimensionality reduction with Pipeline and GridSearchCV

Transforming target in regression

`TransformedTargetRegressor` transforms the targets y before fitting a regression model. The predictions are mapped back to the original space via an inverse transform. It takes as an argument the regressor that will be used for prediction, and the transformer that will be applied to the target variable:

```python
>>> import numpy as np
>>> from sklearn.datasets import fetch_california_housing
>>> from sklearn.compose import TransformedTargetRegressor
>>> from sklearn.preprocessing import QuantileTransformer
>>> from sklearn.linear_model import LinearRegression
>>> from sklearn.model_selection import train_test_split

>>> X, y = fetch_california_housing(return_X_y=True)
>>> X, y = X[:2000, :], y[:2000]  # select a subset of data
>>> transformer = QuantileTransformer(output_distribution='normal')
>>> regressor = LinearRegression()
>>> regr = TransformedTargetRegressor(regressor=regressor,
                                    transformer=transformer)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
>>> regr.fit(X_train, y_train)
TransformedTargetRegressor(...)
>>> print('R2 score: {:.2f}'.format(regr.score(X_test, y_test)))
R2 score: 0.61
>>> raw_target_regr = LinearRegression().fit(X_train, y_train)
>>> print('R2 score: {:.2f}'.format(raw_target_regr.score(X_test, y_test)))
R2 score: 0.59
```

For simple transformations, instead of a Transformer object, a pair of functions can be passed, defining the transformation and its inverse mapping:

```python
>>> def func(x):
...     return np.log(x)
```
Subsequently, the object is created as:

```python
def inverse_func(x):
    return np.exp(x)
```

By default, the provided functions are checked at each fit to be the inverse of each other. However, it is possible to bypass this checking by setting `check_inverse` to `False`:

```python
def inverse_func(x):
    return x
```

**Note:** The transformation can be triggered by setting either `transformer` or the pair of functions `func` and `inverse_func`. However, setting both options will raise an error.

### Examples:

- **Effect of transforming the targets in regression model**

### FeatureUnion: composite feature spaces

`FeatureUnion` combines several transformer objects into a new transformer that combines their output. A `FeatureUnion` takes a list of transformer objects. During fitting, each of these is fit to the data independently. The transformers are applied in parallel, and the feature matrices they output are concatenated side-by-side into a larger matrix.

When you want to apply different transformations to each field of the data, see the related class `ColumnTransformer` (see [user guide](#)).

`FeatureUnion` serves the same purposes as `Pipeline` - convenience and joint parameter estimation and validation.

`FeatureUnion` and `Pipeline` can be combined to create complex models.

(A `FeatureUnion` has no way of checking whether two transformers might produce identical features. It only produces a union when the feature sets are disjoint, and making sure they are is the caller’s responsibility.)
Usage

A `FeatureUnion` is built using a list of `(key, value)` pairs, where the key is the name you want to give to a given transformation (an arbitrary string; it only serves as an identifier) and value is an estimator object:

```python
>>> from sklearn.pipeline import FeatureUnion
>>> from sklearn.decomposition import PCA
>>> from sklearn.decomposition import KernelPCA

estimators = [('linear_pca', PCA()), ('kernel_pca', KernelPCA())]
combined = FeatureUnion(estimators)
```

Like pipelines, feature unions have a shorthand constructor called `make_union` that does not require explicit naming of the components.

Like Pipeline, individual steps may be replaced using `set_params`, and ignored by setting to 'drop':

```python
>>> combined.set_params(kernel_pca='drop')
```

Examples:

- Concatenating multiple feature extraction methods

ColumnTransformer for heterogeneous data

Many datasets contain features of different types, say text, floats, and dates, where each type of feature requires separate preprocessing or feature extraction steps. Often it is easiest to preprocess data before applying scikit-learn methods, for example using pandas. Processing your data before passing it to scikit-learn might be problematic for one of the following reasons:

1. Incorporating statistics from test data into the preprocessor makes cross-validation scores unreliable (known as data leakage), for example in the case of scalers or imputing missing values.

2. You may want to include the parameters of the preprocessors in a parameter search.

The `ColumnTransformer` helps performing different transformations for different columns of the data, within a `Pipeline` that is safe from data leakage and that can be parametrized. `ColumnTransformer` works on arrays, sparse matrices, and pandas DataFrames.

To each column, a different transformation can be applied, such as preprocessing or a specific feature extraction method:

```python
>>> import pandas as pd
>>> X = pd.DataFrame(
...     {'city': ['London', 'London', 'Paris', 'Sallisaw'],
...     'title': ['His Last Bow', "How Watson Learned the Trick",
...               "A Moveable Feast", "The Grapes of Wrath"],
...     'expert_rating': [5, 3, 4, 5],
...     'user_rating': [4, 5, 4, 3]})
```

For this data, we might want to encode the 'city' column as a categorical variable using `OneHotEncoder` but apply a `CountVectorizer` to the 'title' column. As we might use multiple feature extraction methods on the
same column, we give each transformer a unique name, say 'city_category' and 'title_bow'. By default, the remaining rating columns are ignored (remainder='drop'):

```python
>>> from sklearn.compose import ColumnTransformer
>>> from sklearn.feature_extraction.text import CountVectorizer
>>> from sklearn.preprocessing import OneHotEncoder

>>> column_trans = ColumnTransformer(
...     [('city_category', OneHotEncoder(dtype='int'), ['city']),
...      ('title_bow', CountVectorizer(), 'title')],
...     remainder='drop')

>>> column_trans.fit(X)
ColumnTransformer(transformers=[('city_category', OneHotEncoder(dtype='int'),
                                 ['city']),
                                 ('title_bow', CountVectorizer(), 'title')])

>>> column_trans.get_feature_names()
['city_category__x0_London', 'city_category__x0_Paris',
 'city_category__x0_Sallisaw', 'title_bow__bow', 'title_bow__feast',
 'title_bow__grapes', 'title_bow__his', 'title_bow__how', 'title_bow__last',
 'title_bow__learned', 'title_bow__moveable', 'title_bow__of',
 'title_bow__the', 'title_bow__trick', 'title_bow__watson',
 'title_bow__wrath']

>>> column_trans.transform(X).toarray()
array([[1, 0, 0, 0, 1, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0],
       [1, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0, 0, 0, 0],
       [0, 1, 0, 0, 0, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0],
       [0, 0, 1, 0, 0, 0, 0, 0, 0, 0, 0, 1, 0, 0, 0]])
```

In the above example, the CountVectorizer expects a 1D array as input and therefore the columns were specified as a string ('title'). However, OneHotEncoder as most of other transformers expects 2D data, therefore in that case you need to specify the column as a list of strings (['city']).

Apart from a scalar or a single item list, the column selection can be specified as a list of multiple items, an integer array, a slice, a boolean mask, or with a make_column_selector. The make_column_selector is used to select columns based on data type or column name:

```python
>>> from sklearn.preprocessing import StandardScaler
>>> from sklearn.compose import make_column_selector

>>> ct = ColumnTransformer([  
...     ('scale', StandardScaler(),
...      make_column_selector(dtype_include=np.number)),
...     ('onehot',
...      OneHotEncoder(),
...      make_column_selector(pattern='city', dtype_include=object))]

>>> ct.fit_transform(X)
array([[ 0.904..., 0. , 1. , 0. , 0. , 0. ],
       [-1.507..., 1.414..., 1. , 0. , 0. ],
       [-0.301..., 0. , 0. , 1. , 0. , 0. ],
       [ 0.904..., -1.414..., 0. , 0. , 1. ]])
```

Strings can reference columns if the input is a DataFrame, integers are always interpreted as the positional columns.

We can keep the remaining rating columns by setting remainder='passthrough'. The values are appended to the end of the transformation:

```python
>>> column_trans = ColumnTransformer(
...     [('city_category', OneHotEncoder(dtype='int'), ['city']),
```
The `remainder` parameter can be set to an estimator to transform the remaining rating columns. The transformed values are appended to the end of the transformation:

```python
>>> from sklearn.preprocessing import MinMaxScaler

>>> column_trans = ColumnTransformer(  
...     [('city_category', OneHotEncoder(), ['city']),  
...     ('title_bow', CountVectorizer(), 'title'),  
...     remainder=MinMaxScaler())

>>> column_trans.fit_transform(X)[:, -2:]  
array([[1. , 0.5],  
       [0. , 1. ],  
       [0.5, 0.5],  
       [1. , 0. ]])
```

The `make_column_transformer` function is available to more easily create a `ColumnTransformer` object. Specifically, the names will be given automatically. The equivalent for the above example would be:

```python
>>> from sklearn.compose import make_column_transformer

>>> column_trans = make_column_transformer(  
...     (OneHotEncoder(), ['city']),  
...     (CountVectorizer(), 'title'),  
...     remainder=MinMaxScaler())

>>> column_trans
ColumnTransformer(remainder=MinMaxScaler(),  
                 transformers=[('onehotencoder', OneHotEncoder(), ['city']),  
                                ('countvectorizer', CountVectorizer(),  
                                 'title')])
```

### Visualizing Composite Estimators

Estimators can be displayed with a HTML representation when shown in a Jupyter notebook. This can be useful to diagnose or visualize a Pipeline with many estimators. This visualization is activated by setting the `display` option in `set_config`:

```python
>>> from sklearn import set_config

>>> set_config(display='diagram')

>>> # displays HTML representation in a Jupyter context

>>> column_trans
```

An example of the HTML output can be seen in the HTML representation of Pipeline section of *Column Transformer with Mixed Types*. As an alternative, the HTML can be written to a file using `estimator_html_repr`:

```python
>>> from sklearn.utils import estimator_html_repr

>>> with open('my_estimator.html', 'w') as f:
...     f.write(estimator_html_repr(clf))
```
**Examples:**

- *Column Transformer with Heterogeneous Data Sources*
- *Column Transformer with Mixed Types*

### 4.6.2 Feature extraction

The `sklearn.feature_extraction` module can be used to extract features in a format supported by machine learning algorithms from datasets consisting of formats such as text and image.

**Note:** Feature extraction is very different from *Feature selection*: the former consists in transforming arbitrary data, such as text or images, into numerical features usable for machine learning. The latter is a machine learning technique applied on these features.

#### Loading features from dicts

The class `DictVectorizer` can be used to convert feature arrays represented as lists of standard Python `dict` objects to the NumPy/SciPy representation used by scikit-learn estimators.

While not particularly fast to process, Python’s `dict` has the advantages of being convenient to use, being sparse (absent features need not be stored) and storing feature names in addition to values.

`DictVectorizer` implements what is called one-of-K or “one-hot” coding for categorical (aka nominal, discrete) features. Categorical features are “attribute-value” pairs where the value is restricted to a list of discrete of possibilities without ordering (e.g. topic identifiers, types of objects, tags, names...).

In the following, “city” is a categorical attribute while “temperature” is a traditional numerical feature:

```python
>>> measurements = [
    ...     {'city': 'Dubai', 'temperature': 33.},
    ...     {'city': 'London', 'temperature': 12.},
    ...     {'city': 'San Francisco', 'temperature': 18.},
    ... ]

>>> from sklearn.feature_extraction import DictVectorizer
>>> vec = DictVectorizer()

>>> vec.fit_transform(measurements).toarray()
array([[ 1., 0., 0., 33.],
       [ 0., 1., 0., 12.],
       [ 0., 0., 1., 18.]])

>>> vec.get_feature_names()
['city=Dubai', 'city=London', 'city=San Francisco', 'temperature']
```

`DictVectorizer` accepts multiple string values for one feature, like, e.g., multiple categories for a movie.

Assume a database classifies each movie using some categories (not mandated) and its year of release.

```python
>>> movie_entry = [
        ...     {'category': ['thriller', 'drama'], 'year': 2003},
        ...     {'category': ['animation', 'family'], 'year': 2011},
        ...     {'year': 1974},
        ...
    ...
```
DictVectorizer is also a useful representation transformation for training sequence classifiers in Natural Language Processing models that typically work by extracting feature windows around a particular word of interest.

For example, suppose that we have a first algorithm that extracts Part of Speech (PoS) tags that we want to use as complementary tags for training a sequence classifier (e.g. a chunker). The following dict could be such a window of features extracted around the word ‘sat’ in the sentence ‘The cat sat on the mat’:

```python
>>> pos_window = [
...     {
...         'word-2': 'the',
...         'pos-2': 'DT',
...         'word-1': 'cat',
...         'pos-1': 'NN',
...         'word+1': 'on',
...         'pos+1': 'PP',
...     },
...     # in a real application one would extract many such dictionaries
... ]
```

This description can be vectorized into a sparse two-dimensional matrix suitable for feeding into a classifier (maybe after being piped into a TfidfTransformer for normalization):

```python
>>> vec = DictVectorizer()
>>> pos_vectorized = vec.fit_transform(pos_window)
>>> pos_vectorized
<1x6 sparse matrix of type '<... 'numpy.float64'>'
     with 6 stored elements in Compressed Sparse ... format>
>>> pos_vectorized.toarray()
array([[1., 1., 1., 1., 1., 1.]])
>>> vec.get_feature_names()
['pos+1=PP', 'pos-1=NN', 'pos-2=DT', 'word+1=on', 'word-1=cat', 'word-2=the']
```

As you can imagine, if one extracts such a context around each individual word of a corpus of documents the resulting matrix will be very wide (many one-hot-features) with most of them being valued to zero most of the time. So as to make the resulting data structure able to fit in memory the DictVectorizer class uses a scipy.sparse matrix by default instead of a numpy.ndarray.
Feature hashing

The class FeatureHasher is a high-speed, low-memory vectorizer that uses a technique known as feature hashing, or the “hashing trick”. Instead of building a hash table of the features encountered in training, as the vectorizers do, instances of FeatureHasher apply a hash function to the features to determine their column index in sample matrices directly. The result is increased speed and reduced memory usage, at the expense of inspectability; the hasher does not remember what the input features looked like and has no inverse_transform method.

Since the hash function might cause collisions between (unrelated) features, a signed hash function is used and the sign of the hash value determines the sign of the value stored in the output matrix for a feature. This way, collisions are likely to cancel out rather than accumulate error, and the expected mean of any output feature’s value is zero. This mechanism is enabled by default with alternate_sign=True and is particularly useful for small hash table sizes (n_features < 10000). For large hash table sizes, it can be disabled, to allow the output to be passed to estimators like MultinomialNB or chi2 feature selectors that expect non-negative inputs.

FeatureHasher accepts either mappings (like Python’s dict and its variants in the collections module), (feature, value) pairs, or strings, depending on the constructor parameter input_type. Mapping are treated as lists of (feature, value) pairs, while single strings have an implicit value of 1, so ['feat1', 'feat2', 'feat3'] is interpreted as [('feat1', 1), ('feat2', 1), ('feat3', 1)]. If a single feature occurs multiple times in a sample, the associated values will be summed (so ('feat', 2) and ('feat', 3.5) become ('feat', 5.5)). The output from FeatureHasher is always a scipy.sparse matrix in the CSR format.

Feature hashing can be employed in document classification, but unlike CountVectorizer, FeatureHasher does not do word splitting or any other preprocessing except Unicode-to-UTF-8 encoding; see Vectorizing a large text corpus with the hashing trick, below, for a combined tokenizer hasher.

As an example, consider a word-level natural language processing task that needs features extracted from (token, part_of_speech) pairs. One could use a Python generator function to extract features:

```python
def token_features(token, part_of_speech):
    if token.isdigit():
        yield "numeric"
    else:
        yield "token={!r}".format(token.lower())
        yield "token,pos={!r},{!r}".format(token, part_of_speech)
        if token[0].isupper():
            yield "uppercase_initial"
        if token.isupper():
            yield "all_uppercase"
        yield "pos={!r}".format(part_of_speech)
```

Then, the raw_X to be fed to FeatureHasher.transform can be constructed using:

```python
raw_X = (token_features(tok, pos_tagger(tok)) for tok in corpus)
```

and fed to a hasher with:

```python
hasher = FeatureHasher(input_type='string')
X = hasher.transform(raw_X)
```

to get a scipy.sparse matrix X.

Note the use of a generator comprehension, which introduces laziness into the feature extraction: tokens are only processed on demand from the hasher.
Implementation details

*FeatureHasher* uses the signed 32-bit variant of MurmurHash3. As a result (and because of limitations in `scipy.sparse`), the maximum number of features supported is currently $2^{31} - 1$.

The original formulation of the hashing trick by Weinberger et al. used two separate hash functions $h$ and $\zeta$ to determine the column index and sign of a feature, respectively. The present implementation works under the assumption that the sign bit of MurmurHash3 is independent of its other bits.

Since a simple modulo is used to transform the hash function to a column index, it is advisable to use a power of two as the `n_features` parameter; otherwise the features will not be mapped evenly to the columns.

Text feature extraction

The Bag of Words representation

Text Analysis is a major application field for machine learning algorithms. However the raw data, a sequence of symbols cannot be fed directly to the algorithms themselves as most of them expect numerical feature vectors with a fixed size rather than the raw text documents with variable length.

In order to address this, scikit-learn provides utilities for the most common ways to extract numerical features from text content, namely:

- **tokenizing** strings and giving an integer id for each possible token, for instance by using white-spaces and punctuation as token separators.
- **counting** the occurrences of tokens in each document.
- **normalizing** and weighting with diminishing importance tokens that occur in the majority of samples / documents.

In this scheme, features and samples are defined as follows:

- each **individual token occurrence frequency** (normalized or not) is treated as a feature.
- the vector of all the token frequencies for a given **document** is considered a multivariate sample.

A corpus of documents can thus be represented by a matrix with one row per document and one column per token (e.g. word) occurring in the corpus.

We call **vectorization** the general process of turning a collection of text documents into numerical feature vectors. This specific strategy (tokenization, counting and normalization) is called the **Bag of Words** or “Bag of n-grams” representation. Documents are described by word occurrences while completely ignoring the relative position information of the words in the document.
Sparsity

As most documents will typically use a very small subset of the words used in the corpus, the resulting matrix will have many feature values that are zeros (typically more than 99% of them).

For instance a collection of 10,000 short text documents (such as emails) will use a vocabulary with a size in the order of 100,000 unique words in total while each document will use 100 to 1000 unique words individually.

In order to be able to store such a matrix in memory but also to speed up algebraic operations matrix / vector, implementations will typically use a sparse representation such as the implementations available in the `scipy.sparse` package.

Common Vectorizer usage

`CountVectorizer` implements both tokenization and occurrence counting in a single class:

```python
>>> from sklearn.feature_extraction.text import CountVectorizer

This model has many parameters, however the default values are quite reasonable (please see the reference documentation for the details):

```python
>>> vectorizer = CountVectorizer()
>>> vectorizer
CountVectorizer()
```

Let’s use it to tokenize and count the word occurrences of a minimalistic corpus of text documents:

```python
>>> corpus = [
... 'This is the first document.',
... 'This is the second document.',
... 'And the third one.',
... 'Is this the first document?',
... ]
>>> X = vectorizer.fit_transform(corpus)
>>> X
<4x9 sparse matrix of type '<... 'numpy.int64'>'
   with 19 stored elements in Compressed Sparse ... format>
```

The default configuration tokenizes the string by extracting words of at least 2 letters. The specific function that does this step can be requested explicitly:

```python
>>> analyze = vectorizer.build_analyzer()
>>> analyze("This is a text document to analyze.") == ('this', 'is', 'text', 'document', 'to', 'analyze')
True
```

Each term found by the analyzer during the fit is assigned a unique integer index corresponding to a column in the resulting matrix. This interpretation of the columns can be retrieved as follows:

```python
>>> vectorizer.get_feature_names() == ('and', 'document', 'first', 'is', 'one',
... 'second', 'the', 'third', 'this')
True
```

```python
>>> X.toarray()
array([[0, 1, 1, 1, 0, 0, 1, 0, 1],
(continues on next page)
The converse mapping from feature name to column index is stored in the `vocabulary_` attribute of the vectorizer:

```python
>>> vectorizer.vocabulary_.get('document')
```

Hence words that were not seen in the training corpus will be completely ignored in future calls to the transform method:

```python
>>> vectorizer.transform(['Something completely new.']).toarray()
array([[0, 0, 0, 0, 0, 0, 0, 0, 0]])
```

Note that in the previous corpus, the first and the last documents have exactly the same words hence are encoded in equal vectors. In particular we lose the information that the last document is an interrogative form. To preserve some of the local ordering information we can extract 2-grams of words in addition to the 1-grams (individual words):

```python
>>> bigram_vectorizer = CountVectorizer(ngram_range=(1, 2),
... token_pattern=r'\b\w+\b', min_df=1)
>>> analyze = bigram_vectorizer.build_analyzer()
>>> analyze('Bi-grams are cool!') == ('bi', 'grams', 'are', 'cool', 'bi grams', 'grams are', 'are cool')
True
```

The vocabulary extracted by this vectorizer is hence much bigger and can now resolve ambiguities encoded in local positioning patterns:

```python
>>> X_2 = bigram_vectorizer.fit_transform(corpus).toarray()
>>> X_2
```

In particular the interrogative form “Is this” is only present in the last document:

```python
>>> feature_index = bigram_vectorizer.vocabulary_.get('is this')
>>> X_2[:, feature_index]
array([0, 0, 1, ...])
```

### Using stop words

Stop words are words like “and”, “the”, “him”, which are presumed to be uninformative in representing the content of a text, and which may be removed to avoid them being construed as signal for prediction. Sometimes, however, similar words are useful for prediction, such as in classifying writing style or personality.

There are several known issues in our provided ‘english’ stop word list. It does not aim to be a general, ‘one-size-fits-all’ solution as some tasks may require a more custom solution. See [NQY18] for more details.

Please take care in choosing a stop word list. Popular stop word lists may include words that are highly informative to some tasks, such as `computer`.

You should also make sure that the stop word list has had the same preprocessing and tokenization applied as the one used in the vectorizer. The word `we’ve` is split into `we` and `ve` by CountVectorizer’s default tokenizer, so if `we’ve` is in

---

**4.6. Dataset transformations**

---

595
stop_words, but ve is not, ve will be retained from we’ve in transformed text. Our vectorizers will try to identify and warn about some kinds of inconsistencies.

Tf–idf term weighting

In a large text corpus, some words will be very present (e.g. “the”, “a”, “is” in English) hence carrying very little meaningful information about the actual contents of the document. If we were to feed the direct count data directly to a classifier those very frequent terms would shadow the frequencies of rarer yet more interesting terms.

In order to re-weight the count features into floating point values suitable for usage by a classifier it is very common to use the tf–idf transform.

Tf means term-frequency while tf–idf means term-frequency times inverse document-frequency: tf-idf(t,d) = tf(t,d) \times idf(t).

Using the TfidfTransformer’s default settings, TfidfTransformer(norm='l2', use_idf=True, smooth_idf=True, sublinear_tf=False) the term frequency, the number of times a term occurs in a given document, is multiplied with idf component, which is computed as:

$$idf(t) = \log \frac{1+n}{1+df(t)} + 1,$$

where $n$ is the total number of documents in the document set, and $df(t)$ is the number of documents in the document set that contain term $t$. The resulting tf-idf vectors are then normalized by the Euclidean norm:

$$\|u\|_2 = \sqrt{u_1^2 + u_2^2 + \cdots + u_n^2}.$$

This was originally a term weighting scheme developed for information retrieval (as a ranking function for search engines results) that has also found good use in document classification and clustering.

The following sections contain further explanations and examples that illustrate how the tf-ids are computed exactly and how the tf-ids computed in scikit-learn’s TfidfTransformer and TfidfVectorizer differ slightly from the standard textbook notation that defines the idf as:

$$idf(t) = \log \frac{n}{df(t)}.$$

In the TfidfTransformer and TfidfVectorizer with smooth_idf=False, the “1” count is added to the idf instead of the idf’s denominator:

$$idf(t) = \log \frac{n}{df(t)} + 1.$$

This normalization is implemented by the TfidfTransformer class:

```python
>>> from sklearn.feature_extraction.text import TfidfTransformer
>>> transformer = TfidfTransformer(smooth_idf=False)
>>> transformer
TfidfTransformer(smooth_idf=False)
```

Again please see the reference documentation for the details on all the parameters.

Let’s take an example with the following counts. The first term is present 100% of the time hence not very interesting. The two other features only in less than 50% of the time hence probably more representative of the content of the documents:

```python
>>> counts = [[3, 0, 1],
            [2, 0, 0],
            ...
```
...  [3, 0, 0],
...  [4, 0, 0],
...  [3, 2, 0],
...  [3, 0, 2]
...

```python
>>> tfidf = transformer.fit_transform(counts)
>>> tfidf
<6x3 sparse matrix of type '<... 'numpy.float64'>'
   with 9 stored elements in Compressed Sparse ... format>
```
```python
>>> tfidf.toarray()
array([[0.81940995, 0. , 0.57320793],
       [1. , 0. , 0. ],
       [1. , 0. , 0. ],
       [1. , 0. , 0. ],
       [0.47330339, 0.88089948, 0. ],
       [0.58149261, 0. , 0.81355169]])
```

Each row is normalized to have unit Euclidean norm:

\[
\mathbf{v}_{\text{norm}} = \frac{\mathbf{v}}{\|\mathbf{v}\|_2} = \frac{\mathbf{v}}{\sqrt{v_1^2 + v_2^2 + \cdots + v_n^2}}
\]

For example, we can compute the tf-idf of the first term in the first document in the `counts` array as follows:

\[
n = 6
\]

\[
df(t)_{\text{term1}} = 6
\]

\[
idf(t)_{\text{term1}} = \log_2 \frac{n}{df(t)} + 1 = \log(1) + 1 = 1
\]

\[
tf-idf_{\text{term1}} = tf \times idf = 3 \times 1 = 3
\]

Now, if we repeat this computation for the remaining 2 terms in the document, we get

\[
tf-idf_{\text{term2}} = 0 \times (\log(6/1) + 1) = 0
\]

\[
tf-idf_{\text{term3}} = 1 \times (\log(6/2) + 1) \approx 2.0986
\]

and the vector of raw tf-ids:

\[
tf-idf_{\text{raw}} = [3, 0, 2.0986].
\]

Then, applying the Euclidean (L2) norm, we obtain the following tf-ids for document 1:

\[
\frac{[3,0,2.0986]}{\sqrt{3^2+0^2+2.0986^2}} = [0.819, 0, 0.573].
\]

Furthermore, the default parameter `smooth_idf=True` adds “1” to the numerator and denominator as if an extra document was seen containing every term in the collection exactly once, which prevents zero divisions:

\[
idf(t) = \log_2 \frac{1+n}{1+df(t)} + 1
\]

Using this modification, the tf-idf of the third term in document 1 changes to 1.8473:

\[
tf-idf_{\text{term3}} = 1 \times \log(7/3) + 1 \approx 1.8473
\]

And the L2-normalized tf-idf changes to

\[
\frac{[3,0,1.8473]}{\sqrt{3^2+0^2+1.8473^2}} = [0.8515, 0, 0.5243].
\]
```python
>>> transformer = TfidfTransformer()
>>> transformer.fit_transform(counts).toarray()
array([[0.85151335, 0. , 0.52433293],
       [1. , 0. , 0. ],
       [1. , 0. , 0. ],
       [1. , 0. , 0. ],
       [0.55422893, 0.83236428, 0. ],
       [0.63035731, 0. , 0.77630514]])
```

The weights of each feature computed by the `fit` method call are stored in a model attribute:

```python
>>> transformer.idf_
array([1. ..., 2.25..., 1.84...])
```

As tf–idf is very often used for text features, there is also another class called `TfidfVectorizer` that combines all the options of `CountVectorizer` and `TfidfTransformer` in a single model:

```python
>>> from sklearn.feature_extraction.text import TfidfVectorizer
>>> vectorizer = TfidfVectorizer()
>>> vectorizer.fit_transform(corpus)
<4x9 sparse matrix of type '<... 'numpy.float64'>'
  with 19 stored elements in Compressed Sparse ... format>
```

While the tf–idf normalization is often very useful, there might be cases where the binary occurrence markers might offer better features. This can be achieved by using the `binary` parameter of `CountVectorizer`. In particular, some estimators such as `Bernoulli Naive Bayes` explicitly model discrete boolean random variables. Also, very short texts are likely to have noisy tf–idf values while the binary occurrence info is more stable.

As usual the best way to adjust the feature extraction parameters is to use a cross-validated grid search, for instance by pipelining the feature extractor with a classifier:

- Sample pipeline for text feature extraction and evaluation

### Decoding text files

Text is made of characters, but files are made of bytes. These bytes represent characters according to some `encoding`. To work with text files in Python, their bytes must be `decoded` to a character set called Unicode. Common encodings are ASCII, Latin-1 (Western Europe), KOI8-R (Russian) and the universal encodings UTF-8 and UTF-16. Many others exist.

**Note:** An encoding can also be called a ‘character set’, but this term is less accurate: several encodings can exist for a single character set.

The text feature extractors in scikit-learn know how to decode text files, but only if you tell them what encoding the files are in. The `CountVectorizer` takes an encoding parameter for this purpose. For modern text files, the correct encoding is probably UTF-8, which is therefore the default (`encoding="utf-8"`).

If the text you are loading is not actually encoded with UTF-8, however, you will get a `UnicodeDecodeError`. The vectorizers can be told to be silent about decoding errors by setting the `decode_error` parameter to either "ignore" or "replace". See the documentation for the Python function `bytes.decode` for more details (type `help(bytes.decode)` at the Python prompt).

If you are having trouble decoding text, here are some things to try:

- Find out what the actual encoding of the text is. The file might come with a header or README that tells you the encoding, or there might be some standard encoding you can assume based on where the text comes from.
You may be able to find out what kind of encoding it is in general using the UNIX command `file`. The Python `chardet` module comes with a script called `chardetect.py` that will guess the specific encoding, though you cannot rely on its guess being correct.

You could try UTF-8 and disregard the errors. You can decode byte strings with `bytes.decode(errors='replace')` to replace all decoding errors with a meaningless character, or set `decode_error='replace'` in the vectorizer. This may damage the usefulness of your features.

Real text may come from a variety of sources that may have used different encodings, or even be sloppily decoded in a different encoding than the one it was encoded with. This is common in text retrieved from the Web. The Python package `ftfy` can automatically sort out some classes of decoding errors, so you could try decoding the unknown text as `latin-1` and then using `ftfy` to fix errors.

If the text is in a mish-mash of encodings that is simply too hard to sort out (which is the case for the 20 Newsgroups dataset), you can fall back on a simple single-byte encoding such as `latin-1`. Some text may display incorrectly, but at least the same sequence of bytes will always represent the same feature.

For example, the following snippet uses `chardet` (not shipped with scikit-learn, must be installed separately) to figure out the encoding of three texts. It then vectorizes the texts and prints the learned vocabulary. The output is not shown here.

```python
>>> import chardet
>>> text1 = b"Sei mir gegr\xc3\xfc\xc3\xfct mein Sauerkraut"
>>> text2 = b"holdselig sind deine Gera\xfcche"
>>> text3 = b"A\xe4uf\xe4lde\xe4ger leistet das an\xe4lde\xe4ger Stra\xe4lfen\xe4lze"
>>> decoded = [x.decode(chardet.detect(x)['encoding']) for x in (text1, text2, text3)]
>>> v = CountVectorizer().fit(decoded).vocabulary_
>>> for term in v: print(v)
```

(Depending on the version of `chardet`, it might get the first one wrong.)

For an introduction to Unicode and character encodings in general, see Joel Spolsky’s Absolute Minimum Every Software Developer Must Know About Unicode.

### Applications and examples

The bag of words representation is quite simplistic but surprisingly useful in practice.

In particular in a supervised setting it can be successfully combined with fast and scalable linear models to train document classifiers, for instance:

- Classification of text documents using sparse features

In an unsupervised setting it can be used to group similar documents together by applying clustering algorithms such as K-means:

- Clustering text documents using k-means

Finally it is possible to discover the main topics of a corpus by relaxing the hard assignment constraint of clustering, for instance by using Non-negative matrix factorization (NMF or NNMF):

- Topic extraction with Non-negative Matrix Factorization and Latent Dirichlet Allocation
Limitations of the Bag of Words representation

A collection of unigrams (what bag of words is) cannot capture phrases and multi-word expressions, effectively disregarding any word order dependence. Additionally, the bag of words model doesn’t account for potential misspellings or word derivations.

N-grams to the rescue! Instead of building a simple collection of unigrams (n=1), one might prefer a collection of bigrams (n=2), where occurrences of pairs of consecutive words are counted.

One might alternatively consider a collection of character n-grams, a representation resilient against misspellings and derivations.

For example, let’s say we’re dealing with a corpus of two documents: ['words', 'wprds']]. The second document contains a misspelling of the word ‘words’. A simple bag of words representation would consider these two as very distinct documents, differing in both of the two possible features. A character 2-gram representation, however, would find the documents matching in 4 out of 8 features, which may help the preferred classifier decide better:

```python
>>> ngram_vectorizer = CountVectorizer(analyzer='char_wb', ngram_range=(2, 2))
>>> counts = ngram_vectorizer.fit_transform(['words', 'wprds'])
>>> ngram_vectorizer.get_feature_names() == (['w ', 'ds', 'or', 'pr', 'rd', 's ', 'wo', 'wp'])
True
>>> counts.toarray().astype(int)
array([[1, 1, 1, 0, 1, 1, 0, 1],
       [1, 1, 1, 0, 1, 1, 0, 1]])
```

In the above example, char_wb analyzer is used, which creates n-grams only from characters inside word boundaries (padded with space on each side). The char analyzer, alternatively, creates n-grams that span across words:

```python
>>> ngram_vectorizer = CountVectorizer(analyzer='char_wb', ngram_range=(5, 5))
>>> counts = ngram_vectorizer.fit_transform(['jumpy fox'])
<1x4 sparse matrix of type '<... 'numpy.int64'>'
   with 4 stored elements in Compressed Sparse ... format>
>>> ngram_vectorizer.get_feature_names() == (' fox ', ' jump', 'jumpy', 'umpy ')
True

>>> ngram_vectorizer = CountVectorizer(analyzer='char', ngram_range=(5, 5))
>>> counts = ngram_vectorizer.fit_transform(['jumpy fox'])
<1x5 sparse matrix of type '<... 'numpy.int64'>'
   with 5 stored elements in Compressed Sparse ... format>
>>> ngram_vectorizer.get_feature_names() == ('jumpy', 'mpy f', 'py fo', 'umpy ', 'y fox')
True
```

The word boundaries-aware variant char_wb is especially interesting for languages that use white-spaces for word separation as it generates significantly less noisy features than the raw char variant in that case. For such languages it can increase both the predictive accuracy and convergence speed of classifiers trained using such features while retaining the robustness with regards to misspellings and word derivations.

While some local positioning information can be preserved by extracting n-grams instead of individual words, bag of words and bag of n-grams destroy most of the inner structure of the document and hence most of the meaning carried by that internal structure.

In order to address the wider task of Natural Language Understanding, the local structure of sentences and paragraphs should thus be taken into account. Many such models will thus be casted as “Structured output” problems which are currently outside of the scope of scikit-learn.
Vectorizing a large text corpus with the hashing trick

The above vectorization scheme is simple but the fact that it holds an in-memory mapping from the string tokens to the integer feature indices (the vocabulary_ attribute) causes several problems when dealing with large datasets:

- the larger the corpus, the larger the vocabulary will grow and hence the memory use too,
- fitting requires the allocation of intermediate data structures of size proportional to that of the original dataset.
- building the word-mapping requires a full pass over the dataset hence it is not possible to fit text classifiers in a strictly online manner.
- pickling and un-pickling vectorizers with a large vocabulary_ can be very slow (typically much slower than pickling / un-pickling flat data structures such as a NumPy array of the same size),
- it is not easily possible to split the vectorization work into concurrent sub tasks as the vocabulary_ attribute would have to be a shared state with a fine grained synchronization barrier: the mapping from token string to feature index is dependent on ordering of the first occurrence of each token hence would have to be shared, potentially harming the concurrent workers’ performance to the point of making them slower than the sequential variant.

It is possible to overcome those limitations by combining the “hashing trick” (Feature hashing) implemented by the FeatureHasher class and the text preprocessing and tokenization features of the CountVectorizer.

This combination is implementing in HashingVectorizer, a transformer class that is mostly API compatible with CountVectorizer. HashingVectorizer is stateless, meaning that you don’t have to call fit on it:

```python
>>> from sklearn.feature_extraction.text import HashingVectorizer
>>> hv = HashingVectorizer(n_features=10)
>>> hv.transform(corpus)
<4x10 sparse matrix of type '<... 'numpy.float64'>'
  with 16 stored elements in Compressed Sparse ... format>
```

You can see that 16 non-zero feature tokens were extracted in the vector output: this is less than the 19 non-zeros extracted previously by the CountVectorizer on the same toy corpus. The discrepancy comes from hash function collisions because of the low value of the n_features parameter.

In a real world setting, the n_features parameter can be left to its default value of $2^{20}$ (roughly one million possible features). If memory or downstream models size is an issue selecting a lower value such as $2^{18}$ might help without introducing too many additional collisions on typical text classification tasks.

Note that the dimensionality does not affect the CPU training time of algorithms which operate on CSR matrices (LinearSVC(dual=True), Perceptron, SGDClassifier, PassiveAggressive) but it does for algorithms that work with CSC matrices (LinearSVC(dual=False), Lasso(), etc).

Let’s try again with the default setting:

```python
>>> hv = HashingVectorizer()
>>> hv.transform(corpus)
<4x1048576 sparse matrix of type '<... 'numpy.float64'>'
  with 19 stored elements in Compressed Sparse ... format>
```

We no longer get the collisions, but this comes at the expense of a much larger dimensionality of the output space. Of course, other terms than the 19 used here might still collide with each other.

The HashingVectorizer also comes with the following limitations:

- it is not possible to invert the model (no inverse_transform method), nor to access the original string representation of the features, because of the one-way nature of the hash function that performs the mapping.
• it does not provide IDF weighting as that would introduce statefulness in the model. A TfidfTransformer can be appended to it in a pipeline if required.

Performing out-of-core scaling with HashingVectorizer

An interesting development of using a HashingVectorizer is the ability to perform out-of-core scaling. This means that we can learn from data that does not fit into the computer’s main memory.

A strategy to implement out-of-core scaling is to stream data to the estimator in mini-batches. Each mini-batch is vectorized using HashingVectorizer so as to guarantee that the input space of the estimator has always the same dimensionality. The amount of memory used at any time is thus bounded by the size of a mini-batch. Although there is no limit to the amount of data that can be ingested using such an approach, from a practical point of view the learning time is often limited by the CPU time one wants to spend on the task.

For a full-fledged example of out-of-core scaling in a text classification task see Out-of-core classification of text documents.

Customizing the vectorizer classes

It is possible to customize the behavior by passing a callable to the vectorizer constructor:

```python
>>> def my_tokenizer(s):
...     return s.split()
...

>>> vectorizer = CountVectorizer(tokenizer=my_tokenizer)

>>> vectorizer.build_analyzer()(u"Some... punctuation!") == (['some...', 'punctuation!'])
True
```

In particular we name:

• preprocessor: a callable that takes an entire document as input (as a single string), and returns a possibly transformed version of the document, still as an entire string. This can be used to remove HTML tags, lowercase the entire document, etc.

• tokenizer: a callable that takes the output from the preprocessor and splits it into tokens, then returns a list of these.

• analyzer: a callable that replaces the preprocessor and tokenizer. The default analyzers all call the preprocessor and tokenizer, but custom analyzers will skip this. N-gram extraction and stop word filtering take place at the analyzer level, so a custom analyzer may have to reproduce these steps.

(Lucene users might recognize these names, but be aware that scikit-learn concepts may not map one-to-one onto Lucene concepts.)

To make the preprocessor, tokenizer and analyzers aware of the model parameters it is possible to derive from the class and override the build_preprocessor, build_tokenizer and build_analyzer factory methods instead of passing custom functions.

Some tips and tricks:

• If documents are pre-tokenized by an external package, then store them in files (or strings) with the tokens separated by whitespace and pass analyzer=str.split

• Fancy token-level analysis such as stemming, lemmatizing, compound splitting, filtering based on part-of-speech, etc. are not included in the scikit-learn codebase, but can be added by customizing either the tokenizer or the analyzer. Here’s a CountVectorizer with a tokenizer and lemmatizer using NLTK:
from nltk import word_tokenize
from nltk.stem import WordNetLemmatizer

class LemmaTokenizer:
    def __init__(self):
        self.wnl = WordNetLemmatizer()
    def __call__(self, doc):
        return [self.wnl.lemmatize(t) for t in word_tokenize(doc)]

vect = CountVectorizer(tokenizer=LemmaTokenizer())

(Note that this will not filter out punctuation.)

The following example will, for instance, transform some British spelling to American spelling:

import re
def to_british(tokens):
    for t in tokens:
        t = re.sub(r“(...)our$”, r”\1or”, t)
        t = re.sub(r“([bt])re$”, r”\1er”, t)
        t = re.sub(r“([iy])s(e|ing|ation)”, r”\1z\2”, t)
        t = re.sub(r“ogue$”, “og”, t)
    yield t

class CustomVectorizer(CountVectorizer):
    def build_tokenizer(self):
        tokenize = super().build_tokenizer()
        return lambda doc: list(to_british(tokenize(doc)))

print(CustomVectorizer().build_analyzer()(u“color colour”))

for other styles of preprocessing; examples include stemming, lemmatization, or normalizing numerical tokens, with the latter illustrated in:

– Biclustering documents with the Spectral Co-clustering algorithm

Customizing the vectorizer can also be useful when handling Asian languages that do not use an explicit word separator such as whitespace.

Image feature extraction

Patch extraction

The extract_patches_2d function extracts patches from an image stored as a two-dimensional array, or three-dimensional with color information along the third axis. For rebuilding an image from all its patches, use reconstruct_from_patches_2d. For example let use generate a 4x4 pixel picture with 3 color channels (e.g. in RGB format):

import numpy as np
from sklearn.feature_extraction import image

one_image = np.arange(4 * 4 * 3).reshape((4, 4, 3))
one_image[:, :, 0] # R channel of a fake RGB picture
array([[ 0, 3,  6,  9],
       [12, 15, 18, 21],
       [24, 27, 30, 33],
       [36, 39, 42, 45]])
Let us now try to reconstruct the original image from the patches by averaging on overlapping areas:

```python
>>> reconstructed = image.reconstruct_from_patches_2d(patches, (4, 4, 3))
>>> np.testing.assert_array_equal(one_image, reconstructed)
```

The `PatchExtractor` class works in the same way as `extract_patches_2d`, only it supports multiple images as input. It is implemented as an estimator, so it can be used in pipelines. See:

```python
>>> five_images = np.arange(5 * 4 * 4 * 3).reshape(5, 4, 4, 3)
>>> patches = image.PatchExtractor(patch_size=(2, 2)).transform(five_images)
>>> patches.shape
(45, 2, 2, 3)
```

**Connectivity graph of an image**

Several estimators in the scikit-learn can use connectivity information between features or samples. For instance Ward clustering (Hierarchical clustering) can cluster together only neighboring pixels of an image, thus forming contiguous patches:

For this purpose, the estimators use a ‘connectivity’ matrix, giving which samples are connected. The function `img_to_graph` returns such a matrix from a 2D or 3D image. Similarly, `grid_to_graph` build a connectivity matrix for images given the shape of these images.
These matrices can be used to impose connectivity in estimators that use connectivity information, such as Ward clustering (Hierarchical clustering), but also to build precomputed kernels, or similarity matrices.

Note: Examples
• A demo of structured Ward hierarchical clustering on an image of coins
• Spectral clustering for image segmentation
• Feature agglomeration vs. univariate selection

4.6.3 Preprocessing data

The sklearn.preprocessing package provides several common utility functions and transformer classes to change raw feature vectors into a representation that is more suitable for the downstream estimators.

In general, learning algorithms benefit from standardization of the data set. If some outliers are present in the set, robust scalers or transformers are more appropriate. The behaviors of the different scalers, transformers, and normalizers on a dataset containing marginal outliers is highlighted in Compare the effect of different scalers on data with outliers.

Standardization, or mean removal and variance scaling

Standardization of datasets is a common requirement for many machine learning estimators implemented in scikit-learn; they might behave badly if the individual features do not more or less look like standard normally distributed data: Gaussian with zero mean and unit variance.

In practice we often ignore the shape of the distribution and just transform the data to center it by removing the mean value of each feature, then scale it by dividing non-constant features by their standard deviation.

For instance, many elements used in the objective function of a learning algorithm (such as the RBF kernel of Support Vector Machines or the l1 and l2 regularizers of linear models) assume that all features are centered around zero and have variance in the same order. If a feature has a variance that is orders of magnitude larger than others, it might dominate the objective function and make the estimator unable to learn from other features correctly as expected.

The function scale provides a quick and easy way to perform this operation on a single array-like dataset:

```python
>>> from sklearn import preprocessing
>>> import numpy as np

>>> X_train = np.array([[ 1., -1., 2.],
                      [ 2., 0., 0.],
                      [ 0., 1., -1.]])

>>> X_scaled = preprocessing.scale(X_train)

>>> X_scaled
array([[ 0.43..., -1.33..., 1.04...],
       [ 1.33..., 0.04..., -0.33...],
       [-1.33..., 1.33..., -1.04...]])
```

Scaled data has zero mean and unit variance:

```python
>>> X_scaled.mean(axis=0)
array([0., 0., 0.])

>>> X_scaled.std(axis=0)
array([1., 1., 1.])
```
The preprocessing module further provides a utility class `StandardScaler` that implements the Transformer API to compute the mean and standard deviation on a training set so as to be able to later reapply the same transformation on the testing set. This class is hence suitable for use in the early steps of a `Pipeline`:

```python
>>> scaler = preprocessing.StandardScaler().fit(X_train)
>>> scaler
StandardScaler()
>>> scaler.mean_
array([1. ..., 0. ..., 0.33...])
>>> scaler.scale_
array([0.81..., 0.81..., 1.24...])
>>> scaler.transform(X_train)
array([[ 0. ..., -1.22..., 1.33...],
       [ 1.22..., 0. ..., -0.26...],
       [-1.22..., 1.22..., -1.06...]])
```

The scaler instance can then be used on new data to transform it the same way it did on the training set:

```python
>>> X_test = [[-1., 1., 0.]]
>>> scaler.transform(X_test)
array([[-2.44..., 1.22..., -0.26...]])
```

It is possible to disable either centering or scaling by either passing `with_mean=False` or `with_std=False` to the constructor of `StandardScaler`.

## Scaling features to a range

An alternative standardization is scaling features to lie between a given minimum and maximum value, often between zero and one, or so that the maximum absolute value of each feature is scaled to unit size. This can be achieved using `MinMaxScaler` or `MaxAbsScaler`, respectively.

The motivation to use this scaling include robustness to very small standard deviations of features and preserving zero entries in sparse data.

Here is an example to scale a toy data matrix to the $[0, 1]$ range:

```python
>>> X_train = np.array([[ 1., -1., 2.],
...                      [ 2., 0., 0.],
...                      [ 0., 1., -1.]])
... >>> min_max_scaler = preprocessing.MinMaxScaler()
... >>> X_train_minmax = min_max_scaler.fit_transform(X_train)
... >>> X_train_minmax
array([[0.5 , 0. , 1. ],
       [1. , 0.5 , 0.33333333],
       [0. , 1. , 0. ]])
```

The same instance of the transformer can then be applied to some new test data unseen during the fit call: the same scaling and shifting operations will be applied to be consistent with the transformation performed on the train data:

```python
>>> X_test = np.array([[-3., -1., 4.]]),
>>> X_test_minmax = min_max_scaler.transform(X_test)
>>> X_test_minmax
array([[-1.5 , 0. , 1.66666667]])
```
It is possible to introspect the scaler attributes to find about the exact nature of the transformation learned on the training data:

```python
>>> min_max_scaler.scale_
array([0.5 , 0.5 , 0.33...])

>>> min_max_scaler.min_
array([0. , 0.5 , 0.33...])
```

If `MinMaxScaler` is given an explicit `feature_range=(min, max)` the full formula is:

\[
X_{\text{std}} = \frac{X - X.\text{min}(\text{axis}=0)}{X.\text{max}(\text{axis}=0) - X.\text{min}(\text{axis}=0)}
\]

\[
X_{\text{scaled}} = X_{\text{std}} \times (\text{max} - \text{min}) + \text{min}
\]

`MaxAbsScaler` works in a very similar fashion, but scales in a way that the training data lies within the range \([-1, 1]\) by dividing through the largest maximum value in each feature. It is meant for data that is already centered at zero or sparse data.

Here is how to use the toy data from the previous example with this scaler:

```python
>>> X_train = np.array([[ 1., -1., 2.],
                      [ 2., 0., 0.],
                      [ 0., 1., -1.]])
...
>>> max_abs_scaler = preprocessing.MaxAbsScaler()
>>> X_train_maxabs = max_abs_scaler.fit_transform(X_train)
>>> X_train_maxabs
array([[ 0.5, -1. , 1. ],
       [ 1. , 0. , 0. ],
       [ 0. , 1. , -0.5]])
```

As with `scale`, the module further provides convenience functions `minmax_scale` and `maxabs_scale` if you don’t want to create an object.

### Scaling sparse data

Centering sparse data would destroy the sparseness structure in the data, and thus rarely is a sensible thing to do. However, it can make sense to scale sparse inputs, especially if features are on different scales.

`MaxAbsScaler` and `maxabs_scale` were specifically designed for scaling sparse data, and are the recommended way to go about this. However, `scale` and `StandardScaler` can accept `scipy.sparse` matrices as input, as long as `with_mean=False` is explicitly passed to the constructor. Otherwise a `ValueError` will be raised as silently centering would break the sparsity and would often crash the execution by allocating excessive amounts of memory unintentionally. `RobustScaler` cannot be fitted to sparse inputs, but you can use the `transform` method on sparse inputs.

Note that the scalers accept both Compressed Sparse Rows and Compressed Sparse Columns format (see `scipy.sparse.csr_matrix` and `scipy.sparse.csc_matrix`). Any other sparse input will be converted to the Compressed Sparse Rows representation. To avoid unnecessary memory copies, it is recommended to choose the CSR or CSC representation upstream.
Finally, if the centered data is expected to be small enough, explicitly converting the input to an array using the `toarray` method of sparse matrices is another option.

### Scaling data with outliers

If your data contains many outliers, scaling using the mean and variance of the data is likely to not work very well. In these cases, you can use `robust_scale` and `RobustScaler` as drop-in replacements instead. They use more robust estimates for the center and range of your data.

#### References:

Further discussion on the importance of centering and scaling data is available on this FAQ: Should I normalize/standardize/rescale the data?

### Scaling vs Whitening

It is sometimes not enough to center and scale the features independently, since a downstream model can further make some assumption on the linear independence of the features.

To address this issue you can use PCA with `whiten=True` to further remove the linear correlation across features.

### Scaling a 1D array

All above functions (i.e. `scale`, `minmax_scale`, `maxabs_scale`, and `robust_scale`) accept 1D array which can be useful in some specific case.

### Centering kernel matrices

If you have a kernel matrix of a kernel $K$ that computes a dot product in a feature space defined by function $\phi$, a `KernelCenterer` can transform the kernel matrix so that it contains inner products in the feature space defined by $\phi$ followed by removal of the mean in that space.

### Non-linear transformation

Two types of transformations are available: quantile transforms and power transforms. Both quantile and power transforms are based on monotonic transformations of the features and thus preserve the rank of the values along each feature.

Quantile transforms put all features into the same desired distribution based on the formula $G^{-1}(F(X))$ where $F$ is the cumulative distribution function of the feature and $G^{-1}$ the quantile function of the desired output distribution $G$. This formula is using the two following facts: (i) if $X$ is a random variable with a continuous cumulative distribution function $F$ then $F(X)$ is uniformly distributed on [0, 1]; (ii) if $U$ is a random variable with uniform distribution on [0, 1] then $G^{-1}(U)$ has distribution $G$. By performing a rank transformation, a quantile transform smooths out unusual distributions and is less influenced by outliers than scaling methods. It does, however, distort correlations and distances within and across features.

Power transforms are a family of parametric transformations that aim to map data from any distribution to as close to a Gaussian distribution.
Mapping to a Uniform distribution

`QuantileTransformer` and `quantile_transform` provide a non-parametric transformation to map the data to a uniform distribution with values between 0 and 1:

```python
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split

>>> X, y = load_iris(return_X_y=True)
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
>>> quantile_transformer = preprocessing.QuantileTransformer(random_state=0)
>>> X_train_trans = quantile_transformer.fit_transform(X_train)
>>> X_test_trans = quantile_transformer.transform(X_test)

>>> np.percentile(X_train[:, 0], [0, 25, 50, 75, 100])
array([ 4.3, 5.1, 5.8, 6.5, 7.9])
```

This feature corresponds to the sepal length in cm. Once the quantile transformation applied, those landmarks approach closely the percentiles previously defined:

```python
>>> np.percentile(X_train_trans[:, 0], [0, 25, 50, 75, 100])
... array([ 0.00..., 0.24..., 0.49..., 0.73..., 0.99... ])
```

This can be confirmed on an independent testing set with similar remarks:

```python
>>> np.percentile(X_test[:, 0], [0, 25, 50, 75, 100])
... array([ 4.4 , 5.125, 5.75 , 6.175, 7.3 ])
>>> np.percentile(X_test_trans[:, 0], [0, 25, 50, 75, 100])
... array([ 0.01..., 0.25..., 0.46..., 0.60..., 0.94...])
```

Mapping to a Gaussian distribution

In many modeling scenarios, normality of the features in a dataset is desirable. Power transforms are a family of parametric, monotonic transformations that aim to map data from any distribution to as close to a Gaussian distribution as possible in order to stabilize variance and minimize skewness.

`PowerTransformer` currently provides two such power transformations, the Yeo-Johnson transform and the Box-Cox transform.

The Yeo-Johnson transform is given by:

\[
x^{(\lambda)}_i = \begin{cases} 
\frac{[(x_i + 1)^\lambda - 1]}{\lambda} & \text{if } \lambda \neq 0, x_i \geq 0, \\
\ln(x_i + 1) & \text{if } \lambda = 0, x_i \geq 0 \\
-\frac{[(-x_i + 1)^2 - 1]}{(2 - \lambda)} & \text{if } \lambda \neq 2, x_i < 0, \\
-\ln(-x_i + 1) & \text{if } \lambda = 2, x_i < 0
\end{cases}
\]

while the Box-Cox transform is given by:

\[
x^{(\lambda)}_i = \begin{cases} 
\frac{x_i^\lambda - 1}{\lambda} & \text{if } \lambda \neq 0, \\
\ln(x_i) & \text{if } \lambda = 0
\end{cases}
\]
Box-Cox can only be applied to strictly positive data. In both methods, the transformation is parameterized by \( \lambda \), which is determined through maximum likelihood estimation. Here is an example of using Box-Cox to map samples drawn from a lognormal distribution to a normal distribution:

```python
>>> pt = preprocessing.PowerTransformer(method='box-cox', standardize=False)
>>> X_lognormal = np.random.RandomState(616).lognormal(size=(3, 3))
>>> X_lognormal
array([[1.28..., 1.18..., 0.84...],
       [0.94..., 1.60..., 0.38...],
       [1.35..., 0.21..., 1.09...]])
>>> pt.fit_transform(X_lognormal)
array([[ 0.49..., 0.17..., -0.15...],
       [-0.05..., 0.58..., -0.57...],
       [ 0.69..., -0.84...,  0.10...]])
```

While the above example sets the `standardize` option to `False`, `PowerTransformer` will apply zero-mean, unit-variance normalization to the transformed output by default.

Below are examples of Box-Cox and Yeo-Johnson applied to various probability distributions. Note that when applied to certain distributions, the power transforms achieve very Gaussian-like results, but with others, they are ineffective. This highlights the importance of visualizing the data before and after transformation.

It is also possible to map data to a normal distribution using `QuantileTransformer` by setting `output_distribution='normal'`. Using the earlier example with the iris dataset:

```python
>>> quantile_transformer = preprocessing.QuantileTransformer(output_distribution='normal', random_state=0)
>>> X_trans = quantile_transformer.fit_transform(X)
>>> quantile_transformer.quantiles_
array([[4.3, 2. , 1. , 0.1],
       [4.4, 2.2, 1.1, 0.1],
       [4.4, 2.2, 1.2, 0.1],
       ...
       [7.7, 4.1, 6.7, 2.5],
       [7.7, 4.2, 6.7, 2.5],
       [7.9, 4.4, 6.9, 2.5]])
```

Thus the median of the input becomes the mean of the output, centered at 0. The normal output is clipped so that the input's minimum and maximum — corresponding to the 1e-7 and 1 - 1e-7 quantiles respectively — do not become infinite under the transformation.

**Normalization**

**Normalization** is the process of scaling individual samples to have unit norm. This process can be useful if you plan to use a quadratic form such as the dot-product or any other kernel to quantify the similarity of any pair of samples.

This assumption is the base of the Vector Space Model often used in text classification and clustering contexts.

The function `normalize` provides a quick and easy way to perform this operation on a single array-like dataset, either using the 1l or 12 norms:

```python
>>> X = [[ 1., -1., 2.],
       [ 2., 0., 0.],
       [ 0., 1., -1.]]
>>> X_normalized = preprocessing.normalize(X, norm='l2')
>>> X_normalized
```

(continues on next page)
4.6. Dataset transformations
The preprocessing module further provides a utility class `Normalizer` that implements the same operation using the Transformer API (even though the fit method is useless in this case: the class is stateless as this operation treats samples independently).

This class is hence suitable for use in the early steps of a Pipeline:

```python
>>> normalizer = preprocessing.Normalizer().fit(X)  # fit does nothing
>>> normalizer
Normalizer()
```

The normalizer instance can then be used on sample vectors as any transformer:

```python
>>> normalizer.transform(X)
array([[ 0.40..., -0.40..., 0.81...],
[ 1. ..., 0. ..., 0. ...],
[ 0. ..., 0.70..., -0.70...]])
```

```python
>>> normalizer.transform([[-1., 1., 0.]])
array([[-0.70..., 0.70..., 0. ...]])
```

Note: L2 normalization is also known as spatial sign preprocessing.

### Sparse input

`normalize` and `Normalizer` accept both dense array-like and sparse matrices from `scipy.sparse` as input.

For sparse input the data is converted to the Compressed Sparse Rows representation (see `scipy.sparse.csr_matrix`) before being fed to efficient Cython routines. To avoid unnecessary memory copies, it is recommended to choose the CSR representation upstream.

### Encoding categorical features

Often features are not given as continuous values but categorical. For example a person could have features `"male", "female"`, `"from Europe", "from US", "from Asia"`, `"uses Firefox", "uses Chrome", "uses Safari", "uses Internet Explorer"`. Such features can be efficiently coded as integers, for instance `"male", "from US", "uses Internet Explorer"` could be expressed as `[0, 1, 3]` while `"female", "from Asia", "uses Chrome"` would be `[1, 2, 1]`.

To convert categorical features to such integer codes, we can use the `OrdinalEncoder`. This estimator transforms each categorical feature to one new feature of integers (0 to `n_categories` - 1):

```python
>>> enc = preprocessing.OrdinalEncoder()
>>> X = [['male', 'from US', 'uses Safari'], ['female', 'from Europe', 'uses Firefox']]
>>> enc.fit(X)
OrdinalEncoder()
>>> enc.transform([['female', 'from US', 'uses Safari']])
array([[0., 1., 1.]])
```
Such integer representation can, however, not be used directly with all scikit-learn estimators, as these expect continuous input, and would interpret the categories as being ordered, which is often not desired (i.e. the set of browsers was ordered arbitrarily).

Another possibility to convert categorical features to features that can be used with scikit-learn estimators is to use a one-of-K, also known as one-hot or dummy encoding. This type of encoding can be obtained with the `OneHotEncoder`, which transforms each categorical feature with \texttt{n\_categories} possible values into \texttt{n\_categories} binary features, with one of them 1, and all others 0.

Continuing the example above:

```python
>>> enc = preprocessing.OneHotEncoder()
>>> X = [['male', 'from US', 'uses Safari'], ['female', 'from Europe', 'uses Firefox']]
>>> enc.fit(X)
OneHotEncoder()
>>> enc.transform([["female", "from US", "uses Safari"], ...
    ["male", "from Europe", "uses Safari"]]).toarray()
array([[1., 0., 0., 1., 0., 1.],
       [0., 1., 1., 0., 0., 1.]])
```

By default, the values each feature can take is inferred automatically from the dataset and can be found in the \texttt{categories\_attribute}:  

```python
>>> enc.categories_
[array(['female', 'male'], dtype=object), array(['from Europe', 'from US'], dtype=object), array(['uses Firefox', 'uses Safari'], dtype=object)]
```

It is possible to specify this explicitly using the parameter \texttt{categories}. There are two genders, four possible continents and four web browsers in our dataset:

```python
>>> genders = ['female', 'male']
>>> locations = ['from Africa', 'from Asia', 'from Europe', 'from US']
>>> browsers = ['uses Chrome', 'uses Firefox', 'uses IE', 'uses Safari']
>>> enc = preprocessing.OneHotEncoder(categories=[genders, locations, browsers])
>>> # Note that for there are missing categorical values for the 2nd and 3rd feature
>>> X = [['male', 'from US', 'uses Safari'], ['female', 'from Europe', 'uses Firefox']]
>>> enc.fit(X)
OneHotEncoder(categories=[['female', 'male'],
    ['from Africa', 'from Asia', 'from Europe', 'from US'],
    ['uses Chrome', 'uses Firefox', 'uses IE', 'uses Safari']])
>>> enc.transform([["female", "from Asia", "uses Chrome"]])
array([[1., 0., 0., 1., 0., 0., 1., 0., 0., 0.]])
```

If there is a possibility that the training data might have missing categorical features, it can often be better to specify \texttt{handle\_unknown='ignore'} instead of setting the categories manually as above. When \texttt{handle\_unknown='ignore'} is specified and unknown categories are encountered during transform, no error will be raised but the resulting one-hot encoded columns for this feature will be all zeros (\texttt{handle\_unknown='ignore'} is only supported for one-hot encoding):

```python
>>> enc = preprocessing.OneHotEncoder(handle_unknown='ignore')
>>> X = [['male', 'from US', 'uses Safari'], ['female', 'from Europe', 'uses Firefox']]
>>> enc.fit(X)
(continues on next page)
It is also possible to encode each column into \( n_{\text{categories}} - 1 \) columns instead of \( n_{\text{categories}} \) columns by using the `drop` parameter. This parameter allows the user to specify a category for each feature to be dropped. This is useful to avoid co-linearity in the input matrix in some classifiers. Such functionality is useful, for example, when using non-regularized regression (`LinearRegression`), since co-linearity would cause the covariance matrix to be non-invertible. When this parameter is not None, `handle_unknown` must be set to `error`:

```python
>>> X = [['male', 'US', 'Safari'],
...
... ['female', 'Europe', 'Firefox'],
... ['female', 'Asia', 'Chrome']

>>> drop_enc = preprocessing.OneHotEncoder(drop='first').fit(X)

>>> drop_enc.categories_
[array(['female', 'male'], dtype=object),
 array(['Asia', 'Europe', 'US'], dtype=object),
 array(['Chrome', 'Firefox', 'Safari'], dtype=object)]

>>> drop_enc.transform(X).toarray()
array([[1., 1., 1.],
       [0., 0., 0.],
       [0., 0., 0.]])
```

One might want to drop one of the two columns only for features with 2 categories. In this case, you can set the parameter `drop='if_binary'`:

```python
>>> X = [['male', 'US', 'Safari'],
...
... ['female', 'Europe', 'Firefox'],
... ['female', 'Asia', 'Chrome']

>>> drop_enc = preprocessing.OneHotEncoder(drop='if_binary').fit(X)

>>> drop_enc.categories_
[array(['female', 'male'], dtype=object),
 array(['Asia', 'Europe', 'US'], dtype=object),
 array(['Chrome', 'Firefox', 'Safari'], dtype=object)]

>>> drop_enc.transform(X).toarray()
array([[1., 0., 0., 1., 0., 0., 1.],
       [0., 0., 1., 0., 0., 1., 0.],
       [0., 1., 0., 0., 1., 0., 0.]])
```

In the transformed \( X \), the first column is the encoding of the feature with categories “male”/”female”, while the remaining 6 columns is the encoding of the 2 features with respectively 3 categories each.

`OneHotEncoder` supports categorical features with missing values by considering the missing values as an additional category:

```python
>>> X = [['male', 'Safari'],
...
... ['female', None],
... [np.nan, 'Firefox']

>>> enc = preprocessing.OneHotEncoder(handle_unknown='error').fit(X)

>>> enc.categories_
[array(['female', 'male', nan], dtype=object),
 array(['Firefox', 'Safari', None], dtype=object)]

>>> enc.transform(X).toarray()
array([[0., 1., 0., 0., 1., 0.],
       [1., 0., 0., 0., 0., 1.],
       [0., 0., 1., 0., 0., 0.]])
```

If a feature contains both `np.nan` and `None`, they will be considered separate categories:
```python
>>> X = [['Safari'], [None], [np.nan], ['Firefox']]
>>> enc = preprocessing.OneHotEncoder(handle_unknown='error').fit(X)
>>> enc.categories_
array([['Firefox', 'Safari', None, nan], dtype=object])
>>> enc.transform(X).toarray()
array([[0., 1., 0., 0.],
       [0., 0., 1., 0.],
       [0., 0., 0., 1.],
       [1., 0., 0., 0.]])
```

See [Loading features from dicts](#) for categorical features that are represented as a dict, not as scalars.

## Discretization

Discretization (otherwise known as quantization or binning) provides a way to partition continuous features into discrete values. Certain datasets with continuous features may benefit from discretization, because discretization can transform the dataset of continuous attributes to one with only nominal attributes.

One-hot encoded discretized features can make a model more expressive, while maintaining interpretability. For instance, pre-processing with a discretizer can introduce nonlinearity to linear models.

### K-bins discretization

`KBinsDiscretizer` discretizes features into k bins:

```python
>>> X = np.array([[-3., 5., 15.],
                 [0., 6., 14.],
                 [6., 3., 11.]])
>>> est = preprocessing.KBinsDiscretizer(n_bins=[3, 2, 2], encode='ordinal').fit(X)
```

By default the output is one-hot encoded into a sparse matrix (See [Encoding categorical features](#)) and this can be configured with the `encode` parameter. For each feature, the bin edges are computed during `fit` and together with the number of bins, they will define the intervals. Therefore, for the current example, these intervals are defined as:

- **feature 1:** $(-\infty, -1), [-1, 2), [2, \infty)$
- **feature 2:** $(-\infty, 5), [5, \infty)$
- **feature 3:** $(-\infty, 14), [14, \infty)$

Based on these bin intervals, X is transformed as follows:

```python
>>> est.transform(X)
array([[ 0., 1., 1.],
       [ 1., 1., 1.],
       [ 2., 0., 0.]])
```

The resulting dataset contains ordinal attributes which can be further used in a [Pipeline](#).

Discretization is similar to constructing histograms for continuous data. However, histograms focus on counting features which fall into particular bins, whereas discretization focuses on assigning feature values to these bins.

`KBinsDiscretizer` implements different binning strategies, which can be selected with the `strategy` parameter. The ‘uniform’ strategy uses constant-width bins. The ‘quantile’ strategy uses the quantiles values to have equally populated bins in each feature. The ‘kmeans’ strategy defines bins based on a k-means clustering procedure performed on each feature independently.
Examples:

- Using KBinsDiscretizer to discretize continuous features
- Feature discretization
- Demonstrating the different strategies of KBinsDiscretizer

Feature binarization

Feature binarization is the process of thresholding numerical features to get boolean values. This can be useful for downstream probabilistic estimators that make assumption that the input data is distributed according to a multi-variate Bernoulli distribution. For instance, this is the case for the BernoulliRBM.

It is also common among the text processing community to use binary feature values (probably to simplify the probabilistic reasoning) even if normalized counts (a.k.a. term frequencies) or TF-IDF valued features often perform slightly better in practice.

As for the Normalizer, the utility class Binarizer is meant to be used in the early stages of Pipeline. The fit method does nothing as each sample is treated independently of others:

```python
>>> X = [[ 1., -1.,  2.],
      ...      [ 2.,  0.,  0.],
      ...      [ 0.,  1., -1.]]

>>> binarizer = preprocessing.Binarizer().fit(X)  # fit does nothing
>>> binarizer
Binarizer()

>>> binarizer.transform(X)
array([[1., 0., 1.],
       [1., 0., 0.],
       [0., 1., 0.]])
```

It is possible to adjust the threshold of the binarizer:

```python
>>> binarizer = preprocessing.Binarizer(threshold=1.1)
>>> binarizer.transform(X)
array([[0., 0., 1.],
       [1., 0., 0.],
       [0., 0., 0.]])
```

As for the StandardScaler and Normalizer classes, the preprocessing module provides a companion function binarize to be used when the transformer API is not necessary.

Note that the Binarizer is similar to the KBinsDiscretizer when \( k = 2 \), and when the bin edge is at the value threshold.

Sparse input

binarize and Binarizer accept both dense array-like and sparse matrices from scipy.sparse as input.

For sparse input the data is converted to the Compressed Sparse Rows representation (see scipy.sparse.csr_matrix). To avoid unnecessary memory copies, it is recommended to choose the CSR representation up-stream.
Imputation of missing values

Tools for imputing missing values are discussed at *Imputation of missing values*.

Generating polynomial features

Often it’s useful to add complexity to the model by considering nonlinear features of the input data. A simple and common method to use is polynomial features, which can get features’ high-order and interaction terms. It is implemented in *PolynomialFeatures*:

```python
>>> import numpy as np
>>> from sklearn.preprocessing import PolynomialFeatures
>>> X = np.array([[0, 1],
                [2, 3],
                [4, 5]])
>>> poly = PolynomialFeatures(2)
>>> poly.fit_transform(X)
array([[ 1.,  0.,  1.,  0.,  0.,  1.],
       [ 1.,  2.,  3.,  4.,  6.,  9.],
       [ 1.,  4.,  5., 16., 20., 25.]])
```

The features of X have been transformed from \((X_1, X_2)\) to \((1, X_1, X_2, X^2_1, X_1X_2, X^2_2)\).

In some cases, only interaction terms among features are required, and it can be gotten with the setting `interaction_only=True`:

```python
>>> X = np.array([[0, 1, 2],
                [3, 4, 5],
                [6, 7, 8]])
>>> poly = PolynomialFeatures(degree=3, interaction_only=True)
>>> poly.fit_transform(X)
array([[ 1.,  1.,  1.,  0.,  1.,  0.,  2.,  0.,  0.,  2.,  0.],
       [ 1.,  3.,  4.,  5., 12., 15., 20., 60.],
       [ 1.,  6.,  7.,  8., 42., 48., 56., 336.]])
```

The features of X have been transformed from \((X_1, X_2, X_3)\) to \((1, X_1, X_2, X_3, X_1X_2, X_1X_3, X_2X_3, X_1X_2X_3)\).

Note that polynomial features are used implicitly in kernel methods (e.g., *SVC, KernelPCA*) when using polynomial *Kernel functions*.

See *Polynomial interpolation* for Ridge regression using created polynomial features.

Custom transformers

Often, you will want to convert an existing Python function into a transformer to assist in data cleaning or processing. You can implement a transformer from an arbitrary function with *FunctionTransformer*. For example, to build a transformer that applies a log transformation in a pipeline, do:

```python
>>> import numpy as np
>>> from sklearn.preprocessing import FunctionTransformer
>>> transformer = FunctionTransformer(np.log1p, validate=True)
>>> X = np.array([[0, 1], [2, 3]])
```

(continues on next page)
You can ensure that `func` and `inverse_func` are the inverse of each other by setting `check_inverse=True` and calling `fit` before `transform`. Please note that a warning is raised and can be turned into an error with a `filterwarnings`:

```python
>>> import warnings
>>> warnings.filterwarnings("error", message=".*check_inverse*.",
... category=UserWarning, append=False)
```

For a full code example that demonstrates using a `FunctionTransformer` to extract features from text data see `Column Transformer with Heterogeneous Data Sources`.

### 4.6.4 Imputation of missing values

For various reasons, many real world datasets contain missing values, often encoded as blanks, NaNs or other placeholders. Such datasets however are incompatible with scikit-learn estimators which assume that all values in an array are numerical, and that all have and hold meaning. A basic strategy to use incomplete datasets is to discard entire rows and/or columns containing missing values. However, this comes at the price of losing data which may be valuable (even though incomplete). A better strategy is to impute the missing values, i.e., to infer them from the known part of the data. See the `Glossary of Common Terms and API Elements` entry on imputation.

#### Univariate vs. Multivariate Imputation

One type of imputation algorithm is univariate, which imputes values in the i-th feature dimension using only non-missing values in that feature dimension (e.g. `impute.SimpleImputer`). By contrast, multivariate imputation algorithms use the entire set of available feature dimensions to estimate the missing values (e.g. `impute.IterativeImputer`).

### Univariate feature imputation

The `SimpleImputer` class provides basic strategies for imputing missing values. Missing values can be imputed with a provided constant value, or using the statistics (mean, median or most frequent) of each column in which the missing values are located. This class also allows for different missing values encodings.

The following snippet demonstrates how to replace missing values, encoded as `np.nan`, using the mean value of the columns (axis 0) that contain the missing values:

```python
>>> import numpy as np
>>> from sklearn.impute import SimpleImputer
>>> imp = SimpleImputer(missing_values=np.nan, strategy='mean')
>>> imp.fit([[1, np.nan], [np.nan, 3], [7, 6]])
SimpleImputer()
>>> X = [[np.nan, 2], [6, np.nan], [7, 6]]
>>> print(imp.transform(X))
[[4.  2.  ]
 [6.  3.666...]
 [7.  6.  ]]
```

The `SimpleImputer` class also supports sparse matrices:
```python
>>> import scipy.sparse as sp
>>> X = sp.csc_matrix([[1, 2], [0, -1], [8, 4]])
>>> imp = SimpleImputer(missing_values=-1, strategy='mean')
>>> imp.fit(X)
SimpleImputer(missing_values=-1)
>>> X_test = sp.csc_matrix([[[-1, 2], [6, -1], [7, 6]])
>>> print(imp.transform(X_test).toarray())
[[3. 2.]
 [6. 3.]
 [7. 6.]]
```

Note that this format is not meant to be used to implicitly store missing values in the matrix because it would densify it at transform time. Missing values encoded by 0 must be used with dense input.

The `SimpleImputer` class also supports categorical data represented as string values or pandas categoricals when using the `most_frequent` or `constant` strategy:

```python
>>> from pandas import pd
>>> df = pd.DataFrame(["a", "x"],
... [np.nan, "y"],
... ["a", np.nan],
... ["b", "y"],
...)
>>> imp = SimpleImputer(strategy="most_frequent")
>>> print(imp.fit_transform(df))
 [['a' 'x']
  ['a' 'y']
  ['a' 'y']
  ['b' 'y']]
```

**Multivariate feature imputation**

A more sophisticated approach is to use the `IterativeImputer` class, which models each feature with missing values as a function of other features, and uses that estimate for imputation. It does so in an iterated round-robin fashion: at each step, a feature column is designated as output y and the other feature columns are treated as inputs X. A regressor is fit on \((X, y)\) for known \(y\). Then, the regressor is used to predict the missing values of \(y\). This is done for each feature in an iterative fashion, and then is repeated for `max_iter` imputation rounds. The results of the final imputation round are returned.

**Note:** This estimator is still experimental for now: default parameters or details of behaviour might change without any deprecation cycle. Resolving the following issues would help stabilize `IterativeImputer`: convergence criteria (#14338), default estimators (#13286), and use of random state (#15611). To use it, you need to explicitly import `enable_iterative_imputer`.

```python
>>> from sklearn.experimental import enable_iterative_imputer
>>> from sklearn.impute import IterativeImputer
>>> imp = IterativeImputer(max_iter=10, random_state=0)
>>> imp.fit([[1, 2], [3, 6], [4, 8], [np.nan, 3], [7, np.nan]])
IterativeImputer(random_state=0)
>>> X_test = [[np.nan, 2], [6, np.nan], [np.nan, 6]]
>>> # the model learns that the second feature is double the first
>>> print(np.round(imp.transform(X_test)))
```

(continues on next page)
Both `SimpleImputer` and `IterativeImputer` can be used in a Pipeline as a way to build a composite estimator that supports imputation. See *Imputing missing values before building an estimator*.

**Flexibility of IterativeImputer**

There are many well-established imputation packages in the R data science ecosystem: Amelia, mi, mice, missForest, etc. missForest is popular, and turns out to be a particular instance of different sequential imputation algorithms that can all be implemented with `IterativeImputer` by passing in different regressors to be used for predicting missing feature values. In the case of missForest, this regressor is a Random Forest. See *Imputing missing values with variants of IterativeImputer*.

**Multiple vs. Single Imputation**

In the statistics community, it is common practice to perform multiple imputations, generating, for example, $m$ separate imputations for a single feature matrix. Each of these $m$ imputations is then put through the subsequent analysis pipeline (e.g. feature engineering, clustering, regression, classification). The $m$ final analysis results (e.g. held-out validation errors) allow the data scientist to obtain understanding of how analytic results may differ as a consequence of the inherent uncertainty caused by the missing values. The above practice is called multiple imputation.

Our implementation of `IterativeImputer` was inspired by the R MICE package (Multivariate Imputation by Chained Equations)\(^1\), but differs from it by returning a single imputation instead of multiple imputations. However, `IterativeImputer` can also be used for multiple imputations by applying it repeatedly to the same dataset with different random seeds when `sample_posterior=True`. See\(^2\), chapter 4 for more discussion on multiple vs. single imputations.

It is still an open problem as to how useful single vs. multiple imputation is in the context of prediction and classification when the user is not interested in measuring uncertainty due to missing values.

Note that a call to the `transform` method of `IterativeImputer` is not allowed to change the number of samples. Therefore multiple imputations cannot be achieved by a single call to `transform`.

**References**

**Nearest neighbors imputation**

The `KNNImputer` class provides imputation for filling in missing values using the k-Nearest Neighbors approach. By default, a euclidean distance metric that supports missing values, `nan_euclidean_distances`, is used to find the nearest neighbors. Each missing feature is imputed using values from `n_neighbors` nearest neighbors that have a value for the feature. The feature of the neighbors are averaged uniformly or weighted by distance to each neighbor. If a sample has more than one feature missing, then the neighbors for that sample can be different depending on the particular feature being imputed. When the number of available neighbors is less than `n_neighbors` and there are no defined distances to the training set, the training set average for that feature is used during imputation. If there is at least one neighbor with a defined distance, the weighted or unweighted average of the remaining neighbors will be used during imputation. If a feature is always missing in training, it is removed during `transform`. For more information on the methodology, see ref. [OL2001].

The following snippet demonstrates how to replace missing values, encoded as \texttt{np.nan}, using the mean feature value of the two nearest neighbors of samples with missing values:

```python
>>> import numpy as np
>>> from sklearn.impute import KNNImputer
>>> nan = np.nan
>>> X = \[
\begin{bmatrix}
1, 2, nan, \\
3, 4, 3, \\
nan, 6, 5, \\
8, 8, 7
\end{bmatrix}
\]
>>> imputer = KNNImputer(n_neighbors=2, weights="uniform")
>>> imputer.fit_transform(X)
\[
\begin{bmatrix}
1.0, 2.0, 4.0, \\
11.0, 4.0, 3.0, \\
5.5, 6.0, 5.0, \\
8.0, 8.0, 7.0
\end{bmatrix}
\]
```

### Marking imputed values

The \texttt{MissingIndicator} transformer is useful to transform a dataset into corresponding binary matrix indicating the presence of missing values in the dataset. This transformation is useful in conjunction with imputation. When using imputation, preserving the information about which values had been missing can be informative. Note that both the \texttt{SimpleImputer} and \texttt{IterativeImputer} have the boolean parameter \texttt{add_indicator} (\texttt{False} by default) which when set to \texttt{True} provides a convenient way of stacking the output of the \texttt{MissingIndicator} transformer with the output of the imputer.

\texttt{NaN} is usually used as the placeholder for missing values. However, it enforces the data type to be float. The parameter \texttt{missing_values} allows to specify other placeholder such as integer. In the following example, we will use \texttt{-1} as missing values:

```python
>>> from sklearn.impute import MissingIndicator

>>> X = np.array(\[
\begin{bmatrix}
-1, -1, 1, 3, \\
4, -1, 0, -1, \\
8, -1, 1, 0
\end{bmatrix}
\]
...

>>> indicator = MissingIndicator(missing_values=-1)
>>> mask_missing_values_only = indicator.fit_transform(X)
>>> mask_missing_values_only
\[
\begin{bmatrix}
True, True, False, \\
False, True, True, \\
False, True, False
\end{bmatrix}
\]
```

The \texttt{features} parameter is used to choose the features for which the mask is constructed. By default, it is 'missing-only' which returns the imputer mask of the features containing missing values at fit time:

```python
>>> indicator.features_
array([0, 1, 3])
```

The \texttt{features} parameter can be set to 'all' to return all features whether or not they contain missing values:

```python
>>> indicator = MissingIndicator(missing_values=-1, features="all")
>>> mask_all = indicator.fit_transform(X)
>>> mask_all
\[
\begin{bmatrix}
True, True, False, False, \\
False, True, False, True, \\
False, True, False, False
\end{bmatrix}
\]
```

When using the \texttt{MissingIndicator} in a \texttt{Pipeline}, be sure to use the \texttt{FeatureUnion} or \texttt{ColumnTransformer} to add the indicator features to the regular features. First we obtain the \texttt{iris} dataset,
and add some missing values to it.

```python
>>> from sklearn.datasets import load_iris
>>> from sklearn.impute import SimpleImputer, MissingIndicator
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.pipeline import FeatureUnion, make_pipeline
>>> from sklearn.tree import DecisionTreeClassifier

>>> X, y = load_iris(return_X_y=True)
>>> mask = np.random.randint(0, 2, size=X.shape).astype(bool)
>>> X[mask] = np.nan
>>> X_train, X_test, y_train, _ = train_test_split(X, y, test_size=100, random_state=0)

Now we create a `FeatureUnion`. All features will be imputed using `SimpleImputer`, in order to enable classifiers to work with this data. Additionally, it adds the indicator variables from `MissingIndicator`.

```python
>>> transformer = FeatureUnion(
...                     transformer_list=[
...                         ('features', SimpleImputer(strategy='mean')),
...                         ('indicators', MissingIndicator())
...                     ]
...                 )
>>> transformer = transformer.fit(X_train, y_train)
>>> results = transformer.transform(X_test)
>>> results.shape
(100, 8)
```

Of course, we cannot use the transformer to make any predictions. We should wrap this in a `Pipeline` with a classifier (e.g., a `DecisionTreeClassifier`) to be able to make predictions.

```python
>>> clf = make_pipeline(transformer, DecisionTreeClassifier())
>>> clf = clf.fit(X_train, y_train)
>>> results = clf.predict(X_test)
>>> results.shape
(100,)
```

### 4.6.5 Unsupervised dimensionality reduction

If your number of features is high, it may be useful to reduce it with an unsupervised step prior to supervised steps. Many of the `Unsupervised learning` methods implement a `transform` method that can be used to reduce the dimensionality. Below we discuss two specific example of this pattern that are heavily used.

**Pipelining**

The unsupervised data reduction and the supervised estimator can be chained in one step. See `Pipeline: chaining estimators`. 
PCA: principal component analysis

`decomposition.PCA` looks for a combination of features that capture well the variance of the original features. See *Decomposing signals in components (matrix factorization problems)*.

**Examples**

- Faces recognition example using eigenfaces and SVMs

Random projections

The module: `random_projection` provides several tools for data reduction by random projections. See the relevant section of the documentation: *Random Projection*.

**Examples**

- The Johnson-Lindenstrauss bound for embedding with random projections

Feature agglomeration

`cluster.FeatureAgglomeration` applies Hierarchical clustering to group together features that behave similarly.

**Examples**

- Feature agglomeration vs. univariate selection
- Feature agglomeration

Feature scaling

Note that if features have very different scaling or statistical properties, `cluster.FeatureAgglomeration` may not be able to capture the links between related features. Using a `preprocessing.StandardScaler` can be useful in these settings.

4.6.6 Random Projection

The `sklearn.random_projection` module implements a simple and computationally efficient way to reduce the dimensionality of the data by trading a controlled amount of accuracy (as additional variance) for faster processing times and smaller model sizes. This module implements two types of unstructured random matrix: Gaussian random matrix and sparse random matrix.

The dimensions and distribution of random projections matrices are controlled so as to preserve the pairwise distances between any two samples of the dataset. Thus random projection is a suitable approximation technique for distance based method.
The Johnson-Lindenstrauss lemma

The main theoretical result behind the efficiency of random projection is the Johnson-Lindenstrauss lemma (quoting Wikipedia):

In mathematics, the Johnson-Lindenstrauss lemma is a result concerning low-distortion embeddings of points from high-dimensional into low-dimensional Euclidean space. The lemma states that a small set of points in a high-dimensional space can be embedded into a space of much lower dimension in such a way that distances between the points are nearly preserved. The map used for the embedding is at least Lipschitz, and can even be taken to be an orthogonal projection.

Knowing only the number of samples, the `johnson_lindenstrauss_min_dim` estimates conservatively the minimal size of the random subspace to guarantee a bounded distortion introduced by the random projection:

```python
>>> from sklearn.random_projection import johnson_lindenstrauss_min_dim
>>> johnson_lindenstrauss_min_dim(n_samples=1e6, eps=0.5)
663
>>> johnson_lindenstrauss_min_dim(n_samples=1e6, eps=[0.5, 0.1, 0.01])
array([ 663, 11841, 1112658])
>>> johnson_lindenstrauss_min_dim(n_samples=[1e4, 1e5, 1e6], eps=0.1)
array([ 7894,  9868, 11841])
```
Example:

- See *The Johnson-Lindenstrauss bound for embedding with random projections* for a theoretical explication on the Johnson-Lindenstrauss lemma and an empirical validation using sparse random matrices.

References:

Gaussian random projection

The `GaussianRandomProjection` reduces the dimensionality by projecting the original input space on a randomly generated matrix where components are drawn from the following distribution \( N(0, \frac{1}{\text{n\_components}}) \).

Here a small excerpt which illustrates how to use the Gaussian random projection transformer:

```python
>>> import numpy as np
>>> from sklearn import random_projection
>>> X = np.random.rand(100, 10000)
>>> transformer = random_projection.GaussianRandomProjection()
>>> X_new = transformer.transform(X)
>>> X_new.shape
(100, 3947)
```
Sparse random projection

The SparseRandomProjection reduces the dimensionality by projecting the original input space using a sparse random matrix.

Sparse random matrices are an alternative to dense Gaussian random projection matrix that guarantees similar embedding quality while being much more memory efficient and allowing faster computation of the projected data.

If we define \( s = 1 / \text{density} \), the elements of the random matrix are drawn from

\[
\begin{cases}
-\sqrt{s/n_{\text{components}}} & 1/2s \\
0 & 1 - 1/s \\
+\sqrt{s/n_{\text{components}}} & 1/2s
\end{cases}
\]

where \( n_{\text{components}} \) is the size of the projected subspace. By default the density of non zero elements is set to the minimum density as recommended by Ping Li et al.: \( 1/\sqrt{n_{\text{features}}} \).

Here a small excerpt which illustrates how to use the sparse random projection transformer:

```python
>>> import numpy as np
>>> from sklearn import random_projection
>>> X = np.random.rand(100, 10000)
>>> transformer = random_projection.SparseRandomProjection()
>>> X_new = transformer.fit_transform(X)
>>> X_new.shape
(100, 3947)
```

4.6.7 Kernel Approximation

This submodule contains functions that approximate the feature mappings that correspond to certain kernels, as they are used for example in support vector machines (see Support Vector Machines). The following feature functions perform non-linear transformations of the input, which can serve as a basis for linear classification or other algorithms.

The advantage of using approximate explicit feature maps compared to the kernel trick, which makes use of feature maps implicitly, is that explicit mappings can be better suited for online learning and can significantly reduce the cost of learning with very large datasets. Standard kernelized SVMs do not scale well to large datasets, but using an approximate kernel map it is possible to use much more efficient linear SVMs. In particular, the combination of kernel map approximations with SGDClassifier can make non-linear learning on large datasets possible.

Since there has not been much empirical work using approximate embeddings, it is advisable to compare results against exact kernel methods when possible.

See also:

Polynomial regression: extending linear models with basis functions for an exact polynomial transformation.
Nystroem Method for Kernel Approximation

The Nystroem method, as implemented in Nystroem is a general method for low-rank approximations of kernels. It achieves this by essentially subsampling the data on which the kernel is evaluated. By default Nystroem uses the rbf kernel, but it can use any kernel function or a precomputed kernel matrix. The number of samples used - which is also the dimensionality of the features computed - is given by the parameter n_components.

Radial Basis Function Kernel

The RBFSampler constructs an approximate mapping for the radial basis function kernel, also known as Random Kitchen Sinks [RR2007]. This transformation can be used to explicitly model a kernel map, prior to applying a linear algorithm, for example a linear SVM:

```python
>>> from sklearn.kernel_approximation import RBFSampler
>>> from sklearn.linear_model import SGDClassifier
>>> X = [[0, 0], [1, 1], [1, 0], [0, 1]]
>>> y = [0, 0, 1, 1]
>>> rbf_feature = RBFSampler(gamma=1, random_state=1)
>>> X_features = rbf_feature.fit_transform(X)
>>> clf = SGDClassifier(max_iter=5)
>>> clf.fit(X_features, y)
SGDClassifier(max_iter=5)
>>> clf.score(X_features, y)
1.0
```

The mapping relies on a Monte Carlo approximation to the kernel values. The fit function performs the Monte Carlo sampling, whereas the transform method performs the mapping of the data. Because of the inherent randomness of the process, results may vary between different calls to the fit function.

The fit function takes two arguments: n_components, which is the target dimensionality of the feature transform, and gamma, the parameter of the RBF-kernel. A higher n_components will result in a better approximation of the kernel and will yield results more similar to those produced by a kernel SVM. Note that “fitting” the feature function does not actually depend on the data given to the fit function. Only the dimensionality of the data is used. Details on the method can be found in [RR2007].

For a given value of n_components RBFSampler is often less accurate as Nystroem. RBFSampler is cheaper to compute, though, making use of larger feature spaces more efficient.

Examples:

• Explicit feature map approximation for RBF kernels

Additive Chi Squared Kernel

The additive chi squared kernel is a kernel on histograms, often used in computer vision.

The additive chi squared kernel as used here is given by

\[ k(x, y) = \sum_i \frac{2x_i y_i}{x_i + y_i} \]

This is not exactly the same as `sklearn.metrics.additive_chi2_kernel`. The authors of [VZ2010] prefer the version above as it is always positive definite. Since the kernel is additive, it is possible to treat all components
Fig. 10: Comparing an exact RBF kernel (left) with the approximation (right)

$x_i$ separately for embedding. This makes it possible to sample the Fourier transform in regular intervals, instead of approximating using Monte Carlo sampling.

The class `AdditiveChi2Sampler` implements this component wise deterministic sampling. Each component is sampled $n$ times, yielding $2n + 1$ dimensions per input dimension (the multiple of two stems from the real and complex part of the Fourier transform). In the literature, $n$ is usually chosen to be 1 or 2, transforming the dataset to size $n_{\text{samples}} \times 5 \times n_{\text{features}}$ (in the case of $n = 2$).

The approximate feature map provided by `AdditiveChi2Sampler` can be combined with the approximate feature map provided by `RBFSampler` to yield an approximate feature map for the exponentiated chi squared kernel. See the [VZ2010] for details and [VVZ2010] for combination with the `RBFSampler`.

### Skewed Chi Squared Kernel

The skewed chi squared kernel is given by:

$$ k(x, y) = \prod_i \frac{2\sqrt{x_i + c} \sqrt{y_i + c}}{x_i + y_i + 2c} $$

It has properties that are similar to the exponentiated chi squared kernel often used in computer vision, but allows for a simple Monte Carlo approximation of the feature map.

The usage of the `SkewedChi2Sampler` is the same as the usage described above for the `RBFSampler`. The only difference is in the free parameter, that is called $c$. For a motivation for this mapping and the mathematical details see [LS2010].
Polynomial Kernel Approximation via Tensor Sketch

The polynomial kernel is a popular type of kernel function given by:

\[ k(x, y) = (\gamma x^\top y + c_0)^d \]

where:

- \( x, y \) are the input vectors
- \( d \) is the kernel degree

Intuitively, the feature space of the polynomial kernel of degree \( d \) consists of all possible degree-\( d \) products among input features, which enables learning algorithms using this kernel to account for interactions between features.

The TensorSketch [PP2013] method, as implemented in `PolynomialCountSketch`, is a scalable, input data independent method for polynomial kernel approximation. It is based on the concept of Count sketch [WIKICS] [CCF2002], a dimensionality reduction technique similar to feature hashing, which instead uses several independent hash functions. TensorSketch obtains a Count Sketch of the outer product of two vectors (or a vector with itself), which can be used as an approximation of the polynomial kernel feature space. In particular, instead of explicitly computing the outer product, TensorSketch computes the Count Sketch of the vectors and then uses polynomial multiplication via the Fast Fourier Transform to compute the Count Sketch of their outer product.

Conveniently, the training phase of TensorSketch simply consists of initializing some random variables. It is thus independent of the input data, i.e. it only depends on the number of input features, but not the data values. In addition, this method can transform samples in \( \mathcal{O}(n_{\text{samples}} (n_{\text{features}} + n_{\text{components}} \log(n_{\text{components}}))) \) time, where \( n_{\text{components}} \) is the desired output dimension, determined by \( n_{\text{components}} \).

Examples:

- Scalable learning with polynomial kernel approximation

Mathematical Details

Kernel methods like support vector machines or kernelized PCA rely on a property of reproducing kernel Hilbert spaces. For any positive definite kernel function \( k \) (a so called Mercer kernel), it is guaranteed that there exists a mapping \( \phi \) into a Hilbert space \( \mathcal{H} \), such that

\[ k(x, y) = \langle \phi(x), \phi(y) \rangle \]

Where \( \langle \cdot, \cdot \rangle \) denotes the inner product in the Hilbert space.

If an algorithm, such as a linear support vector machine or PCA, relies only on the scalar product of data points \( x_i \), one may use the value of \( k(x_i, x_j) \), which corresponds to applying the algorithm to the mapped data points \( \phi(x_i) \). The advantage of using \( k \) is that the mapping \( \phi \) never has to be calculated explicitly, allowing for arbitrary large features (even infinite).

One drawback of kernel methods is, that it might be necessary to store many kernel values \( k(x_i, x_j) \) during optimization. If a kernelized classifier is applied to new data \( y_j \), \( k(x_i, y_j) \) needs to be computed to make predictions, possibly for many different \( x_i \) in the training set.

The classes in this submodule allow to approximate the embedding \( \phi \), thereby working explicitly with the representations \( \phi(x_i) \), which obviates the need to apply the kernel or store training examples.
4.6.8 Pairwise metrics, Affinities and Kernels

The sklearn.metrics.pairwise submodule implements utilities to evaluate pairwise distances or affinity of sets of samples.

This module contains both distance metrics and kernels. A brief summary is given on the two here.

Distance metrics are functions \( d(a, b) \) such that \( d(a, b) < d(a, c) \) if objects \( a \) and \( b \) are considered “more similar” than objects \( a \) and \( c \). Two objects exactly alike would have a distance of zero. One of the most popular examples is Euclidean distance. To be a ‘true’ metric, it must obey the following four conditions:

1. \( d(a, b) \geq 0 \), for all \( a \) and \( b \)
2. \( d(a, b) = 0 \), if and only if \( a = b \), positive definiteness
3. \( d(a, b) = d(b, a) \), symmetry
4. \( d(a, c) \leq d(a, b) + d(b, c) \), the triangle inequality

Kernels are measures of similarity, i.e. \( s(a, b) > s(a, c) \) if objects \( a \) and \( b \) are considered “more similar” than objects \( a \) and \( c \). A kernel must also be positive semi-definite.

There are a number of ways to convert between a distance metric and a similarity measure, such as a kernel. Let \( D \) be the distance, and \( S \) be the kernel:

1. \( S = \exp(-D \times \text{gamma}) \), where one heuristic for choosing \( \text{gamma} \) is \( 1 / \text{num\_features} \)
2. \( S = 1. / (D / \text{np\_max}(D)) \)

The distances between the row vectors of \( X \) and the row vectors of \( Y \) can be evaluated using pairwise_distances. If \( Y \) is omitted the pairwise distances of the row vectors of \( X \) are calculated. Similarly, pairwise_kernels can be used to calculate the kernel between \( X \) and \( Y \) using different kernel functions. See the API reference for more details.

```python
>>> import numpy as np
>>> from sklearn.metrics import pairwise_distances
>>> from sklearn.metrics.pairwise import pairwise_kernels
>>> X = np.array([[2, 3], [3, 5], [5, 8]])
>>> Y = np.array([[1, 0], [2, 1]])
>>> pairwise_distances(X, Y, metric='manhattan')
array([[ 4.,  2.],
       [ 7.,  5.],
       [12., 10.]])
>>> pairwise_distances(X, metric='manhattan')
array([[0.,  3.],
       [3.,  0.],
       [8.,  5.],
       [5.,  0.]])
>>> pairwise_kernels(X, Y, metric='linear')
array([[ 2.,  7.],
       [ 3., 11.],
       [ 5., 18.]]
```
Cosine similarity

*cosine_similarity* computes the L2-normalized dot product of vectors. That is, if \( x \) and \( y \) are row vectors, their cosine similarity \( k \) is defined as:

\[
k(x, y) = \frac{xy^\top}{\|x\| \|y\|}
\]

This is called cosine similarity, because Euclidean (L2) normalization projects the vectors onto the unit sphere, and their dot product is then the cosine of the angle between the points denoted by the vectors.

This kernel is a popular choice for computing the similarity of documents represented as tf-idf vectors. *cosine_similarity* accepts scipy.sparse matrices. (Note that the tf-idf functionality in sklearn.feature_extraction.text can produce normalized vectors, in which case *cosine_similarity* is equivalent to *linear_kernel*, only slower.)

References:

Linear kernel

The function *linear_kernel* computes the linear kernel, that is, a special case of *polynomial_kernel* with `degree=1` and `coef0=0` (homogeneous). If \( x \) and \( y \) are column vectors, their linear kernel is:

\[
k(x, y) = x^\top y
\]

Polynomial kernel

The function *polynomial_kernel* computes the degree-\( d \) polynomial kernel between two vectors. The polynomial kernel represents the similarity between two vectors. Conceptually, the polynomial kernels considers not only the similarity between vectors under the same dimension, but also across dimensions. When used in machine learning algorithms, this allows to account for feature interaction.

The polynomial kernel is defined as:

\[
k(x, y) = (\gamma x^\top y + c_0)^d
\]

where:

- \( x, y \) are the input vectors
- \( d \) is the kernel degree

If \( c_0 = 0 \) the kernel is said to be homogeneous.
Sigmoid kernel

The function `sigmoid_kernel` computes the sigmoid kernel between two vectors. The sigmoid kernel is also known as hyperbolic tangent, or Multilayer Perceptron (because, in the neural network field, it is often used as neuron activation function). It is defined as:

\[ k(x, y) = \tanh(\gamma x^\top y + c_0) \]

where:
- \( x, y \) are the input vectors
- \( \gamma \) is known as slope
- \( c_0 \) is known as intercept

RBF kernel

The function `rbf_kernel` computes the radial basis function (RBF) kernel between two vectors. This kernel is defined as:

\[ k(x, y) = \exp(-\gamma \|x - y\|^2) \]

where \( x \) and \( y \) are the input vectors. If \( \gamma = \sigma^{-2} \) the kernel is known as the Gaussian kernel of variance \( \sigma^2 \).

Laplacian kernel

The function `laplacian_kernel` is a variant on the radial basis function kernel defined as:

\[ k(x, y) = \exp(-\gamma \|x - y\|_1) \]

where \( x \) and \( y \) are the input vectors and \( \|x - y\|_1 \) is the Manhattan distance between the input vectors.

It has proven useful in ML applied to noiseless data. See e.g. Machine learning for quantum mechanics in a nutshell.

Chi-squared kernel

The chi-squared kernel is a very popular choice for training non-linear SVMs in computer vision applications. It can be computed using `chi2_kernel` and then passed to an `SVC` with `kernel="precomputed"`:

```python
>>> from sklearn.svm import SVC
>>> from sklearn.metrics.pairwise import chi2_kernel
>>> X = [[0, 1], [1, 0], [.2, .8], [.7, .3]]
>>> y = [0, 1, 0, 1]
>>> K = chi2_kernel(X, gamma=.5)
>>> K
array([[ 1.,  0.36787944,  0.89483932,  0.58364548],
       [ 0.36787944,  1.,  0.51341712,  0.83822343],
       [ 0.89483932,  0.51341712,  1.,  0.7768366 ],
       [ 0.58364548,  0.83822343,  0.7768366 ,  1. ]])

>>> svm = SVC(kernel='precomputed').fit(K, y)
>>> svm.predict(K)
array([0, 1, 0, 1])
```

It can also be directly used as the `kernel` argument:
The chi squared kernel is given by

\[ k(x, y) = \exp \left( -\gamma \sum_i \frac{(x[i] - y[i])^2}{x[i] + y[i]} \right) \]

The data is assumed to be non-negative, and is often normalized to have an L1-norm of one. The normalization is rationalized with the connection to the chi squared distance, which is a distance between discrete probability distributions.

The chi squared kernel is most commonly used on histograms (bags) of visual words.

References:

4.6.9 Transforming the prediction target (y)

These are transformers that are not intended to be used on features, only on supervised learning targets. See also Transforming target in regression if you want to transform the prediction target for learning, but evaluate the model in the original (untransformed) space.

Label binarization

LabelBinarizer

LabelBinarizer is a utility class to help create a label indicator matrix from a list of multiclass labels:

```python
>>> from sklearn import preprocessing
>>> lb = preprocessing.LabelBinarizer()
>>> lb.fit([1, 2, 6, 4, 2])
LabelBinarizer()
>>> lb.classes_
array([1, 2, 4, 6])
>>> lb.transform([1, 6])
array([[1, 0, 0, 0],
       [0, 0, 0, 1]])
```

Using this format can enable multiclass classification in estimators that support the label indicator matrix format.

Warning: LabelBinarizer is not needed if you are using an estimator that already supports multiclass data.

For more information about multiclass classification, refer to Multiclass classification.
**MultiLabelBinarizer**

In multilabel learning, the joint set of binary classification tasks is expressed with a label binary indicator array: each sample is one row of a 2d array of shape \((n_{samples}, n_{classes})\) with binary values where the one, i.e. the non zero elements, corresponds to the subset of labels for that sample. An array such as `np.array([[1, 0, 0], [0, 1, 1], [0, 0, 0]])` represents label 0 in the first sample, labels 1 and 2 in the second sample, and no labels in the third sample.

Producing multilabel data as a list of sets of labels may be more intuitive. The `MultiLabelBinarizer` transformer can be used to convert between a collection of collections of labels and the indicator format:

```python
>>> from sklearn.preprocessing import MultiLabelBinarizer
>>> y = [[2, 3, 4], [2], [0, 1, 3], [0, 1, 2, 3, 4], [0, 1, 2]]
>>> MultiLabelBinarizer().transform(y)
array([[0, 0, 1, 1, 1],
       [0, 0, 1, 0, 0],
       [1, 1, 0, 1, 0],
       [1, 1, 1, 1, 1],
       [1, 1, 1, 0, 0]])
```

For more information about multilabel classification, refer to *Multilabel classification*.

**Label encoding**

`LabelEncoder` is a utility class to help normalize labels such that they contain only values between 0 and \(n_{classes}-1\). This is sometimes useful for writing efficient Cython routines. `LabelEncoder` can be used as follows:

```python
>>> from sklearn import preprocessing
>>> le = preprocessing.LabelEncoder()
>>> le.fit([1, 2, 2, 6])
LabelEncoder()
>>> le.classes_
array([1, 2, 6])
>>> le.transform([1, 1, 2, 6])
array([0, 0, 1, 2])
>>> le.inverse_transform([0, 0, 1, 2])
array([1, 1, 2, 6])
```

It can also be used to transform non-numerical labels (as long as they are hashable and comparable) to numerical labels:

```python
>>> le = preprocessing.LabelEncoder()
>>> le.fit(['paris', 'paris', 'tokyo', 'amsterdam'])
LabelEncoder()
>>> le.classes_
['amsterdam', 'paris', 'tokyo']
>>> le.transform(['tokyo', 'tokyo', 'paris'])
array([2, 2, 1])
>>> list(le.inverse_transform([2, 2, 1]))
['tokyo', 'tokyo', 'paris']
```
4.7 Dataset loading utilities

The `sklearn.datasets` package embeds some small toy datasets as introduced in the *Getting Started* section. This package also features helpers to fetch larger datasets commonly used by the machine learning community to benchmark algorithms on data that comes from the ‘real world’.

To evaluate the impact of the scale of the dataset (n_samples and n_features) while controlling the statistical properties of the data (typically the correlation and informativeness of the features), it is also possible to generate synthetic data.

**General dataset API.** There are three main kinds of dataset interfaces that can be used to get datasets depending on the desired type of dataset.

- **The dataset loaders.** They can be used to load small standard datasets, described in the *Toy datasets* section.
- **The dataset fetchers.** They can be used to download and load larger datasets, described in the *Real world datasets* section.
- **The datasets also contain a full description in their DESCR attribute and some contain feature_names and target_names. See the dataset descriptions below for details.**

- **The dataset generation functions.** They can be used to generate controlled synthetic datasets, described in the *Generated datasets* section.

- **In addition, there are also miscellaneous tools to load datasets of other formats or from other locations, described in the *Loading other datasets* section.**

4.7.1 Toy datasets

scikit-learn comes with a few small standard datasets that do not require to download any file from some external website.

They can be loaded using the following functions:

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>load_boston(*)[, return_X_y]</code></td>
<td>Load and return the boston house-prices dataset (regression).</td>
</tr>
<tr>
<td><code>load_iris(*)[, return_X_y, as_frame]</code></td>

These datasets are useful to quickly illustrate the behavior of the various algorithms implemented in scikit-learn. They are however often too small to be representative of real world machine learning tasks.

**Boston house prices dataset**

Data Set Characteristics:
- **Number of Instances** 506
- **Number of Attributes** 13 numeric/categorical predictive. Median Value (attribute 14) is usually the target.

Attribute Information (in order)
- CRIM per capita crime rate by town
- ZN proportion of residential land zoned for lots over 25,000 sq.ft.
- INDUS proportion of non-retail business acres per town
- CHAS Charles River dummy variable (= 1 if tract bounds river; 0 otherwise)
- NOX nitric oxides concentration (parts per 10 million)
- RM average number of rooms per dwelling
- AGE proportion of owner-occupied units built prior to 1940
- DIS weighted distances to five Boston employment centres
- RAD index of accessibility to radial highways
- TAX full-value property-tax rate per $10,000
- PTRATIO pupil-teacher ratio by town
- B 1000(Bk - 0.63)^2 where Bk is the proportion of blacks by town
- LSTAT % lower status of the population
- MEDV Median value of owner-occupied homes in $1000’s

Missing Attribute Values  None

**Creator** Harrison, D. and Rubinfeld, D.L.

This is a copy of UCI ML housing dataset. [https://archive.ics.uci.edu/ml/machine-learning-databases/housing/](https://archive.ics.uci.edu/ml/machine-learning-databases/housing/)

This dataset was taken from the StatLib library which is maintained at Carnegie Mellon University.

The Boston house-price data has been used in many machine learning papers that address regression problems.

Class Distribution  33.3% for each of 3 classes.

Creator  R.A. Fisher
Donor  Michael Marshall (MARSHALL%PLU@io.arc.nasa.gov)
Date  July, 1988

The famous Iris database, first used by Sir R.A. Fisher. The dataset is taken from Fisher’s paper. Note that it’s the same as in R, but not as in the UCI Machine Learning Repository, which has two wrong data points.

This is perhaps the best known database to be found in the pattern recognition literature. Fisher’s paper is a classic in the field and is referenced frequently to this day. (See Duda & Hart, for example.) The data set contains 3 classes of 50 instances each, where each class refers to a type of iris plant. One class is linearly separable from the other 2; the latter are NOT linearly separable from each other.

Diabetes dataset

Ten baseline variables, age, sex, body mass index, average blood pressure, and six blood serum measurements were obtained for each of \( n = 442 \) diabetes patients, as well as the response of interest, a quantitative measure of disease progression one year after baseline.

**Data Set Characteristics:**

- **Number of Instances** 442
- **Number of Attributes** First 10 columns are numeric predictive values
- **Target** Column 11 is a quantitative measure of disease progression one year after baseline

**Attribute Information**

- age age in years
- sex
- bmi body mass index
- bp average blood pressure
- s1 tc, T-Cells (a type of white blood cells)
- s2 ldl, low-density lipoproteins
- s3 hdl, high-density lipoproteins
- s4 tch, thyroid stimulating hormone
- s5 ltg, lamotrigine
- s6 glu, blood sugar level

Note: Each of these 10 feature variables have been mean centered and scaled by the standard deviation times \( n_{\text{samples}} \) (i.e. the sum of squares of each column totals 1).

Optical recognition of handwritten digits dataset

Data Set Characteristics:

Number of Instances  5620
Number of Attributes  64
Attribute Information  8x8 image of integer pixels in the range 0..16.
Missing Attribute Values  None
Creator
E. Alpaydin (alpaydin ‘@’ boun.edu.tr)
Date  July; 1998

This is a copy of the test set of the UCI ML hand-written digits datasets https://archive.ics.uci.edu/ml/datasets/Optical+Recognition+of+Handwritten+Digits

The data set contains images of hand-written digits: 10 classes where each class refers to a digit.

Preprocessing programs made available by NIST were used to extract normalized bitmaps of handwritten digits from a preprinted form. From a total of 43 people, 30 contributed to the training set and different 13 to the test set. 32x32 bitmaps are divided into nonoverlapping blocks of 4x4 and the number of on pixels are counted in each block. This generates an input matrix of 8x8 where each element is an integer in the range 0..16. This reduces dimensionality and gives invariance to small distortions.

The data was used with many others for comparing various classifiers. The classes are separable, though only RDA has achieved 100% correct classification. (RDA : 100%, QDA 99.4%, LDA 98.9%, INN 96.1% (z-transformed data)) (All results using the leave-one-out technique)

Breast cancer wisconsin (diagnostic) dataset

Data Set Characteristics:

- **Number of Instances**: 569
- **Number of Attributes**: 30 numeric, predictive attributes and the class

**Attribute Information**

- radius (mean of distances from center to points on the perimeter)
- texture (standard deviation of gray-scale values)
- perimeter
- area
- smoothness (local variation in radius lengths)
- compactness (perimeter^2 / area - 1.0)
- concavity (severity of concave portions of the contour)
- concave points (number of concave portions of the contour)
- symmetry
- fractal dimension (“coastline approximation” - 1)

The mean, standard error, and “worst” or largest (mean of the three worst/largest values) of these features were computed for each image, resulting in 30 features. For instance, field 0 is Mean Radius, field 10 is Radius SE, field 20 is Worst Radius.

Missing Attribute Values  None

Class Distribution  212 - Malignant, 357 - Benign

Creator  Dr. William H. Wolberg, W. Nick Street, Olvi L. Mangasarian

Donor  Nick Street

Date  November, 1995

This is a copy of UCI ML Breast Cancer Wisconsin (Diagnostic) datasets. https://goo.gl/U2Uwz2

Features are computed from a digitized image of a fine needle aspirate (FNA) of a breast mass. They describe characteristics of the cell nuclei present in the image.

Separating plane described above was obtained using Multisurface Method-Tree (MSM-T) [K. P. Bennett, “Decision Tree Construction Via Linear Programming.” Proceedings of the 4th Midwest Artificial Intelligence and Cognitive Science Society, pp. 97-101, 1992], a classification method which uses linear programming to construct a decision tree. Relevant features were selected using an exhaustive search in the space of 1-4 features and 1-3 separating planes.

The actual linear program used to obtain the separating plane in the 3-dimensional space is that described in: [K. P. Bennett and O. L. Mangasarian: “Robust Linear Programming Discrimination of Two Linearly Inseparable Sets”, Optimization Methods and Software 1, 1992, 23-34].

This database is also available through the UW CS ftp server:

4.7.2 Real world datasets

scikit-learn provides tools to load larger datasets, downloading them if necessary. They can be loaded using the following functions:

- `fetch_olivetti_faces([, data_home, ...])` Load the Olivetti faces data-set from AT&T (classification).
- `fetch_20newsgroups([, data_home, subset, ...])` Load the filenames and data from the 20 newsgroups dataset (classification).
- `fetch_20newsgroups_vectorized([, subset, ...])` Load the 20 newsgroups dataset and vectorize it into token counts (classification).
- `fetch_lfw_people([, data_home, funneled, ...])` Load the Labeled Faces in the Wild (LFW) people dataset (classification).
- `fetch_lfw_pairs([, subset, data_home, ...])` Load the Labeled Faces in the Wild (LFW) pairs dataset (classification).
- `fetch_covtype([, data_home, ...])` Load the covertype dataset (classification).
- `fetch_rcv1([, data_home, subset, ...])` Load the RCV1 multilabel dataset (classification).
- `fetch_kddcup99([, subset, data_home, ...])` Load the kddcup99 dataset (classification).
- `fetch_california_housing([, data_home, ...])` Load the California housing dataset (regression).

The Olivetti faces dataset

This dataset contains a set of face images taken between April 1992 and April 1994 at AT&T Laboratories Cambridge. The `sklearn.datasets.fetch_olivetti_faces` function is the data fetching / caching function that downloads the data archive from AT&T.

As described on the original website:

There are ten different images of each of 40 distinct subjects. For some subjects, the images were taken at different times, varying the lighting, facial expressions (open / closed eyes, smiling / not smiling) and facial details (glasses / no glasses). All the images were taken against a dark homogeneous background with the subjects in an upright, frontal position (with tolerance for some side movement).

Data Set Characteristics:

</tbody>
</table>

The image is quantized to 256 grey levels and stored as unsigned 8-bit integers; the loader will convert these to floating point values on the interval [0, 1], which are easier to work with for many algorithms.

The “target” for this database is an integer from 0 to 39 indicating the identity of the person pictured; however, with only 10 examples per class, this relatively small dataset is more interesting from an unsupervised or semi-supervised perspective.

The original dataset consisted of 92 x 112, while the version available here consists of 64x64 images.

When using these images, please give credit to AT&T Laboratories Cambridge.
The 20 newsgroups text dataset

The 20 newsgroups dataset comprises around 18000 newsgroups posts on 20 topics split in two subsets: one for training (or development) and the other one for testing (or for performance evaluation). The split between the train and test set is based upon messages posted before and after a specific date.

This module contains two loaders. The first one, `sklearn.datasets.fetch_20newsgroups`, returns a list of the raw texts that can be fed to text feature extractors such as `CountVectorizer` with custom parameters so as to extract feature vectors. The second one, `sklearn.datasets.fetch_20newsgroups_vectorized`, returns ready-to-use features, i.e., it is not necessary to use a feature extractor.

**Data Set Characteristics:**

<p>| | |</p>
<table>

</tr>
</tbody>
</table>

**Usage**

The `sklearn.datasets.fetch_20newsgroups` function is a data fetching / caching functions that downloads the data archive from the original 20 newsgroups website, extracts the archive contents in the `~/scikit_learn_data/20news_home` folder and calls the `sklearn.datasets.load_files` on either the training or testing set folder, or both of them:

```python
>>> from sklearn.datasets import fetch_20newsgroups
>>> newsgroups_train = fetch_20newsgroups(subset='train')
```

```python
>>> from pprint import pprint
>>> pprint(list(newsgroups_train.target_names))
```

The real data lies in the `filenames` and `target` attributes. The target attribute is the integer index of the category:

```python
>>> newsgroups_train.filenames.shape
(11314,)
```

(continues on next page)
It is possible to load only a sub-selection of the categories by passing the list of the categories to load to the `sklearn.datasets.fetch_20newsgroups` function:

```python
>>> cats = ['alt.atheism', 'sci.space']
>>> newsgroups_train = fetch_20newsgroups(subset='train', categories=cats)

>>> list(newsgroups_train.target_names)
['alt.atheism', 'sci.space']
>>> newsgroups_train.filenames.shape
(1073,)
>>> newsgroups_train.target.shape
(1073,)
>>> newsgroups_train.target[:10]
array([0, 1, 1, 1, 0, 1, 1, 0, 0, 0])
```

## Converting text to vectors

In order to feed predictive or clustering models with the text data, one first need to turn the text into vectors of numerical values suitable for statistical analysis. This can be achieved with the utilities of the `sklearn.feature_extraction.text` as demonstrated in the following example that extract TF-IDF vectors of unigram tokens from a subset of 20news:

```python
>>> from sklearn.feature_extraction.text import TfidfVectorizer
>>> categories = ['alt.atheism', 'talk.religion.misc',
...    'comp.graphics', 'sci.space']
>>> newsgroups_train = fetch_20newsgroups(subset='train',
...    categories=categories)
>>> vectorizer = TfidfVectorizer()
>>> vectors = vectorizer.fit_transform(newsgroups_train.data)
>>> vectors.shape
(2034, 34118)
```

The extracted TF-IDF vectors are very sparse, with an average of 159 non-zero components by sample in a more than 30000-dimensional space (less than .5% non-zero features):

```python
>>> vectors.nnz / float(vectors.shape[0])
159.01327...
```

`sklearn.datasets.fetch_20newsgroups_vectorized` is a function which returns ready-to-use token counts features instead of file names.
Filtering text for more realistic training

It is easy for a classifier to overfit on particular things that appear in the 20 Newsgroups data, such as newsgroup headers. Many classifiers achieve very high F-scores, but their results would not generalize to other documents that aren’t from this window of time.

For example, let’s look at the results of a multinomial Naive Bayes classifier, which is fast to train and achieves a decent F-score:

```python
>>> from sklearn.naive_bayes import MultinomialNB
>>> from sklearn import metrics
>>> newsgroups_test = fetch_20newsgroups(subset='test',
... categories=categories)
>>> vectors_test = vectorizer.transform(newsgroups_test.data)
>>> clf = MultinomialNB(alpha=.01)
>>> clf.fit(vectors, newsgroups_train.target)
MultinomialNB(alpha=0.01, class_prior=None, fit_prior=True)
>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(newsgroups_test.target, pred, average='macro')
0.88213...
```

(The example Classification of text documents using sparse features shuffles the training and test data, instead of segmenting by time, and in that case multinomial Naive Bayes gets a much higher F-score of 0.88. Are you suspicious yet of what’s going on inside this classifier?)

Let’s take a look at what the most informative features are:

```python
>>> import numpy as np
>>> def show_top10(classifier, vectorizer, categories):
...     feature_names = np.asarray(vectorizer.get_feature_names())
...     for i, category in enumerate(categories):
...         top10 = np.argsort(classifier.coef_[i])[-10:]
...         print("%s: %s
...         
... >>> show_top10(clf, vectorizer, newsgroups_train.target_names)
alt.atheism: edu it and in you that is of to the
comp.graphics: edu in graphics it is for and of to the
sci.space: edu it that is in and space to of the
talk.religion.misc: not it you in is that and to of the
```

You can now see many things that these features have overfit to:

- Almost every group is distinguished by whether headers such as NNTP-Posting-Host: and Distribution: appear more or less often.

- Another significant feature involves whether the sender is affiliated with a university, as indicated either by their headers or their signature.

- The word “article” is a significant feature, based on how often people quote previous posts like this: “In article [article ID], [name] <[e-mail address]> wrote:”

- Other features match the names and e-mail addresses of particular people who were posting at the time.

With such an abundance of clues that distinguish newsgroups, the classifiers barely have to identify topics from text at all, and they all perform at the same high level.

For this reason, the functions that load 20 Newsgroups data provide a parameter called remove, telling it what kinds of information to strip out of each file. remove should be a tuple containing any subset of ('headers', 'footers', 'quotes'), telling it to remove headers, signature blocks, and quotation blocks respectively.
This classifier lost over a lot of its F-score, just because we removed metadata that has little to do with topic classification. It loses even more if we also strip this metadata from the training data:

```python
groups_train = fetch_20newsgroups(subset='train',
... remove=('headers', 'footers', 'quotes'),
... categories=categories)
groups_train = vectorizer.transform(groups_train.data)
c = MultinomialNB(alpha=.01)
c.fit(vectors, groups_train.target)
```

Some other classifiers cope better with this harder version of the task. Try running `Sample pipeline for text feature extraction and evaluation` with and without the `--filter` option to compare the results.

**Recommendation**

When evaluating text classifiers on the 20 Newsgroups data, you should strip newsgroup-related metadata. In scikit-learn, you can do this by setting `remove=('headers', 'footers', 'quotes')`. The F-score will be lower because it is more realistic.

**Examples**

- `Sample pipeline for text feature extraction and evaluation`
- `Classification of text documents using sparse features`

**The Labeled Faces in the Wild face recognition dataset**

This dataset is a collection of JPEG pictures of famous people collected over the internet, all details are available on the official website:

http://vis-www.cs.umass.edu/lfw/

Each picture is centered on a single face. The typical task is called Face Verification: given a pair of two pictures, a binary classifier must predict whether the two images are from the same person.

An alternative task, Face Recognition or Face Identification is: given the picture of the face of an unknown person, identify the name of the person by referring to a gallery of previously seen pictures of identified persons.

Both Face Verification and Face Recognition are tasks that are typically performed on the output of a model trained to perform Face Detection. The most popular model for Face Detection is called Viola-Jones and is implemented in the
OpenCV library. The LFW faces were extracted by this face detector from various online websites.

Usage

scikit-learn provides two loaders that will automatically download, cache, parse the metadata files, decode the jpeg and convert the interesting slices into memmapped numpy arrays. This dataset size is more than 200 MB. The first load typically takes more than a couple of minutes to fully decode the relevant part of the JPEG files into numpy arrays. If the dataset has been loaded once, the following times the loading times less than 200ms by using a memmapped version memoized on the disk in the ~/scikit_learn_data/lfw_home/ folder using joblib.

The first loader is used for the Face Identification task: a multi-class classification task (hence supervised learning):

```python
>>> from sklearn.datasets import fetch_lfw_people
>>> lfw_people = fetch_lfw_people(min_faces_per_person=70, resize=0.4)

>>> for name in lfw_people.target_names:
...    print(name)
... Ariel Sharon
... Colin Powell
... Donald Rumsfeld
... George W Bush
... Gerhard Schroeder
... Hugo Chavez
... Tony Blair
```

The default slice is a rectangular shape around the face, removing most of the background:

```python
>>> lfw_people.data.dtype
dtype('float32')

>>> lfw_people.data.shape
(1288, 1850)

>>> lfw_people.images.shape
(1288, 50, 37)
```

Each of the 1140 faces is assigned to a single person id in the target array:

```python
>>> lfw_people.target.shape
(1288,)

>>> list(lfw_people.target[:10])
[5, 6, 3, 1, 0, 1, 3, 4, 3, 0]
```

The second loader is typically used for the face verification task: each sample is a pair of two picture belonging or not to the same person:
Both for the `sklearn.datasets.fetch_lfw_people` and `sklearn.datasets.fetch_lfw_pairs` function it is possible to get an additional dimension with the RGB color channels by passing `color=True`, in that case the shape will be `(2200, 2, 62, 47, 3)`.

The `sklearn.datasets.fetch_lfw_pairs` datasets is subdivided into 3 subsets: the development train set, the development test set and an evaluation 10_folds set meant to compute performance metrics using a 10-folds cross validation scheme.

Examples

Faces recognition example using eigenfaces and SVMs

Forest covetypes

The samples in this dataset correspond to 30x30m patches of forest in the US, collected for the task of predicting each patch’s cover type, i.e. the dominant species of tree. There are seven covertypes, making this a multiclass classification problem. Each sample has 54 features, described on the dataset’s homepage. Some of the features are boolean indicators, while others are discrete or continuous measurements.

Data Set Characteristics:

<table>
<thead>
<tr>
<th>Classes</th>
<th>7</th>
</tr>
</thead>
<tbody>
<tr>
<td>Samples total</td>
<td>581012</td>
</tr>
<tr>
<td>Dimensionality</td>
<td>54</td>
</tr>
<tr>
<td>Features</td>
<td>int</td>
</tr>
</tbody>
</table>

`sklearn.datasets.fetch_covtype` will load the covertype dataset; it returns a dictionary-like ‘Bunch’ object with the feature matrix in the data member and the target values in target. If optional argument ‘as_frame’ is set to ‘True’, it will return data and target as pandas data frame, and there will be an additional member frame as well. The dataset will be downloaded from the web if necessary.
RCV1 dataset

Reuters Corpus Volume I (RCV1) is an archive of over 800,000 manually categorized newswire stories made available by Reuters, Ltd. for research purposes. The dataset is extensively described in\(^1\).

**Data Set Characteristics:**

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Classes</td>
<td>103</td>
</tr>
<tr>
<td>Samples total</td>
<td>804414</td>
</tr>
<tr>
<td>Dimensionality</td>
<td>47236</td>
</tr>
<tr>
<td>Features</td>
<td>real, between 0 and 1</td>
</tr>
</tbody>
</table>

`sklearn.datasets.fetch_rcv1` will load the following version: RCV1-v2, vectors, full sets, topics multilabels:

```
>>> from sklearn.datasets import fetch_rcv1
>>> rcv1 = fetch_rcv1()
```

It returns a dictionary-like object, with the following attributes:

**data:** The feature matrix is a scipy CSR sparse matrix, with 804414 samples and 47236 features. Non-zero values contains cosine-normalized, log TF-IDF vectors. A nearly chronological split is proposed in\(^1\): The first 23149 samples are the training set. The last 781265 samples are the testing set. This follows the official LYRL2004 chronological split. The array has 0.16% of non zero values:

```
>>> rcv1.data.shape
(804414, 47236)
```

**target:** The target values are stored in a scipy CSR sparse matrix, with 804414 samples and 103 categories. Each sample has a value of 1 in its categories, and 0 in others. The array has 3.15% of non zero values:

```
>>> rcv1.target.shape
(804414, 103)
```

**sample_id:** Each sample can be identified by its ID, ranging (with gaps) from 2286 to 810596:

```
>>> rcv1.sample_id[:3]
array([2286, 2287, 2288], dtype=uint32)
```

**target_names:** The target values are the topics of each sample. Each sample belongs to at least one topic, and to up to 17 topics. There are 103 topics, each represented by a string. Their corpus frequencies span five orders of magnitude, from 5 occurrences for ’GMIL’, to 381327 for ’CCAT’:

```
>>> rcv1.target_names[:3].tolist()
['E11', 'ECAT', 'M11']
```

The dataset will be downloaded from the rcv1 homepage if necessary. The compressed size is about 656 MB.

Kddcup 99 dataset

The KDD Cup ‘99 dataset was created by processing the tcpdump portions of the 1998 DARPA Intrusion Detection System (IDS) Evaluation dataset, created by MIT Lincoln Lab\(^2\). The artificial data (described on the dataset’s homepage) was generated using a closed network and hand-injected attacks to produce a large number of different types of attack with normal activity in the background. As the initial goal was to produce a large training set for supervised learning algorithms, there is a large proportion (80.1\%) of abnormal data which is unrealistic in real world, and inappropriate for unsupervised anomaly detection which aims at detecting ‘abnormal’ data, i.e.:

- qualitatively different from normal data
- in large minority among the observations.

We thus transform the KDD Data set into two different data sets: SA and SF:

- SA is obtained by simply selecting all the normal data, and a small proportion of abnormal data to gives an anomaly proportion of 1\%.
- SF is obtained as in\(^3\) by simply picking up the data whose attribute logged_in is positive, thus focusing on the intrusion attack, which gives a proportion of 0.3\% of attack.
- http and smtp are two subsets of SF corresponding with third feature equal to ‘http’ (resp. to ‘smtp’).

General KDD structure:

| Samples total | 4898431 |
| Dimensionality | 41 |
| Features | discrete (int) or continuous (float) |
| Targets | str, ‘normal.’ or name of the anomaly type |

SA structure:

| Samples total | 976158 |
| Dimensionality | 41 |
| Features | discrete (int) or continuous (float) |
| Targets | str, ‘normal.’ or name of the anomaly type |

SF structure:

| Samples total | 699691 |
| Dimensionality | 4 |
| Features | discrete (int) or continuous (float) |
| Targets | str, ‘normal.’ or name of the anomaly type |

http structure:

| Samples total | 619052 |
| Dimensionality | 3 |
| Features | discrete (int) or continuous (float) |
| Targets | str, ‘normal.’ or name of the anomaly type |

smtp structure:

<p>| | |</p>
<table>
<thead>

</tr>
<tr>
<td>Targets</td>
<td>str, ‘normal.’ or name of the anomaly type</td>
</tr>
</tbody>
</table>

`sklearn.datasets.fetch_kddcup99` will load the kddcup99 dataset; it returns a dictionary-like object with the feature matrix in the `data` member and the target values in `target`. The “as_frame” optional argument converts `data` into a pandas DataFrame and `target` into a pandas Series. The dataset will be downloaded from the web if necessary.

**References**

**California Housing dataset**

**Data Set Characteristics:**

- **Number of Instances** 20640
- **Number of Attributes** 8 numeric, predictive attributes and the target

**Attribute Information**

- MedInc median income in block
- HouseAge median house age in block
- AveRooms average number of rooms
- AveBedrms average number of bedrooms
- Population block population
- AveOccup average house occupancy
- Latitude house block latitude
- Longitude house block longitude

**Missing Attribute Values** None

This dataset was obtained from the StatLib repository. http://lib.stat.cmu.edu/datasets/

The target variable is the median house value for California districts.

This dataset was derived from the 1990 U.S. census, using one row per census block group. A block group is the smallest geographical unit for which the U.S. Census Bureau publishes sample data (a block group typically has a population of 600 to 3,000 people).

It can be downloaded/loaded using the `sklearn.datasets.fetch_california_housing` function.

4.7.3 Generated datasets

In addition, scikit-learn includes various random sample generators that can be used to build artificial datasets of controlled size and complexity.

Generators for classification and clustering

These generators produce a matrix of features and corresponding discrete targets.

Single label

Both `make_blobs` and `make_classification` create multiclass datasets by allocating each class one or more normally-distributed clusters of points. `make_blobs` provides greater control regarding the centers and standard deviations of each cluster, and is used to demonstrate clustering. `make_classification` specialises in introducing noise by way of: correlated, redundant and uninformative features; multiple Gaussian clusters per class; and linear transformations of the feature space.

`make_gaussian_quantiles` divides a single Gaussian cluster into near-equal-size classes separated by concentric hyperspheres. `make_hastie_10_2` generates a similar binary, 10-dimensional problem.

`make_circles` and `make_moons` generate 2d binary classification datasets that are challenging to certain algorithms (e.g. centroid-based clustering or linear classification), including optional Gaussian noise. They are useful for visualisation. `make_circles` produces Gaussian data with a spherical decision boundary for binary classification, while `make_moons` produces two interleaving half circles.
Multilabel

`make_multilabel_classification` generates random samples with multiple labels, reflecting a bag of words drawn from a mixture of topics. The number of topics for each document is drawn from a Poisson distribution, and the topics themselves are drawn from a fixed random distribution. Similarly, the number of words is drawn from Poisson, with words drawn from a multinomial, where each topic defines a probability distribution over words. Simplifications with respect to true bag-of-words mixtures include:

- Per-topic word distributions are independently drawn, where in reality all would be affected by a sparse base distribution, and would be correlated.
- For a document generated from multiple topics, all topics are weighted equally in generating its bag of words.
- Documents without labels words at random, rather than from a base distribution.

Biclustering

- `make_biclusters` generates an array with constant block diagonal structure for biclustering.
- `make_checkerboard` generates an array with block checkerboard structure for biclustering.

Generators for regression

- `make_regression` produces regression targets as an optionally-sparse random linear combination of random features, with noise. Its informative features may be uncorrelated, or low rank (few features account for most of the variance).

Other regression generators generate functions deterministically from randomized features. `make_sparse_uncorrelated` produces a target as a linear combination of four features with fixed coefficients. Others encode explicitly non-linear relations: `make_friedman1` is related by polynomial and sine transforms; `make_friedman2` includes feature multiplication and reciprocation; and `make_friedman3` is similar with an arctan transformation on the target.
Generators for manifold learning

- `make_s_curve([n_samples, noise, random_state])`: Generate an S curve dataset.
- `make_swiss_roll([n_samples, noise, random_state])`: Generate a swiss roll dataset.

Generators for decomposition

- `make_low_rank_matrix([n_samples, ...])`: Generate a mostly low rank matrix with bell-shaped singular values.
- `make_sparse_coded_signal([n_samples, *[, random_state]])`: Generate a signal as a sparse combination of dictionary elements.
- `make_spd_matrix([n_dim, *[, random_state]])`: Generate a random symmetric, positive-definite matrix.
- `make_sparse_spd_matrix([dim, alpha, ...])`: Generate a sparse symmetric definite positive matrix.

4.7.4 Loading other datasets

Sample images

Scikit-learn also embeds a couple of sample JPEG images published under Creative Commons license by their authors. Those images can be useful to test algorithms and pipelines on 2D data.

- `load_sample_images()`: Load sample images for image manipulation.
- `load_sample_image(image_name)`: Load the numpy array of a single sample image

![Original image 06:023 colors](image)

**Warning:** The default coding of images is based on the `uint8` dtype to spare memory. Often machine learning algorithms work best if the input is converted to a floating point representation first. Also, if you plan to use `matplotlib.pyplot.imshow`, don’t forget to scale to the range 0 - 1 as done in the following example.

**Examples:**

- *Color Quantization using K-Means*
Datasets in svmlight / libsvm format

scikit-learn includes utility functions for loading datasets in the svmlight / libsvm format. In this format, each line takes the form `<label> <feature-id>:<feature-value> <feature-id>:<feature-value> ..`. This format is especially suitable for sparse datasets. In this module, scipy sparse CSR matrices are used for X and numpy arrays are used for y.

You may load a dataset like as follows:

```python
>>> from sklearn.datasets import load_svmlight_file

>>> X_train, y_train = load_svmlight_file("/path/to/train_dataset.txt")
```

You may also load two (or more) datasets at once:

```python
>>> X_train, y_train, X_test, y_test = load_svmlight_files(
...     "/path/to/train_dataset.txt", "/path/to/test_dataset.txt")
```

In this case, `X_train` and `X_test` are guaranteed to have the same number of features. Another way to achieve the same result is to fix the number of features:

```python
>>> X_test, y_test = load_svmlight_file(
...     "/path/to/test_dataset.txt", n_features=X_train.shape[1])
```

Downloading datasets from the openml.org repository

openml.org is a public repository for machine learning data and experiments, that allows everybody to upload open datasets.

The sklearn.datasets package is able to download datasets from the repository using the function `sklearn.datasets.fetch_openml`.

For example, to download a dataset of gene expressions in mice brains:

```python
>>> from sklearn.datasets import fetch_openml

>>> mice = fetch_openml(name='miceprotein', version=4)
```

To fully specify a dataset, you need to provide a name and a version, though the version is optional, see Dataset Versions below. The dataset contains a total of 1080 examples belonging to 8 different classes:

```python
>>> mice.data.shape
(1080, 77)

>>> mice.target.shape
(1080,)

>>> np.unique(mice.target)
array(['c-CS-m', 'c-CS-s', 'c-SC-m', 'c-SC-s', 't-CS-m', 't-CS-s', 't-SC-m', 't-SC-s'], dtype=object)
```
You can get more information on the dataset by looking at the `DESCR` and `details` attributes:

```python
>>> print(mice.DESCR)
**Author**: Clara Higuera, Katheleen J. Gardiner, Krzysztof J. Cios
**Source**: [UCI](https://archive.ics.uci.edu/ml/datasets/Mice+Protein+Expression) - 2015

```mice.DESCR```

The `DESCR` contains a free-text description of the data, while `details` contains a dictionary of meta-data stored by openml, like the dataset id. For more details, see the OpenML documentation. The data_id of the mice protein dataset is 40966, and you can use this (or the name) to get more information on the dataset on the openml website:

```python
>>> mice.url
'https://www.openml.org/d/40966'

The data_id also uniquely identifies a dataset from OpenML:

```python
>>> mice = fetch_openml(data_id=40966)
>>> mice.details
```

**Dataset Versions**

A dataset is uniquely specified by its data_id, but not necessarily by its name. Several different “versions” of a dataset with the same name can exist which can contain entirely different datasets. If a particular version of a dataset has been found to contain significant issues, it might be deactivated. Using a name to specify a dataset will yield the earliest version of a dataset that is still active. That means that `fetch_openml(name="miceprotein")` can yield different results at different times if earlier versions become inactive. You can see that the dataset with data_id 40966 that we fetched above is the first version of the “miceprotein” dataset:

```python
>>> mice.details['version']
'1'
```

In fact, this dataset only has one version. The iris dataset on the other hand has multiple versions:
Specifying the dataset by the name “iris” yields the lowest version, version 1, with the `data_id` 61. To make sure you always get this exact dataset, it is safest to specify it by the dataset `data_id`. The other dataset, with `data_id` 969, is version 3 (version 2 has become inactive), and contains a binarized version of the data:

```python
>>> np.unique(iris_969.target)
array(['N', 'P'], dtype=object)
```

You can also specify both the name and the version, which also uniquely identifies the dataset:

```python
>>> iris_version_3 = fetch_openml(name="iris", version=3)
>>> iris_version_3.details['version']
'3'
>>> iris_version_3.details['id']
'969'
```

**References:**

**Loading from external datasets**

scikit-learn works on any numeric data stored as numpy arrays or scipy sparse matrices. Other types that are convertible to numeric arrays such as pandas DataFrame are also acceptable.

Here are some recommended ways to load standard columnar data into a format usable by scikit-learn:

- `pandas.io` provides tools to read data from common formats including CSV, Excel, JSON and SQL. DataFrames may also be constructed from lists of tuples or dicts. Pandas handles heterogeneous data smoothly and provides tools for manipulation and conversion into a numeric array suitable for scikit-learn.
- `scipy.io` specializes in binary formats often used in scientific computing context such as .mat and .arff
- `numpy/routines.io` for standard loading of columnar data into numpy arrays
- `scikit-learn`'s `datasets.load_svmlight_file` for the svmlight or libSVM sparse format
- scikit-learn’s `datasets.load_files` for directories of text files where the name of each directory is the name of each category and each file inside of each directory corresponds to one sample from that category.

For some miscellaneous data such as images, videos, and audio, you may wish to refer to:
- `skimage.io` or `Imageio` for loading images and videos into numpy arrays
- `scipy.io.wavfile.read` for reading WAV files into a numpy array

Categorical (or nominal) features stored as strings (common in pandas DataFrames) will need converting to numerical features using `OneHotEncoder` or `OrdinalEncoder` or similar. See Preprocessing data.

Note: if you manage your own numerical data it is recommended to use an optimized file format such as HDF5 to reduce data load times. Various libraries such as H5Py, PyTables and pandas provides a Python interface for reading and writing data in that format.

4.8 Computing with scikit-learn

4.8.1 Strategies to scale computationally: bigger data

For some applications the amount of examples, features (or both) and/or the speed at which they need to be processed are challenging for traditional approaches. In these cases scikit-learn has a number of options you can consider to make your system scale.

Scaling with instances using out-of-core learning

Out-of-core (or “external memory”) learning is a technique used to learn from data that cannot fit in a computer’s main memory (RAM).

Here is a sketch of a system designed to achieve this goal:

1. a way to stream instances
2. a way to extract features from instances
3. an incremental algorithm

Streaming instances

Basically, 1. may be a reader that yields instances from files on a hard drive, a database, from a network stream etc. However, details on how to achieve this are beyond the scope of this documentation.

Extracting features

2. could be any relevant way to extract features among the different `feature extraction` methods supported by scikit-learn. However, when working with data that needs vectorization and where the set of features or values is not known in advance one should take explicit care. A good example is text classification where unknown terms are likely to be found during training. It is possible to use a stateful vectorizer if making multiple passes over the data is reasonable from an application point of view. Otherwise, one can turn up the difficulty by using a stateless feature extractor. Currently the preferred way to do this is to use the so-called `hashing trick` as implemented by `sklearn.feature_extraction.FeatureHasher` for datasets with categorical variables represented as list of Python dicts or `sklearn.feature_extraction.text.HashingVectorizer` for text documents.
Incremental learning

Finally, for 3. we have a number of options inside scikit-learn. Although not all algorithms can learn incrementally (i.e. without seeing all the instances at once), all estimators implementing the `partial_fit` API are candidates. Actually, the ability to learn incrementally from a mini-batch of instances (sometimes called “online learning”) is key to out-of-core learning as it guarantees that at any given time there will be only a small amount of instances in the main memory. Choosing a good size for the mini-batch that balances relevancy and memory footprint could involve some tuning\(^1\).

Here is a list of incremental estimators for different tasks:

- **Classification**
  - `sklearn.naive_bayes.MultinomialNB`
  - `sklearn.naive_bayes.BernoulliNB`
  - `sklearn.linear_model.Perceptron`
  - `sklearn.linear_model.SGDClassifier`
  - `sklearn.linear_model.PassiveAggressiveClassifier`
  - `sklearn.neural_network.MLPClassifier`

- **Regression**
  - `sklearn.linear_model.SGDRegressor`
  - `sklearn.linear_model.PassiveAggressiveRegressor`
  - `sklearn.neural_network.MLPRegressor`

- **Clustering**
  - `sklearn.cluster.MiniBatchKMeans`
  - `sklearn.cluster.Birch`

- **Decomposition / feature Extraction**
  - `sklearn.decomposition.MiniBatchDictionaryLearning`
  - `sklearn.decomposition.IncrementalPCA`
  - `sklearn.decomposition.LatentDirichletAllocation`

- **Preprocessing**
  - `sklearn.preprocessing.StandardScaler`
  - `sklearn.preprocessing.MinMaxScaler`
  - `sklearn.preprocessing.MaxAbsScaler`

For classification, a somewhat important thing to note is that although a stateless feature extraction routine may be able to cope with new/unseen attributes, the incremental learner itself may be unable to cope with new/unseen targets classes. In this case you have to pass all the possible classes to the first `partial_fit` call using the `classes=` parameter.

Another aspect to consider when choosing a proper algorithm is that not all of them put the same importance on each example over time. Namely, the `Perceptron` is still sensitive to badly labeled examples even after many examples whereas the `SGD*` and `PassiveAggressive*` families are more robust to this kind of artifacts. Conversely, the\(^1\)

---

\(^1\) Depending on the algorithm the mini-batch size can influence results or not. `SGD*`, `PassiveAggressive*`, and discrete NaiveBayes are truly online and are not affected by batch size. Conversely, MiniBatchKMeans convergence rate is affected by the batch size. Also, its memory footprint can vary dramatically with batch size.
latter also tend to give less importance to remarkably different, yet properly labeled examples when they come late in the stream as their learning rate decreases over time.

Examples

Finally, we have a full-fledged example of *Out-of-core classification of text documents*. It is aimed at providing a starting point for people wanting to build out-of-core learning systems and demonstrates most of the notions discussed above.

Furthermore, it also shows the evolution of the performance of different algorithms with the number of processed examples.

Now looking at the computation time of the different parts, we see that the vectorization is much more expensive than learning itself. From the different algorithms, *MultinomialNB* is the most expensive, but its overhead can be mitigated by increasing the size of the mini-batches (exercise: change *minibatch_size* to 100 and 10000 in the program and compare).
Notes

4.8.2 Computational Performance

For some applications the performance (mainly latency and throughput at prediction time) of estimators is crucial. It may also be of interest to consider the training throughput but this is often less important in a production setup (where it often takes place offline).

We will review here the orders of magnitude you can expect from a number of scikit-learn estimators in different contexts and provide some tips and tricks for overcoming performance bottlenecks.

Prediction latency is measured as the elapsed time necessary to make a prediction (e.g. in micro-seconds). Latency is often viewed as a distribution and operations engineers often focus on the latency at a given percentile of this distribution (e.g. the 90 percentile).

Prediction throughput is defined as the number of predictions the software can deliver in a given amount of time (e.g. in predictions per second).

An important aspect of performance optimization is also that it can hurt prediction accuracy. Indeed, simpler models (e.g. linear instead of non-linear, or with fewer parameters) often run faster but are not always able to take into account the same exact properties of the data as more complex ones.
Prediction Latency

One of the most straight-forward concerns one may have when using/choosing a machine learning toolkit is the latency at which predictions can be made in a production environment.

**The main factors that influence the prediction latency are**

1. Number of features
2. Input data representation and sparsity
3. Model complexity
4. Feature extraction

A last major parameter is also the possibility to do predictions in bulk or one-at-a-time mode.

**Bulk versus Atomic mode**

In general doing predictions in bulk (many instances at the same time) is more efficient for a number of reasons (branching predictability, CPU cache, linear algebra libraries optimizations etc.). Here we see on a setting with few features that independently of estimator choice the bulk mode is always faster, and for some of them by 1 to 2 orders of magnitude:
To benchmark different estimators for your case you can simply change the `n_features` parameter in this example:

**Prediction Latency**. This should give you an estimate of the order of magnitude of the prediction latency.

### Configuring Scikit-learn for reduced validation overhead

Scikit-learn does some validation on data that increases the overhead per call to `predict` and similar functions. In particular, checking that features are finite (not NaN or infinite) involves a full pass over the data. If you ensure that your data is acceptable, you may suppress checking for finiteness by setting the environment variable `SKLEARN_ASSUME_FINITE` to a non-empty string before importing scikit-learn, or configure it in Python with `set_config`. For more control than these global settings, a `config_context` allows you to set this configuration within a specified context:

```python
>>> import sklearn
>>> with sklearn.config_context(assume_finite=True):
...     pass  # do learning/prediction here with reduced validation
```

Note that this will affect all uses of `assert_all_finite` within the context.

### Influence of the Number of Features

Obviously when the number of features increases so does the memory consumption of each example. Indeed, for a matrix of $M$ instances with $N$ features, the space complexity is in $O(NM)$. From a computing perspective it also means that the number of basic operations (e.g., multiplications for vector-matrix products in linear models) increases too. Here is a graph of the evolution of the prediction latency with the number of features:
Overall you can expect the prediction time to increase at least linearly with the number of features (non-linear cases can happen depending on the global memory footprint and estimator).

**Influence of the Input Data Representation**

Scipy provides sparse matrix data structures which are optimized for storing sparse data. The main feature of sparse formats is that you don’t store zeros so if your data is sparse then you use much less memory. A non-zero value in a sparse (CSR or CSC) representation will only take on average one 32bit integer position + the 64 bit floating point value + an additional 32bit per row or column in the matrix. Using sparse input on a dense (or sparse) linear model can speedup prediction by quite a bit as only the non zero valued features impact the dot product and thus the model predictions. Hence if you have 100 non zeros in 1e6 dimensional space, you only need 100 multiply and add operation instead of 1e6.

Calculation over a dense representation, however, may leverage highly optimised vector operations and multithreading in BLAS, and tends to result in fewer CPU cache misses. So the sparsity should typically be quite high (10% non-zeros max, to be checked depending on the hardware) for the sparse input representation to be faster than the dense input representation on a machine with many CPUs and an optimized BLAS implementation.

Here is sample code to test the sparsity of your input:

```python
def sparsity_ratio(X):
    return 1.0 - np.count_nonzero(X) / float(X.shape[0] * X.shape[1])
print("input sparsity ratio:", sparsity_ratio(X))
```

As a rule of thumb you can consider that if the sparsity ratio is greater than 90% you can probably benefit from sparse formats. Check Scipy’s sparse matrix formats documentation for more information on how to build (or convert your data to) sparse matrix formats. Most of the time the CSR and CSC formats work best.
Influence of the Model Complexity

Generally speaking, when model complexity increases, predictive power and latency are supposed to increase. Increasing predictive power is usually interesting, but for many applications we would better not increase prediction latency too much. We will now review this idea for different families of supervised models.

For *sklearn.linear_model* (e.g. Lasso, ElasticNet, SGDClassifier/Regressor, Ridge & RidgeClassifier, PassiveAggressiveClassifier/Regressor, LinearSVC, LogisticRegression...) the decision function that is applied at prediction time is the same (a dot product), so latency should be equivalent.

Here is an example using *SGDClassifier* with the *elasticnet* penalty. The regularization strength is globally controlled by the *alpha* parameter. With a sufficiently high *alpha*, one can then increase the *l1_ratio* parameter of *elasticnet* to enforce various levels of sparsity in the model coefficients. Higher sparsity here is interpreted as less model complexity as we need fewer coefficients to describe it fully. Of course sparsity influences in turn the prediction time as the sparse dot-product takes time roughly proportional to the number of non-zero coefficients.

For the *sklearn.svm* family of algorithms with a non-linear kernel, the latency is tied to the number of support vectors (the fewer the faster). Latency and throughput should (asymptotically) grow linearly with the number of support vectors in a SVC or SVR model. The kernel will also influence the latency as it is used to compute the projection of the input vector once per support vector. In the following graph the *nu* parameter of *NuSVR* was used to influence the number of support vectors.
For `sklearn.ensemble` of trees (e.g. RandomForest, GBT, ExtraTrees etc) the number of trees and their depth play the most important role. Latency and throughput should scale linearly with the number of trees. In this case we used directly the `n_estimators` parameter of `GradientBoostingRegressor`.

In any case be warned that decreasing model complexity can hurt accuracy as mentioned above. For instance a non-linearly separable problem can be handled with a speedy linear model but prediction power will very likely suffer in the process.
Feature Extraction Latency

Most scikit-learn models are usually pretty fast as they are implemented either with compiled Cython extensions or optimized computing libraries. On the other hand, in many real world applications the feature extraction process (i.e. turning raw data like database rows or network packets into numpy arrays) governs the overall prediction time. For example on the Reuters text classification task the whole preparation (reading and parsing SGML files, tokenizing the text and hashing it into a common vector space) is taking 100 to 500 times more time than the actual prediction code, depending on the chosen model.

In many cases it is thus recommended to carefully time and profile your feature extraction code as it may be a good place to start optimizing when your overall latency is too slow for your application.

Prediction Throughput

Another important metric to care about when sizing production systems is the throughput i.e. the number of predictions you can make in a given amount of time. Here is a benchmark from the Prediction Latency example that measures this quantity for a number of estimators on synthetic data:
These throughputs are achieved on a single process. An obvious way to increase the throughput of your application is to spawn additional instances (usually processes in Python because of the GIL) that share the same model. One might also add machines to spread the load. A detailed explanation on how to achieve this is beyond the scope of this documentation though.

**Tips and Tricks**

**Linear algebra libraries**

As scikit-learn relies heavily on Numpy/Scipy and linear algebra in general it makes sense to take explicit care of the versions of these libraries. Basically, you ought to make sure that Numpy is built using an optimized BLAS / LAPACK library.

Not all models benefit from optimized BLAS and Lapack implementations. For instance models based on (randomized) decision trees typically do not rely on BLAS calls in their inner loops, nor do kernel SVMs (SVC, SVR, NuSVC, NuSVR). On the other hand a linear model implemented with a BLAS DGEMM call (via numpy.dot) will typically benefit hugely from a tuned BLAS implementation and lead to orders of magnitude speedup over a non-optimized BLAS.

You can display the BLAS / LAPACK implementation used by your NumPy / SciPy / scikit-learn install with the following commands:

```python
from numpy.distutils.system_info import get_info
print(get_info('blas_opt'))
print(get_info('lapack_opt'))
```

Optimized BLAS / LAPACK implementations include:

- Atlas (need hardware specific tuning by rebuilding on the target machine)
- OpenBLAS
• MKL
• Apple Accelerate and vecLib frameworks (OSX only)

More information can be found on the Scipy install page and in this blog post from Daniel Nouri which has some nice step by step install instructions for Debian / Ubuntu.

Limiting Working Memory

Some calculations when implemented using standard numpy vectorized operations involve using a large amount of temporary memory. This may potentially exhaust system memory. Where computations can be performed in fixed-memory chunks, we attempt to do so, and allow the user to hint at the maximum size of this working memory (defaulting to 1GB) using `set_config` or `config_context`. The following suggests to limit temporary working memory to 128 MiB:

```python
>>> import sklearn
>>> with sklearn.config_context(working_memory=128):
...    pass  # do chunked work here
```

An example of a chunked operation adhering to this setting is `pairwise_distances_chunked`, which facilitates computing row-wise reductions of a pairwise distance matrix.

Model Compression

Model compression in scikit-learn only concerns linear models for the moment. In this context it means that we want to control the model sparsity (i.e. the number of non-zero coordinates in the model vectors). It is generally a good idea to combine model sparsity with sparse input data representation.

Here is sample code that illustrates the use of the `sparsify()` method:

```python
clf = SGDRegressor(penalty='elasticnet', l1_ratio=0.25)
clf.fit(X_train, y_train).sparsify()
clf.predict(X_test)
```

In this example we prefer the `elasticnet` penalty as it is often a good compromise between model compactness and prediction power. One can also further tune the `l1_ratio` parameter (in combination with the regularization strength `alpha`) to control this tradeoff.

A typical benchmark on synthetic data yields a >30% decrease in latency when both the model and input are sparse (with 0.000024 and 0.027400 non-zero coefficients ratio respectively). Your mileage may vary depending on the sparsity and size of your data and model. Furthermore, sparsifying can be very useful to reduce the memory usage of predictive models deployed on production servers.

Model Reshaping

Model reshaping consists in selecting only a portion of the available features to fit a model. In other words, if a model discards features during the learning phase we can then strip those from the input. This has several benefits. Firstly it reduces memory (and therefore time) overhead of the model itself. It also allows to discard explicit feature selection components in a pipeline once we know which features to keep from a previous run. Finally, it can help reduce processing time and I/O usage upstream in the data access and feature extraction layers by not collecting and building features that are discarded by the model. For instance if the raw data come from a database, it can make it possible to write simpler and faster queries or reduce I/O usage by making the queries return lighter records. At the moment, reshaping needs to be performed manually in scikit-learn. In the case of sparse input (particularly in CSR format), it is generally sufficient to not generate the relevant features, leaving their columns empty.
4.8.3 Parallelism, resource management, and configuration

Parallelism

Some scikit-learn estimators and utilities can parallelize costly operations using multiple CPU cores, thanks to the following components:

- via the joblib library. In this case the number of threads or processes can be controlled with the `n_jobs` parameter.
- via OpenMP, used in C or Cython code.

In addition, some of the numpy routines that are used internally by scikit-learn may also be parallelized if numpy is installed with specific numerical libraries such as MKL, OpenBLAS, or BLIS.

We describe these 3 scenarios in the following subsections.

Joblib-based parallelism

When the underlying implementation uses joblib, the number of workers (threads or processes) that are spawned in parallel can be controlled via the `n_jobs` parameter.

Note: Where (and how) parallelization happens in the estimators is currently poorly documented. Please help us by improving our docs and tackle issue 14228!

Joblib is able to support both multi-processing and multi-threading. Whether joblib chooses to spawn a thread or a process depends on the `backend` that it’s using.

Scikit-learn generally relies on the `loky` backend, which is joblib’s default backend. Loky is a multi-processing back-end. When doing multi-processing, in order to avoid duplicating the memory in each process (which isn’t reasonable with big datasets), joblib will create a `memmap` that all processes can share, when the data is bigger than 1MB.

In some specific cases (when the code that is run in parallel releases the GIL), scikit-learn will indicate to `joblib` that a multi-threading backend is preferable.

As a user, you may control the backend that joblib will use (regardless of what scikit-learn recommends) by using a context manager:

```
from joblib import parallel_backend

with parallel_backend('threading', n_jobs=2):
    # Your scikit-learn code here
```

Please refer to the joblib’s docs for more details.

In practice, whether parallelism is helpful at improving runtime depends on many factors. It is usually a good idea to experiment rather than assuming that increasing the number of workers is always a good thing. In some cases it can be highly detrimental to performance to run multiple copies of some estimators or functions in parallel (see oversubscription below).
OpenMP-based parallelism

OpenMP is used to parallelize code written in Cython or C, relying on multi-threading exclusively. By default (and unless joblib is trying to avoid oversubscription), the implementation will use as many threads as possible.

You can control the exact number of threads that are used via the `OMP_NUM_THREADS` environment variable:

```
OMP_NUM_THREADS=4 python my_script.py
```

Parallel Numpy routines from numerical libraries

Scikit-learn relies heavily on NumPy and SciPy, which internally call multi-threaded linear algebra routines implemented in libraries such as MKL, OpenBLAS or BLIS.

The number of threads used by the OpenBLAS, MKL or BLIS libraries can be set via the `MKL_NUM_THREADS`, `OPENBLAS_NUM_THREADS`, and `BLIS_NUM_THREADS` environment variables.

Please note that scikit-learn has no direct control over these implementations. Scikit-learn solely relies on Numpy and Scipy.

Note: At the time of writing (2019), NumPy and SciPy packages distributed on pypi.org (used by pip) and on the conda-forge channel are linked with OpenBLAS, while conda packages shipped on the “defaults” channel from anaconda.org are linked by default with MKL.

Oversubscription: spawning too many threads

It is generally recommended to avoid using significantly more processes or threads than the number of CPUs on a machine. Over-subscription happens when a program is running too many threads at the same time.

Suppose you have a machine with 8 CPUs. Consider a case where you’re running a `GridSearchCV` (parallelized with joblib) with `n_jobs=8` over a `HistGradientBoostingClassifier` (parallelized with OpenMP). Each instance of `HistGradientBoostingClassifier` will spawn 8 threads (since you have 8 CPUs). That’s a total of $8 \times 8 = 64$ threads, which leads to oversubscription of physical CPU resources and to scheduling overhead.

Oversubscription can arise in the exact same fashion with parallelized routines from MKL, OpenBLAS or BLIS that are nested in joblib calls.

Starting from joblib >= 0.14, when the `loky` backend is used (which is the default), joblib will tell its child processes to limit the number of threads they can use, so as to avoid oversubscription. In practice the heuristic that joblib uses is to tell the processes to use `max_threads = n_cpus // n_jobs`, via their corresponding environment variable. Back to our example from above, since the joblib backend of `GridSearchCV` is `loky`, each process will only be able to use 1 thread instead of 8, thus mitigating the oversubscription issue.

Note that:

- Manually setting one of the environment variables (`OMP_NUM_THREADS`, `MKL_NUM_THREADS`, `OPENBLAS_NUM_THREADS`, or `BLIS_NUM_THREADS`) will take precedence over what joblib tries to do. The total number of threads will be `n_jobs * <LIB>_NUM_THREADS`. Note that setting this limit will also impact your computations in the main process, which will only use `<LIB>_NUM_THREADS`. Joblib exposes a context manager for finer control over the number of threads in its workers (see joblib docs linked below).

- Joblib is currently unable to avoid oversubscription in a multi-threading context. It can only do so with the `loky` backend (which spawns processes).

You will find additional details about joblib mitigation of oversubscription in joblib documentation.
Configuration switches

Python runtime

`sklearn.set_config` controls the following behaviors:

- `assume_finite` used to skip validation, which enables faster computations but may lead to segmentation faults if the data contains NaNs.
- `working_memory` the optimal size of temporary arrays used by some algorithms.

Environment variables

These environment variables should be set before importing scikit-learn.

- `SKLEARN_SITE_JOBLIB` When this environment variable is set to a non zero value, scikit-learn uses the site joblib rather than its vendored version. Consequently, joblib must be installed for scikit-learn to run. Note that using the site joblib is at your own risks: the versions of scikit-learn and joblib need to be compatible. Currently, joblib 0.11+ is supported. In addition, dumps from joblib.Memory might be incompatible, and you might loose some caches and have to redownload some datasets.
  
  Deprecated since version 0.21: As of version 0.21 this parameter has no effect, vendored joblib was removed and site joblib is always used.

- `SKLEARN_ASSUME_FINITE` Sets the default value for the `assume_finite` argument of `sklearn.set_config`.

- `SKLEARN_WORKING_MEMORY` Sets the default value for the `working_memory` argument of `sklearn.set_config`.

- `SKLEARN_SEED` Sets the seed of the global random generator when running the tests, for reproducibility.

- `SKLEARN_SKIP_NETWORK_TESTS` When this environment variable is set to a non zero value, the tests that need network access are skipped.

4.9 Model persistence

After training a scikit-learn model, it is desirable to have a way to persist the model for future use without having to retrain. The following sections give you some hints on how to persist a scikit-learn model.

4.9.1 Python specific serialization

It is possible to save a model in scikit-learn by using Python’s built-in persistence model, namely `pickle`:

```python
>>> from sklearn import svm
>>> from sklearn import datasets

>>> clf = svm.SVC()

>>> X, y = datasets.load_iris(return_X_y=True)

>>> clf.fit(X, y)
SVC()

>>> import pickle

>>> s = pickle.dumps(clf)
```
In the specific case of scikit-learn, it may be better to use joblib’s replacement of pickle (`dump` & `load`), which is more efficient on objects that carry large numpy arrays internally as is often the case for fitted scikit-learn estimators, but can only pickle to the disk and not to a string:

```python
>>> from joblib import dump, load
>>> dump(clf, 'filename.joblib')
```

Later you can load back the pickled model (possibly in another Python process) with:

```python
>>> clf = load('filename.joblib')
```

**Note:** `dump` and `load` functions also accept file-like object instead of filenames. More information on data persistence with Joblib is available [here](#).

### Security & maintainability limitations

pickle (and joblib by extension), has some issues regarding maintainability and security. Because of this,

- Never unpickle untrusted data as it could lead to malicious code being executed upon loading.
- While models saved using one version of scikit-learn might load in other versions, this is entirely unsupported and inadvisable. It should also be kept in mind that operations performed on such data could give different and unexpected results.

In order to rebuild a similar model with future versions of scikit-learn, additional metadata should be saved along the pickled model:

- The training data, e.g. a reference to an immutable snapshot
- The python source code used to generate the model
- The versions of scikit-learn and its dependencies
- The cross validation score obtained on the training data

This should make it possible to check that the cross-validation score is in the same range as before.

Since a model internal representation may be different on two different architectures, dumping a model on one architecture and loading it on another architecture is not a supported behaviour, even if it might work on some cases. To overcome the issue of portability, pickle models are often deployed in production using containers, like docker.

If you want to know more about these issues and explore other possible serialization methods, please refer to this [talk by Alex Gaynor](#).
4.9.2 Interoperable formats

For reproducibility and quality control needs, when different architectures and environments should be taken into account, exporting the model in Open Neural Network Exchange format or Predictive Model Markup Language (PMML) format might be a better approach than using pickle alone. These are helpful where you may want to use your model for prediction in a different environment from where the model was trained.

ONNX is a binary serialization of the model. It has been developed to improve the usability of the interoperable representation of data models. It aims to facilitate the conversion of the data models between different machine learning frameworks, and to improve their portability on different computing architectures. More details are available from the ONNX tutorial. To convert scikit-learn model to ONNX a specific tool sklearn-onnx has been developed.

PMML is an implementation of the XML document standard defined to represent data models together with the data used to generate them. Being human and machine readable, PMML is a good option for model validation on different platforms and long term archiving. On the other hand, as XML in general, its verbosity does not help in production when performance is critical. To convert scikit-learn model to PMML you can use for example sklearn2pmml distributed under the Affero GPLv3 license.

4.10 Common pitfalls

The purpose of this chapter is to illustrate some common pitfalls and anti-patterns that occur when using scikit-learn. It provides examples of what not to do, along with a corresponding correct example.

4.10.1 Data leakage

Data leakage occurs when information that would not be available at prediction time is used when building the model. This results in overly optimistic performance estimates, for example from cross-validation, and thus poorer performance when the model is used on actually novel data, for example during production.

A common cause is not keeping the test and train data subsets separate. Test data should never be used to make choices about the model. The general rule is to never call fit on test data. This is particularly important for ‘supervised transformations’ where the fit method requires both the data, X and the target values, y. While this may sound obvious, this is easy to miss in some cases, for example when applying certain pre-processing steps.

Although both train and test data subsets should receive the same preprocessing transformation, it is important that these transformations are only learnt from the training data. For example, if you have a normalization step where you divide by the average value, the average should be the average of the train subset, not the average of all the data. If the test subset is included in the average calculation, information from the test subset is influencing the model.

Including the test data when tuning model hyperparameters will also inadvertently introduce information from the test data into the model. Practically, this means that only the train data subset should be fed into the fit method of Hyper-parameter optimizers, as is the case with all scikit-learn estimators.

An example of data leakage during preprocessing is detailed below.

See Also:

- Nested versus non-nested cross-validation
Data leakage during feature selection

A number of Feature selection functions are available in scikit-learn. They can help remove irrelevant, redundant and noisy features as well as improve your model build time and performance. As with any other type of preprocessing, feature selection should only use the training data. Including the test data in feature selection will optimistically bias your model.

To demonstrate we will create this binary classification problem with 10,000 randomly generated features:

```python
>>> import numpy as np
>>> n_samples, n_features, n_classes = 200, 10000, 2
>>> rng = np.random.RandomState(42)
>>> X = rng.standard_normal((n_samples, n_features))
>>> y = rng.choice(n_classes, n_samples)
```

Wrong

Using all the data to perform feature selection results in an accuracy score much higher than chance, even though our targets are completely random. This randomness means that our $X$ and $y$ are independent and we thus expect the accuracy to be around 0.5. However, since the feature selection step ‘sees’ the test data, the model has an unfair advantage. In the incorrect example below we first use all the data for feature selection and then split the data into training and test subsets for model fitting. The result is a much higher than expected accuracy score:

```python
>>> from sklearn.model_selection import train_test_split
>>> from sklearn.feature_selection import SelectKBest
>>> from sklearn.ensemble import GradientBoostingClassifier
>>> from sklearn.metrics import accuracy_score

>>> X_selected = SelectKBest(k=25).fit_transform(X, y)
>>> X_train, X_test, y_train, y_test = train_test_split(... X_selected, y, random_state=42)
>>> gbc = GradientBoostingClassifier(random_state=1)
>>> gbc.fit(X_train, y_train)
GradientBoostingClassifier(random_state=1)
>>> X_test_selected = select.transform(X_test)
>>> y_pred = gbc.predict(X_test_selected)
>>> score = accuracy_score(y_test, y_pred)
>>> print(f"Accuracy: {score}")
Accuracy: 0.76
```

Right

To prevent data leakage, it is good practice to split your data into train and test subsets first. Feature selection can then be formed using just the train dataset. Notice that whenever we use fit or fit_transform, we only use the train dataset. The score is now what we would expect for the data, close to chance:

```python
>>> X_train, X_test, y_train, y_test = train_test_split(... X, y, random_state=42)
>>> select = SelectKBest(k=25)
>>> X_train_selected = select.fit_transform(X_train, y_train)
>>> gbc = GradientBoostingClassifier(random_state=1)
>>> gbc.fit(X_train_selected, y_train)
GradientBoostingClassifier(random_state=1)
>>> X_test_selected = select.transform(X_test)
>>> y_pred = gbc.predict(X_test_selected)
>>> score = accuracy_score(y_test, y_pred)
>>> print(f"Accuracy: {score}")
Accuracy: 0.46
```

Another way to prevent data leakage is to use the Pipeline to chain together the feature selection and model estimators. The pipeline ensures that only the training data is used when performing fit and the test data is used only...
for calculating the accuracy score:

```python
>>> from sklearn.pipeline import make_pipeline
>>> X_train, X_test, y_train, y_test = train_test_split(...     X, y, random_state=42)
>>> pipeline = make_pipeline(SelectKBest(k=25),
...     GradientBoostingClassifier(random_state=1))
>>> pipeline.fit(X_train, y_train)
Pipeline(steps=[('selectkbest', SelectKBest(k=25)),
               ('gradientboostingclassifier',
                GradientBoostingClassifier(random_state=1))])
>>> y_pred = pipeline.predict(X_test)
>>> score = accuracy_score(y_test, y_pred)
>>> print(f"Accuracy: {score.mean():.2f}\n")
Accuracy: 0.46
```

The pipeline can also be fed into a cross-validation function such as `cross_val_score`. Again, the pipeline ensures that the correct data subset and estimator method is used during fitting and predicting:

```python
>>> from sklearn.model_selection import cross_val_score
>>> scores = cross_val_score(pipeline, X, y)
>>> print(f"Mean accuracy: {scores.mean():.2f} +/- {scores.std():.2f}\n")
Mean accuracy: 0.45 +/- 0.07
```

### How to avoid data leakage

Below are some tips on avoiding data leakage:

- Always split the data into train and test subsets first, particularly before any preprocessing steps.
- Never include test data when using estimator `fit` and `fit_transform` methods. Using all the data, e.g., `fit(X)`, can result in overly optimistic scores. Only using the test data, e.g., `fit(X_test)`, can harm performance as preprocessing or model fitting is only performed using the, generally smaller, test subset. Conversely, the `transform` method should be used on both train and test subsets as the same preprocessing should be applied to all the data. This can be achieved by using `fit_transform`, which combines the `fit` and `transform` methods, on the train subset and `transform` on the test subset.
- The scikit-learn `pipeline` is a great way to prevent data leakage as it ensures that the appropriate method is performed on the correct data subset. The pipeline is ideal for use in cross-validation and hyper-parameter tuning functions.
This glossary hopes to definitively represent the tacit and explicit conventions applied in Scikit-learn and its API, while providing a reference for users and contributors. It aims to describe the concepts and either detail their corresponding API or link to other relevant parts of the documentation which do so. By linking to glossary entries from the API Reference and User Guide, we may minimize redundancy and inconsistency.

We begin by listing general concepts (and any that didn’t fit elsewhere), but more specific sets of related terms are listed below: Class APIs and Estimator Types, Target Types, Methods, Parameters, Attributes, Data and sample properties.

5.1 General Concepts

1d

1d array  One-dimensional array. A NumPy array whose .shape has length 1. A vector.

2d

2d array  Two-dimensional array. A NumPy array whose .shape has length 2. Often represents a matrix.

API  Refers to both the specific interfaces for estimators implemented in Scikit-learn and the generalized conventions across types of estimators as described in this glossary and overviewed in the contributor documentation.

The specific interfaces that constitute Scikit-learn’s public API are largely documented in API Reference. However, we less formally consider anything as public API if none of the identifiers required to access it begins with __. We generally try to maintain backwards compatibility for all objects in the public API.

Private API, including functions, modules and methods beginning _ are not assured to be stable.

array-like  The most common data format for input to Scikit-learn estimators and functions, array-like is any type object for which numpy.asarray will produce an array of appropriate shape (usually 1 or 2-dimensional) of appropriate dtype (usually numeric).

This includes:

- a numpy array
- a list of numbers
- a list of length-k lists of numbers for some fixed length k
- a pandas.DataFrame with all columns numeric
- a numeric pandas.Series

It excludes:

- a sparse matrix
- an iterator
• a generator

Note that output from scikit-learn estimators and functions (e.g. predictions) should generally be arrays or sparse matrices, or lists thereof (as in multi-output `tree.DecisionTreeClassifier`

's predict_proba'). An estimator where predict() returns a list or a pandas.Series is not valid.

attribute

attributes We mostly use attribute to refer to how model information is stored on an estimator during fitting. Any public attribute stored on an estimator instance is required to begin with an alphabetic character and end in a single underscore if it is set in fit or partial_fit. These are what is documented under an estimator’s Attributes documentation. The information stored in attributes is usually either: sufficient statistics used for prediction or transformation; transductive outputs such as labels_ or embedding_; or diagnostic data, such as feature_importances_. Common attributes are listed below.

A public attribute may have the same name as a constructor parameter, with a _ appended. This is used to store a validated or estimated version of the user’s input. For example, decomposition.PCA is constructed with an n_components parameter. From this, together with other parameters and the data, PCA estimates the attribute n_components_.

Further private attributes used in prediction/transformation/etc. may also be set when fitting. These begin with a single underscore and are not assured to be stable for public access.

A public attribute on an estimator instance that does not end in an underscore should be the stored, unmodified value of an __init__ parameter of the same name. Because of this equivalence, these are documented under an estimator’s Parameters documentation.

backwards compatibility We generally try to maintain backward compatibility (i.e. interfaces and behaviors may be extended but not changed or removed) from release to release but this comes with some exceptions:

Public API only The behavior of objects accessed through private identifiers (those beginning _) may be changed arbitrarily between versions.

As documented We will generally assume that the users have adhered to the documented parameter types and ranges. If the documentation asks for a list and the user gives a tuple, we do not assure consistent behavior from version to version.

Deprecation Behaviors may change following a deprecation period (usually two releases long). Warnings are issued using Python’s warnings module.

Keyword arguments We may sometimes assume that all optional parameters (other than X and y to fit and similar methods) are passed as keyword arguments only and may be positionally reordered.

Bug fixes and enhancements Bug fixes and – less often – enhancements may change the behavior of estimators, including the predictions of an estimator trained on the same data and random_state. When this happens, we attempt to note it clearly in the changelog.

Serialization We make no assurances that pickling an estimator in one version will allow it to be unpickled to an equivalent model in the subsequent version. (For estimators in the sklearn package, we issue a warning when this unpickling is attempted, even if it may happen to work.) See Security & maintainability limitations.

utils.estimator_checks.check_estimator We provide limited backwards compatibility assurances for the estimator checks: we may add extra requirements on estimators tested with this function, usually when these were informally assumed but not formally tested.

Despite this informal contract with our users, the software is provided as is, as stated in the license. When a release inadvertently introduces changes that are not backward compatible, these are known as software regressions.

callable A function, class or an object which implements the __call__ method; anything that returns True when the argument of callable().

680 Chapter 5. Glossary of Common Terms and API Elements
categorical feature A categorical or nominal feature is one that has a finite set of discrete values across the population of data. These are commonly represented as columns of integers or strings. Strings will be rejected by most scikit-learn estimators, and integers will be treated as ordinal or count-valued. For the use with most estimators, categorical variables should be one-hot encoded. Notable exceptions include tree-based models such as random forests and gradient boosting models that often work better and faster with integer-coded categorical variables. **OrdinalEncoder** helps encoding string-valued categorical features as ordinal integers, and **OneHotEncoder** can be used to one-hot encode categorical features. See also **Encoding categorical features** and the **categorical-encoding** package for tools related to encoding categorical features.

clone

cloned To copy an estimator instance and create a new one with identical parameters, but without any fitted attributes, using `clone`.

When `fit` is called, a meta-estimator usually clones a wrapped estimator instance before fitting the cloned instance. (Exceptions, for legacy reasons, include `Pipeline` and `FeatureUnion`.)

common tests This refers to the tests run on almost every estimator class in Scikit-learn to check they comply with basic API conventions. They are available for external use through `utils.estimator_checks.check_estimator`, with most of the implementation in `sklearn/utils/estimator_checks.py`.

Note: Some exceptions to the common testing regime are currently hard-coded into the library, but we hope to replace this by marking exceptional behaviours on the estimator using semantic estimator tags.

deprecation We use deprecation to slowly violate our backwards compatibility assurances, usually to to:

- change the default value of a parameter; or
- remove a parameter, attribute, method, class, etc.

We will ordinarily issue a warning when a deprecated element is used, although there may be limitations to this. For instance, we will raise a warning when someone sets a parameter that has been deprecated, but may not when they access that parameter's attribute on the estimator instance.

See the **Contributors’ Guide**.

dimensionality May be used to refer to the number of features (i.e. `n_features`), or columns in a 2d feature matrix. Dimensions are, however, also used to refer to the length of a NumPy array’s shape, distinguishing a 1d array from a 2d matrix.

docstring The embedded documentation for a module, class, function, etc., usually in code as a string at the beginning of the object’s definition, and accessible as the object’s `__doc__` attribute.

We try to adhere to PEP257, and follow NumpyDoc conventions.

double underscore

double underscore notation When specifying parameter names for nested estimators, `__` may be used to separate between parent and child in some contexts. The most common use is when setting parameters through a meta-estimator with `set_params` and hence in specifying a search grid in `parameter search`. See parameter. It is also used in `pipeline.Pipeline.fit` for passing sample properties to the `fit` methods of estimators in the pipeline.

dtype

data type NumPy arrays assume a homogeneous data type throughout, available in the `.dtype` attribute of an array (or sparse matrix). We generally assume simple data types for scikit-learn data: float or integer. We may support object or string data types for arrays before encoding or vectorizing. Our estimators do not work with struct arrays, for instance.

TODO: Mention efficiency and precision issues; casting policy.
duck typing  We try to apply duck typing to determine how to handle some input values (e.g. checking whether a given estimator is a classifier). That is, we avoid using `isinstance` where possible, and rely on the presence or absence of attributes to determine an object’s behaviour. Some nuance is required when following this approach:

- For some estimators, an attribute may only be available once it is fitted. For instance, we cannot a priori determine if `predict_proba` is available in a grid search where the grid includes alternating between a probabilistic and a non-probabilistic predictor in the final step of the pipeline. In the following, we can only determine if `clf` is probabilistic after fitting it on some data:

```python
>>> from sklearn.model_selection import GridSearchCV
>>> from sklearn.linear_model import SGDClassifier
>>> clf = GridSearchCV(SGDClassifier(),
... param_grid={'loss': ['log', 'hinge']})
```

This means that we can only check for duck-typed attributes after fitting, and that we must be careful to make `meta-estimators` only present attributes according to the state of the underlying estimator after fitting.

- Checking if an attribute is present (using `hasattr`) is in general just as expensive as getting the attribute (`getattr` or dot notation). In some cases, getting the attribute may indeed be expensive (e.g. for some implementations of `feature_importances_`, which may suggest this is an API design flaw). So code which does `hasattr` followed by `getattr` should be avoided; `getattr` within a try-except block is preferred.

- For determining some aspects of an estimator’s expectations or support for some feature, we use `estimator tags` instead of duck typing.

early stopping This consists in stopping an iterative optimization method before the convergence of the training loss, to avoid over-fitting. This is generally done by monitoring the generalization score on a validation set. When available, it is activated through the parameter `early_stopping` or by setting a positive `n_iter_no_change`.

estimator instance We sometimes use this terminology to distinguish an `estimator` class from a constructed instance. For example, in the following, `cls` is an estimator class, while `est1` and `est2` are instances:

```python
cls = RandomForestClassifier
est1 = cls()
est2 = RandomForestClassifier()
```

evaluation metric
evaluation metrics Evaluation metrics give a measure of how well a model performs. We may use this term specifically to refer to the functions in `metrics` (disregarding `metrics.pairwise`), as distinct from the `score` method and the `scoring` API used in cross validation. See `Metrics and scoring: quantifying the quality of predictions`.

These functions usually accept a ground truth (or the raw data where the metric evaluates clustering without a ground truth) and a prediction, be it the output of `predict` (`y_pred`), of `predict_proba` (`y_proba`), or of an arbitrary score function including `decision_function` (`y_score`). Functions are usually named to end with `_score` if a greater score indicates a better model, and `_loss` if a lesser score indicates a better model. This diversity of interface motivates the scoring API.
Note that some estimators can calculate metrics that are not included in `metrics` and are estimator-specific, notably model likelihoods.

**estimator tags** A proposed feature (e.g. #8022) by which the capabilities of an estimator are described through a set of semantic tags. This would enable some runtime behaviors based on estimator inspection, but it also allows each estimator to be tested for appropriate invariances while being excepted from other common tests.

Some aspects of estimator tags are currently determined through the *duck typing* of methods like `predict_proba` and through some special attributes on estimator objects:

- **_estimator_type** This string-valued attribute identifies an estimator as being a classifier, regressor, etc. It is set by mixins such as `base.ClassifierMixin`, but needs to be more explicitly adopted on a `meta-estimator`. Its value should usually be checked by way of a helper such as `base.is_classifier`.

- **_pairwise** This boolean attribute indicates whether the data (X) passed to `fit` and similar methods consists of pairwise measures over samples rather than a feature representation for each sample. It is usually `True` where an estimator has a `metric` or `affinity` or `kernel` parameter with value 'precomputed'. Its primary purpose is that when a `meta-estimator` extracts a sub-sample of data intended for a pairwise estimator, the data needs to be indexed on both axes, while other data is indexed only on the first axis.

  Deprecated since version 0.24: The `_pairwise` attribute is deprecated in 0.24. From 0.26 onward, the `pairwise` estimator tag should be used instead.

For more detailed info, see *Estimator Tags*.

**feature**

**features**

**feature vector** In the abstract, a feature is a function (in its mathematical sense) mapping a sampled object to a numeric or categorical quantity. “Feature” is also commonly used to refer to these quantities, being the individual elements of a vector representing a sample. In a data matrix, features are represented as columns: each column contains the result of applying a feature function to a set of samples.

Elsewhere features are known as attributes, predictors, regressors, or independent variables.

Nearly all estimators in scikit-learn assume that features are numeric, finite and not missing, even when they have semantically distinct domains and distributions (categorical, ordinal, count-valued, real-valued, interval). See also *categorical feature* and *missing values*.

**n_features** indicates the number of features in a dataset.

**fitting** Calling `fit` (or `fit_transform`, `fit_predict`, etc.) on an estimator.

**fitted** The state of an estimator after `fitting`.

There is no conventional procedure for checking if an estimator is fitted. However, an estimator that is not fitted:

- should raise `exceptions.NotFittedError` when a prediction method (`predict`, `transform`, etc.) is called. (`utils.validation.check_is_fitted` is used internally for this purpose.)

  - should not have any `attributes` beginning with an alphabetic character and ending with an underscore.

(Note that a descriptor for the attribute may still be present on the class, but `hasattr` should return `False`)

**function** We provide ad hoc function interfaces for many algorithms, while `estimator` classes provide a more consistent interface.

In particular, Scikit-learn may provide a function interface that fits a model to some data and returns the learnt model parameters, as in `linear_model.enet_path`. For transductive models, this also returns the embedding or cluster labels, as in `manifold.spectral_embedding` or `cluster.dbscan`. Many preprocessing transformers also provide a function interface, akin to calling `fit_transform`, as in `preprocessing.maxabs_scale`. Users should be careful to avoid `data leakage` when making use of these `fit_transform`-equivalent functions.

---

**5.1. General Concepts**
We do not have a strict policy about when to or when not to provide function forms of estimators, but maintainers should consider consistency with existing interfaces, and whether providing a function would lead users astray from best practices (as regards data leakage, etc.)

**gallery**  See examples.

**hyperparameter**

**hyper-parameter**  See parameter.

**impute**

**imputation**  Most machine learning algorithms require that their inputs have no missing values, and will not work if this requirement is violated. Algorithms that attempt to fill in (or impute) missing values are referred to as imputation algorithms.

**indexable**  An array-like, sparse matrix, pandas DataFrame or sequence (usually a list).

**induction**

**inductive**  Inductive (contrasted with transductive) machine learning builds a model of some data that can then be applied to new instances. Most estimators in Scikit-learn are inductive, having predict and/or transform methods.

**joblib**  A Python library (https://joblib.readthedocs.io) used in Scikit-learn to facilitate simple parallelism and caching. Joblib is oriented towards efficiently working with numpy arrays, such as through use of memory mapping. See Parallelism for more information.

**label indicator matrix**

**multilabel indicator matrix**

**multilabel indicator matrices**  The format used to represent multilabel data, where each row of a 2d array or sparse matrix corresponds to a sample, each column corresponds to a class, and each element is 1 if the sample is labeled with the class and 0 if not.

**leakage**

**data leakage**  A problem in cross validation where generalization performance can be over-estimated since knowledge of the test data was inadvertently included in training a model. This is a risk, for instance, when applying a transformer to the entirety of a dataset rather than each training portion in a cross validation split.

We aim to provide interfaces (such as pipeline and model_selection) that shield the user from data leakage.

**memmapping**

**memory map**

**memory mapping**  A memory efficiency strategy that keeps data on disk rather than copying it into main memory. Memory maps can be created for arrays that can be read, written, or both, using numpy.memmap. When using joblib to parallelize operations in Scikit-learn, it may automatically memmap large arrays to reduce memory duplication overhead in multiprocessing.

**missing values**  Most Scikit-learn estimators do not work with missing values. When they do (e.g. in impute.SimpleImputer), NaN is the preferred representation of missing values in float arrays. If the array has integer dtype, NaN cannot be represented. For this reason, we support specifying another missing_values value when imputation or learning can be performed in integer space. Unlabeled data is a special case of missing values in the target.

**n_features**  The number of features.

**n_outputs**  The number of outputs in the target.

**n_samples**  The number of samples.
**n_targets** Synonym for `n_outputs`.

**narrative docs**

**narrative documentation** An alias for *User Guide*, i.e. documentation written in `doc/modules/`. Unlike the *API reference* provided through docstrings, the User Guide aims to:
- group tools provided by Scikit-learn together thematically or in terms of usage;
- motivate why someone would use each particular tool, often through comparison;
- provide both intuitive and technical descriptions of tools;
- provide or link to *examples* of using key features of a tool.

**np** A shorthand for Numpy due to the conventional import statement:

```python
import numpy as np
```

**online learning** Where a model is iteratively updated by receiving each batch of ground truth *targets* soon after making predictions on corresponding batch of data. Intrinsically, the model must be usable for prediction after each batch. See *partial_fit*.

**out-of-core** An efficiency strategy where not all the data is stored in main memory at once, usually by performing learning on batches of data. See *partial_fit*.

**outputs** Individual scalar/categorical variables per sample in the *target*. For example, in multilabel classification each possible label corresponds to a binary output. Also called *responses*, *tasks* or *targets*. See *multiclass multioutput* and *continuous multioutput*.

**pair** A tuple of length two.

**parameter**

**parameters**

**param**

**params** We mostly use *parameter* to refer to the aspects of an estimator that can be specified in its construction. For example, `max_depth` and `random_state` are parameters of RandomForestClassifier. Parameters to an estimator’s constructor are stored unmodified as attributes on the estimator instance, and conventionally start with an alphabetic character and end with an alphanumeric character. Each estimator’s constructor parameters are described in the estimator’s docstring.

We do not use parameters in the statistical sense, where parameters are values that specify a model and can be estimated from data. What we call parameters might be what statisticians call hyperparameters to the model: aspects for configuring model structure that are often not directly learnt from data. However, our parameters are also used to prescribe modeling operations that do not affect the learnt model, such as *n_jobs* for controlling parallelism.

When talking about the parameters of a *meta-estimator*, we may also be including the parameters of the estimators wrapped by the meta-estimator. Ordinarily, these nested parameters are denoted by using a *double underscore* (``) to separate between the estimator-as-parameter and its parameter. Thus `clf = BaggingClassifier(base_estimator=DecisionTreeClassifier(max_depth=3))` has a deep parameter `base_estimator__max_depth` with value 3, which is accessible with `clf.base_estimator.max_depth` or `clf.get_params()['base_estimator__max_depth']`.

The list of parameters and their current values can be retrieved from an *estimator instance* using its *get_params* method.

Between construction and fitting, parameters may be modified using *set_params*. To enable this, parameters are not ordinarily validated or altered when the estimator is constructed, or when each parameter is set. Parameter validation is performed when *fit* is called.

---

**5.1. General Concepts**
Common parameters are listed below.

**pairwise metric**

**pairwise metrics** In its broad sense, a pairwise metric defines a function for measuring similarity or dissimilarity between two samples (with each ordinarily represented as a feature vector). We particularly provide implementations of distance metrics (as well as improper metrics like Cosine Distance) through metrics.pairwise_distances, and of kernel functions (a constrained class of similarity functions) in metrics.pairwise_kernels. These can compute pairwise distance matrices that are symmetric and hence store data redundantly.

See also precomputed and metric.

Note that for most distance metrics, we rely on implementations from scipy.spatial.distance, but may reimplement for efficiency in our context. The neighbors module also duplicates some metric implementations for integration with efficient binary tree search data structures.

**pd** A shorthand for Pandas due to the conventional import statement:

```python
import pandas as pd
```

**precomputed** Where algorithms rely on pairwise metrics, and can be computed from pairwise metrics alone, we often allow the user to specify that the X provided is already in the pairwise (dis)similarity space, rather than in a feature space. That is, when passed to fit, it is a square, symmetric matrix, with each vector indicating (dis)similarity to every sample, and when passed to prediction/transformation methods, each row corresponds to a testing sample and each column to a training sample.

Use of precomputed X is usually indicated by setting a metric, affinity or kernel parameter to the string ‘precomputed’. If this is the case, then the estimator should set the pairwise estimator tag as True.

**rectangular** Data that can be represented as a matrix with samples on the first axis and a fixed, finite set of features on the second is called rectangular.

This term excludes samples with non-vectorial structures, such as text, an image of arbitrary size, a time series of arbitrary length, a set of vectors, etc. The purpose of a vectorizer is to produce rectangular forms of such data.

**sample**

**samples** We usually use this term as a noun to indicate a single feature vector. Elsewhere a sample is called an instance, data point, or observation. n_samples indicates the number of samples in a dataset, being the number of rows in a data array X.

**sample property**

**sample properties** A sample property is data for each sample (e.g. an array of length n_samples) passed to an estimator method or a similar function, alongside but distinct from the features (X) and target (y). The most prominent example is sample_weight; see others at Data and sample properties.

As of version 0.19 we do not have a consistent approach to handling sample properties and their routing in meta-estimators, though a fit_params parameter is often used.

**scikit-learn-contrib** A venue for publishing Scikit-learn-compatible libraries that are broadly authorized by the core developers and the contrib community, but not maintained by the core developer team. See https://scikit-learn-contrib.github.io.

**scikit-learn enhancement proposals**

**SLEP**

**SLEPs** Changes to the API principles and changes to dependencies or supported versions happen via a SLEP and follows the decision-making process outlined in Scikit-learn governance and decision-making. For all votes, a proposal must have been made public and discussed before the vote. Such a proposal must be a consolidated
document, in the form of a ‘Scikit-Learn Enhancement Proposal’ (SLEP), rather than a long discussion on an issue. A SLEP must be submitted as a pull-request to enhancement proposals using the SLEP template.

semi-supervised

semi-supervised learning

semisupervised Learning where the expected prediction (label or ground truth) is only available for some samples provided as training data when fitting the model. We conventionally apply the label −1 to unlabeled samples in semi-supervised classification.

sparse matrix

sparse graph A representation of two-dimensional numeric data that is more memory efficient the corresponding dense numpy array where almost all elements are zero. We use the scipy.sparse framework, which provides several underlying sparse data representations, or formats. Some formats are more efficient than others for particular tasks, and when a particular format provides especial benefit, we try to document this fact in Scikit-learn parameter descriptions.

Some sparse matrix formats (notably CSR, CSC, COO and LIL) distinguish between implicit and explicit zeros. Explicit zeros are stored (i.e. they consume memory in a data array) in the data structure, while implicit zeros correspond to every element not otherwise defined in explicit storage.

Two semantics for sparse matrices are used in Scikit-learn:

matrix semantics The sparse matrix is interpreted as an array with implicit and explicit zeros being interpreted as the number 0. This is the interpretation most often adopted, e.g. when sparse matrices are used for feature matrices or multilabel indicator matrices.

graph semantics As with scipy.sparse.csgraph, explicit zeros are interpreted as the number 0, but implicit zeros indicate a masked or absent value, such as the absence of an edge between two vertices of a graph, where an explicit value indicates an edge’s weight. This interpretation is adopted to represent connectivity in clustering, in representations of nearest neighborhoods (e.g. neighbors.kneighbors_graph), and for precomputed distance representation where only distances in the neighborhood of each point are required.

When working with sparse matrices, we assume that it is sparse for a good reason, and avoid writing code that densifies a user-provided sparse matrix, instead maintaining sparsity or raising an error if not possible (i.e. if an estimator does not / cannot support sparse matrices).

supervised

supervised learning Learning where the expected prediction (label or ground truth) is available for each sample when fitting the model, provided as y. This is the approach taken in a classifier or regressor among other estimators.

targets The dependent variable in supervised (and semisupervised) learning, passed as y to an estimator’s fit method. Also known as dependent variable, outcome variable, response variable, ground truth or label. Scikit-learn works with targets that have minimal structure: a class from a finite set, a finite real-valued number, multiple classes, or multiple numbers. See Target Types.

transduction

transductive A transductive (contrasted with inductive) machine learning method is designed to model a specific dataset, but not to apply that model to unseen data. Examples include manifold.TSNE, cluster.AgglomerativeClustering and neighbors.LocalOutlierFactor.

unlabeled

unlabeled data Samples with an unknown ground truth when fitting; equivalently, missing values in the target. See also semisupervised and unsupervised learning.
unsupervised

unsupervised learning Learning where the expected prediction (label or ground truth) is not available for each sample when fitting the model, as in clusterers and outlier detectors. Unsupervised estimators ignore any y passed to fit.

5.2 Class APIs and Estimator Types

classifier
classifiers A supervised (or semi-supervised) predictor with a finite set of discrete possible output values.

A classifier supports modeling some of binary, multiclass, multilabel, or multiclass multioutput targets. Within scikit-learn, all classifiers support multi-class classification, defaulting to using a one-vs-rest strategy over the binary classification problem.

Classifiers must store a classes_ attribute after fitting, and usually inherit from base.ClassifierMixin, which sets their _estimator_type attribute.

A classifier can be distinguished from other estimators with is_classifier.

A classifier must implement:

- fit
- predict
- score

It may also be appropriate to implement decision_function, predict_proba and predict_log_proba.

clusterer
clusterers A unsupervised predictor with a finite set of discrete output values.

A clusterer usually stores labels_ after fitting, and must do so if it is transductive.

A clusterer must implement:

- fit
- fit_predict if transductive
- predict if inductive

density estimator TODO
estimator
estimators An object which manages the estimation and decoding of a model. The model is estimated as a deterministic function of:

- parameters provided in object construction or with set_params;
- the global numpy.random random state if the estimator’s random_state parameter is set to None; and
- any data or sample properties passed to the most recent call to fit, fit_transform or fit_predict, or data similarly passed in a sequence of calls to partial_fit.

The estimated model is stored in public and private attributes on the estimator instance, facilitating decoding through prediction and transformation methods.

Estimators must provide a fit method, and should provide set_params and get_params, although these are usually provided by inheritance from base.BaseEstimator.
The core functionality of some estimators may also be available as a function.

**feature extractor**

**feature extractors** A *transformer* which takes input where each sample is not represented as an *array-like* object of fixed length, and produces an *array-like* object of *features* for each sample (and thus a 2-dimensional array-like for a set of samples). In other words, it (lossily) maps a non-rectangular data representation into *rectangular* data.

Feature extractors must implement at least:

- *fit*
- *transform*
- *get_feature_names*

**meta-estimator**

**meta-estimators**

**metaestimator**

**metaestimators** An *estimator* which takes another estimator as a parameter. Examples include *pipeline*, *Pipeline*, *model_selection.GridSearchCV*, *feature_selection.SelectFromModel* and *ensemble.BaggingClassifier*.

In a meta-estimator’s *fit* method, any contained estimators should be *cloned* before they are fit (although FIXME: Pipeline and FeatureUnion do not do this currently). An exception to this is that an estimator may explicitly document that it accepts a pre-fitted estimator (e.g. using *prefit=True* in *feature_selection.SelectFromModel*). One known issue with this is that the pre-fitted estimator will lose its model if the meta-estimator is cloned. A meta-estimator should have *fit* called before prediction, even if all contained estimators are pre-fitted.

In cases where a meta-estimator’s primary behaviors (e.g. *predict* or *transform* implementation) are functions of prediction/transformation methods of the provided *base estimator* (or multiple base estimators), a meta-estimator should provide at least the standard methods provided by the base estimator. It may not be possible to identify which methods are provided by the underlying estimator until the meta-estimator has been *fitted* (see also *duck typing*), for which *utils.metaestimators.if_delegate_has_method* may help. It should also provide (or modify) the *estimator tags* and *classes_* attribute provided by the base estimator.

Meta-estimators should be careful to validate data as minimally as possible before passing it to an underlying estimator. This saves computation time, and may, for instance, allow the underlying estimator to easily work with data that is not *rectangular*.

**outlier detector**

**outlier detectors** An *unsupervised* binary *predictor* which models the distinction between core and outlying samples.

Outlier detectors must implement:

- *fit*
- *fit_predict* if transductive
- *predict* if inductive

Inductive outlier detectors may also implement *decision_function* to give a normalized inlier score where outliers have score below 0. *score_samples* may provide an unnormalized score per sample.

**predictor**

**predictors** An *estimator* supporting *predict* and/or *fit_predict*. This encompasses *classifier*, *regressor*, *outlier detector* and *clusterer*. 

---

5.2. Class APIs and Estimator Types 689
In statistics, “predictors” refers to features.

**Regressor**

**Regressors** A *supervised* (or *semi-supervised*) predictor with *continuous* output values.

Regressors usually inherit from `base.RegressorMixin`, which sets their `_estimator_type` attribute.

A regressor can be distinguished from other estimators with `is_regressor`.

A regressor must implement:

- `fit`
- `predict`
- `score`

**Transformer**

**Transformers** An estimator supporting `transform` and/or `fit_transform`. A purely *transductive* transformer, such as `manifold.TSNE`, may not implement `transform`.

**Vectorizer**

**Vectorizers** See `feature extractor`.

There are further APIs specifically related to a small family of estimators, such as:

**Cross-validation splitter**

**CV splitter**

**Cross-validation generator** A non-estimator family of classes used to split a dataset into a sequence of train and test portions (see *Cross-validation: evaluating estimator performance*), by providing `split` and `get_n_splits` methods. Note that unlike estimators, these do not have `fit` methods and do not provide `set_params` or `get_params`. Parameter validation may be performed in `__init__`.

**Cross-validation estimator** An estimator that has built-in cross-validation capabilities to automatically select the best hyper-parameters (see the *User Guide*). Some example of cross-validation estimators are `ElasticNetCV` and `LogisticRegressionCV`. Cross-validation estimators are named `EstimatorCV` and tend to be roughly equivalent to `GridSearchCV(Estimator(), ...)`. The advantage of using a cross-validation estimator over the canonical `estimator` class along with `grid search` is that they can take advantage of warm-starting by reusing precomputed results in the previous steps of the cross-validation process. This generally leads to speed improvements. An exception is the `RidgeCV` class, which can instead perform efficient Leave-One-Out CV.

**Scorer** A non-estimator callable object which evaluates an estimator on given test data, returning a number. Unlike *evaluation metrics*, a greater returned number must correspond with a *better* score. See *The scoring parameter: defining model evaluation rules*.

Further examples:

- `neighbors.DistanceMetric`
- `gaussian_process.kernels.Kernel`
- `tree.Criterion`
5.3 Target Types

**binary** A classification problem consisting of two classes. A binary target may be represented as for a *multiclass* problem but with only two labels. A binary decision function is represented as a 1d array.

Semantically, one class is often considered the “positive” class. Unless otherwise specified (e.g. using `pos_label` in *evaluation metrics*), we consider the class label with the greater value (numerically or lexicographically) as the positive class: of labels [0, 1], 1 is the positive class; of [1, 2], 2 is the positive class; of [‘no’, ‘yes’], ‘yes’ is the positive class; of [‘no’, ‘YES’], ‘no’ is the positive class. This affects the output of *decision_function*, for instance.

Note that a dataset sampled from a multiclass *y* or a continuous *y* may appear to be binary.

*type_of_target* will return ‘binary’ for binary input, or a similar array with only a single class present.

**continuous** A regression problem where each sample’s target is a finite floating point number represented as a 1-dimensional array of floats (or sometimes ints).

*type_of_target* will return ‘continuous’ for continuous input, but if the data is all integers, it will be identified as ‘multiclass’.

**continuous multioutput**

**multioutput continuous** A regression problem where each sample’s target consists of *n_outputs* outputs, each one a finite floating point number, for a fixed int *n_outputs* > 1 in a particular dataset.

Continuous multioutput targets are represented as multiple **continuous** targets, horizontally stacked into an array of shape *(n_samples, n_outputs)*.

*type_of_target* will return ‘continuous-multioutput’ for continuous multioutput input, but if the data is all integers, it will be identified as ‘multiclass-multioutput’.

**multiclass**

**multi-class** A classification problem consisting of more than two classes. A multiclass target may be represented as a 1-dimensional array of strings or integers. A 2d column vector of integers (i.e. a single output in *multioutput* terms) is also accepted.

We do not officially support other orderable, hashable objects as class labels, even if estimators may happen to work when given classification targets of such type.

For semi-supervised classification, *unlabeled* samples should have the special label -1 in *y*.

Within scikit-learn, all estimators supporting binary classification also support multiclass classification, using One-vs-Rest by default.

A `preprocessing.LabelEncoder` helps to canonicalize multiclass targets as integers.

*type_of_target* will return ‘multiclass’ for multiclass input. The user may also want to handle ‘binary’ input identically to ‘multiclass’.

**multiclass multioutput**

**multi-class multi-output**

**multioutput multiclass**

**multi-output multi-class** A classification problem where each sample’s target consists of *n_outputs* outputs, each a class label, for a fixed int *n_outputs* > 1 in a particular dataset. Each output has a fixed set of available
classes, and each sample is labeled with a class for each output. An output may be binary or multiclass, and in
the case where all outputs are binary, the target is `multilabel`.

Multiclass multioutput targets are represented as multiple `multiclass` targets, horizontally stacked into an array
of shape `(n_samples, n_outputs)`.

XXX: For simplicity, we may not always support string class labels for multiclass multioutput, and integer class
labels should be used.

`multioutput` provides estimators which estimate multi-output problems using multiple single-output estima-
tors. This may not fully account for dependencies among the different outputs, which methods natively handling
the multioutput case (e.g. decision trees, nearest neighbors, neural networks) may do better.

`type_of_target` will return `‘multiclass-multioutput’` for multiclass multioutput input.

**multilabel**

**multi-label** A `multiclass multioutput` target where each output is `binary`. This may be represented as a 2d (dense)
array or sparse matrix of integers, such that each column is a separate binary target, where positive labels are
indicated with 1 and negative labels are usually -1 or 0. Sparse multilabel targets are not supported everywhere
that dense multilabel targets are supported.

Semantically, a multilabel target can be thought of as a set of labels for each sample. While not used intern-
ally, `preprocessing.MultiLabelBinarizer` is provided as a utility to convert from a list of sets
representation to a 2d array or sparse matrix. One-hot encoding a multiclass target with `preprocessing.
LabelBinarizer` turns it into a multilabel problem.

`type_of_target` will return `‘multilabel-indicator’` for multilabel input, whether sparse or dense.

**multioutput**

**multi-output** A target where each sample has multiple classification/regression labels. See `multiclass multioutput`
and `continuous multioutput`. We do not currently support modelling mixed classification and regression targets.

### 5.4 Methods

decision function In a fitted classifier or outlier detector, predicts a “soft” score for each sample in relation
to each class, rather than the “hard” categorical prediction produced by `predict`. Its input is usually only some
observed data, `X`.

If the estimator was not already fitted, calling this method should raise a `exceptions.NotFittedError`.

Output conventions:

**binary classification** A 1-dimensional array, where values strictly greater than zero indicate the positive class
(i.e. the last class in `classes_`).

**multiclass classification** A 2-dimensional array, where the row-wise arg-maximum is the predicted class.
Columns are ordered according to `classes_`.

**multilabel classification** Scikit-learn is inconsistent in its representation of multilabel decision functions.
Some estimators represent it like multiclass multioutput, i.e. a list of 2d arrays, each with two columns.
Others represent it with a single 2d array, whose columns correspond to the individual binary classification
decisions. The latter representation is ambiguously identical to the multiclass classification format, though
its semantics differ: it should be interpreted, like in the binary case, by thresholding at 0.

TODO: This gist highlights the use of the different formats for multilabel.

**multioutput classification** A list of 2d arrays, corresponding to each multiclass decision function.

**outlier detection** A 1-dimensional array, where a value greater than or equal to zero indicates an inlier.
The `fit` method is provided on every estimator. It usually takes some `samples X, targets y` if the model is supervised, and potentially other `sample properties` such as `sample_weight`. It should:

- clear any prior `attributes` stored on the estimator, unless `warm_start` is used;
- validate and interpret any `parameters`, ideally raising an error if invalid;
- validate the input data;
- estimate and store model attributes from the estimated parameters and provided data; and
- return the now `fitted` estimator to facilitate method chaining.

`Target Types` describes possible formats for `y`.

`fit_predict` Used especially for `unsupervised, transductive` estimators, this fits the model and returns the predictions (similar to `predict`) on the training data. In clusterers, these predictions are also stored in the `labels_` attribute, and the output of `.fit_predict(X)` is usually equivalent to `.fit(X).predict(X)`. The parameters to `fit_predict` are the same as those to `fit`.

`fit_transform` A method on `transformers` which fits the estimator and returns the transformed training data. It takes parameters as in `fit` and its output should have the same shape as calling `.fit(X, ...).transform(X)`. There are nonetheless rare cases where `.fit_transform(X, ...) and .fit(X, ...).transform(X)` do not return the same value, wherein training data needs to be handled differently (due to model blending in stacked ensembles, for instance; such cases should be clearly documented). `Transductive` transformers may also provide `fit_transform` but not `transform`.

One reason to implement `fit_transform` is that performing `fit` and `transform` separately would be less efficient than together. `base.TransformerMixin` provides a default implementation, providing a consistent interface across transformers where `fit_transform` is or is not specialized.

In `inductive` learning – where the goal is to learn a generalized model that can be applied to new data – users should be careful not to apply `fit_transform` to the entirety of a dataset (i.e. training and test data together) before further modelling, as this results in `data leakage`.

`get_feature_names` Primarily for `feature extractors`, but also used for other transformers to provide string names for each column in the output of the estimator’s `transform` method. It outputs a list of strings and may take a list of strings as input, corresponding to the names of input columns from which output column names can be generated. By default input features are named `x0, x1, ...`.

`get_n_splits` On a `CV splitter` (not an estimator), returns the number of elements one would get if iterating through the return value of `split` given the same parameters. Takes the same parameters as split.

`get_params` Gets all `parameters`, and their values, that can be set using `set_params`. A parameter `deep` can be used, when set to `False` to only return those parameters not including `__`, i.e. not due to indirection via contained estimators.

Most estimators adopt the definition from `base.BaseEstimator`, which simply adopts the parameters defined for `__init__`. `pipeline.Pipeline`, among others, reimplements `get_params` to declare the estimators named in its `steps` parameters as themselves being parameters.

`partial_fit` Facilitates fitting an estimator in an online fashion. Unlike `fit`, repeatedly calling `partial_fit` does not clear the model, but updates it with the data provided. The portion of data provided to `partial_fit` may be called a mini-batch. Each mini-batch must be of consistent shape, etc. In iterative estimators, `partial_fit` often only performs a single iteration.

`partial_fit` may also be used for `out-of-core` learning, although usually limited to the case where learning can be performed online, i.e. the model is usable after each `partial_fit` and there is no separate processing needed to finalize the model. `cluster.Birch` introduces the convention that calling `partial_fit(X)` will produce a model that is not finalized, but the model can be finalized by calling `partial_fit()` i.e. without passing a further mini-batch.
Generally, estimator parameters should not be modified between calls to `partial_fit`, although `partial_fit` should validate them as well as the new mini-batch of data. In contrast, `warm_start` is used to repeatedly fit the same estimator with the same data but varying parameters.

Like `fit`, `partial_fit` should return the estimator object.

To clear the model, a new estimator should be constructed, for instance with `base.clone`.

**NOTE:** Using `partial_fit` after `fit` results in undefined behavior.

**predict** Makes a prediction for each sample, usually only taking \(X\) as input (but see under regressor output conventions below). In a **classifier** or **regressor**, this prediction is in the same target space used in fitting (e.g. one of {'red', 'amber', 'green'} if the \(y\) in fitting consisted of these strings). Despite this, even when \(y\) passed to `fit` is a list or other array-like, the output of `predict` should always be an array or sparse matrix. In a **clusterer** or **outlier detector** the prediction is an integer.

If the estimator was not already fitted, calling this method should raise a `exceptions.NotFittedError`.

**Output conventions:**

- **classifier** An array of shape \((n\_samples,)\) (\(n\_samples, n\_outputs\)). **Multilabel** data may be represented as a sparse matrix if a sparse matrix was used in fitting. Each element should be one of the values in the classifier's `classes_` attribute.

- **clusterer** An array of shape \((n\_samples,)\) where each value is from 0 to \(n\_clusters - 1\) if the corresponding sample is clustered, and -1 if the sample is not clustered, as in `cluster.dbscan`.

- **outlier detector** An array of shape \((n\_samples,)\) where each value is -1 for an outlier and 1 otherwise.

- **regressor** A numeric array of shape \((n\_samples,)\), usually float64. Some regressors have extra options in their `predict` method, allowing them to return standard deviation (`return_std=True`) or covariance (`return_cov=True`) relative to the predicted value. In this case, the return value is a tuple of arrays corresponding to (prediction mean, std, cov) as required.

**predict_log_proba** The natural logarithm of the output of `predict_proba`, provided to facilitate numerical stability.

**predict_proba** A method in classifiers and clusterers that can return probability estimates for each class/cluster. Its input is usually only some observed data, \(X\).

If the estimator was not already fitted, calling this method should raise a `exceptions.NotFittedError`.

**Output conventions** are like those for `decision_function` except in the binary classification case, where one column is output for each class (while `decision_function` outputs a 1d array). For binary and multiclass predictions, each row should add to 1.

Like other methods, `predict_proba` should only be present when the estimator can make probabilistic predictions (see *duck typing*). This means that the presence of the method may depend on estimator parameters (e.g. in `linear_model.SGDClassifier`) or training data (e.g. in `model_selection.GridSearchCV`) and may only appear after fitting.

**score** A method on an estimator, usually a predictor, which evaluates its predictions on a given dataset, and returns a single numerical score. A greater return value should indicate better predictions; accuracy is used for classifiers and \(R^2\) for regressors by default.

If the estimator was not already fitted, calling this method should raise a `exceptions.NotFittedError`.

Some estimators implement a custom, estimator-specific score function, often the likelihood of the data under the model.

**score_samples** TODO

If the estimator was not already fitted, calling this method should raise a `exceptions.NotFittedError`. 
**set_params** Available in any estimator, takes keyword arguments corresponding to keys in `get_params`. Each is provided a new value to assign such that calling `get_params` after `set_params` will reflect the changed parameters. Most estimators use the implementation in `base.BaseEstimator`, which handles nested parameters and otherwise sets the parameter as an attribute on the estimator. The method is overridden in `pipeline.Pipeline` and related estimators.

**split** On a CV splitter (not an estimator), this method accepts parameters (`X`, `y`, `groups`), where all may be optional, and returns an iterator over `train_idx`, `test_idx` pairs. Each of `[train,test]_idx` is a 1d integer array, with values from 0 from `X.shape[0] - 1` of any length, such that no values appear in both some train_idx and its corresponding test_idx.

**transform** In a transformer, transforms the input, usually only `X`, into some transformed space (conventionally notated as `Xt`). Output is an array or sparse matrix of length `n_samples` and with the number of columns fixed after fitting.

If the estimator was not already fitted, calling this method should raise an `exceptions.NotFittedError`.

### 5.5 Parameters

These common parameter names, specifically used in estimator construction (see concept parameter), sometimes also appear as parameters of functions or non-estimator constructors.

**class_weight** Used to specify sample weights when fitting classifiers as a function of the target class. Where `sample_weight` is also supported and given, it is multiplied by the class_weight contribution. Similarly, where `class_weight` is used in a multioutput (including multilabel) tasks, the weights are multiplied across outputs (i.e. columns of `y`).

By default, all samples have equal weight such that classes are effectively weighted by their prevalence in the training data. This could be achieved explicitly with `class_weight={label1: 1, label2: 1, ...}` for all class labels.

More generally, `class_weight` is specified as a dict mapping class labels to weights (`{class_label: weight}`), such that each sample of the named class is given that weight.

`class_weight='balanced'` can be used to give all classes equal weight by giving each sample a weight inversely related to its class’s prevalence in the training data: `n_samples / (n_classes * np.bincount(y))`. Class weights will be used differently depending on the algorithm: for linear models (such as linear SVM or logistic regression), the class weights will alter the loss function by weighting the loss of each sample by its class weight. For tree-based algorithms, the class weights will be used for reweighting the splitting criterion. **Note** however that this rebalancing does not take the weight of samples in each class into account.

For multioutput classification, a list of dicts is used to specify weights for each output. For example, for four-class multilabel classification weights should be `[(0: 1, 1: 1), (0: 1, 1: 5), (0: 1, 1: 1), (0: 1, 1: 1)]` instead of `{1:1}, (2:5), (3:1), (4:1])`.

The `class_weight` parameter is validated and interpreted with `utils.compute_class_weight`.

**cv** Determines a cross validation splitting strategy, as used in cross-validation based routines. `cv` is also available in estimators such as `multioutput.ClassifierChain` or `calibration.CalibratedClassifierCV` which use the predictions of one estimator as training data for another, to not overfit the training supervision.

Possible inputs for `cv` are usually:

- An integer, specifying the number of folds in K-fold cross validation. K-fold will be stratified over classes if the estimator is a classifier (determined by `base.is_classifier`) and the `targets` may represent a binary or multiclass (but not multioutput) classification problem (determined by `utils.multiclass.type_of_target`).
• A cross-validation splitter instance. Refer to the User Guide for splitters available within Scikit-learn.
• An iterable yielding train/test splits.

With some exceptions (especially where not using cross validation at all is an option), the default is 5-fold.

cv values are validated and interpreted with utils.check_cv.

kernel TODO

max_iter For estimators involving iterative optimization, this determines the maximum number of iterations to be performed in fit. If max_iter iterations are run without convergence, a exceptions.ConvergenceWarning should be raised. Note that the interpretation of “a single iteration” is inconsistent across estimators: some, but not all, use it to mean a single epoch (i.e. a pass over every sample in the data).

FIXME perhaps we should have some common tests about the relationship between ConvergenceWarning and max_iter.

memory Some estimators make use of joblib.Memory to store partial solutions during fitting. Thus when fit is called again, those partial solutions have been memoized and can be reused.

A memory parameter can be specified as a string with a path to a directory, or a joblib.Memory instance (or an object with a similar interface, i.e. a cache method) can be used.

memory values are validated and interpreted with utils.validation.check_memory.

metric As a parameter, this is the scheme for determining the distance between two data points. See metrics.pairwise_distances. In practice, for some algorithms, an improper distance metric (one that does not obey the triangle inequality, such as Cosine Distance) may be used.

XXX: hierarchical clustering uses affinity with this meaning.

We also use metric to refer to evaluation metrics, but avoid using this sense as a parameter name.

n_components The number of features which a transformer should transform the input into. See components_ for the special case of affine projection.

n_iter_no_change Number of iterations with no improvement to wait before stopping the iterative procedure. This is also known as a patience parameter. It is typically used with early stopping to avoid stopping too early.

n_jobs This parameter is used to specify how many concurrent processes or threads should be used for routines that are parallelized with joblib.

n_jobs is an integer, specifying the maximum number of concurrently running workers. If 1 is given, no joblib parallelism is used at all, which is useful for debugging. If set to -1, all CPUs are used. For n_jobs below -1, (n_cpus + 1 + n_jobs) are used. For example with n_jobs=-2, all CPUs but one are used.

n_jobs is None by default, which means unset; it will generally be interpreted as n_jobs=1, unless the current joblib.Parallel backend context specifies otherwise.

For more details on the use of joblib and its interactions with scikit-learn, please refer to our parallelism notes.

pos_label Value with which positive labels must be encoded in binary classification problems in which the positive class is not assumed. This value is typically required to compute asymmetric evaluation metrics such as precision and recall.

random_state Whenever randomization is part of a Scikit-learn algorithm, a random_state parameter may be provided to control the random number generator used. Note that the mere presence of random_state doesn’t mean that randomization is always used, as it may be dependent on another parameter, e.g. shuffle, being set.

The passed value will have an effect on the reproducibility of the results returned by the function (fit, split, or any other function like k_means). random_state’s value may be:
None (default) Use the global random state instance from numpy.random. Calling the function multiple times will reuse the same instance, and will produce different results.

An integer Use a new random number generator seeded by the given integer. Using an int will produce the same results across different calls. However, it may be worthwhile checking that your results are stable across a number of different distinct random seeds. Popular integer random seeds are 0 and 42.

A numpy.random.RandomState instance Use the provided random state, only affecting other users of that same random state instance. Calling the function multiple times will reuse the same instance, and will produce different results.

utils.check_random_state is used internally to validate the input random_state and return a RandomState instance.

scoring Specifies the score function to be maximized (usually by cross validation), or – in some cases – multiple score functions to be reported. The score function can be a string accepted by metrics.get_scorer or a callable scorer, not to be confused with an evaluation metric, as the latter have a more diverse API. scoring may also be set to None, in which case the estimator’s score method is used. See The scoring parameter: defining model evaluation rules in the User Guide.

Where multiple metrics can be evaluated, scoring may be given either as a list of unique strings, a dictionary with names as keys and callables as values or a callable that returns a dictionary. Note that this does not specify which score function is to be maximized, and another parameter such as refit maybe used for this purpose.

The scoring parameter is validated and interpreted using metrics.check_scoring.

verbose Logging is not handled very consistently in Scikit-learn at present, but when it is provided as an option, the verbose parameter is usually available to choose no logging (set to False). Any True value should enable some logging, but larger integers (e.g. above 10) may be needed for full verbosity. Verbose logs are usually printed to Standard Output. Estimators should not produce any output on Standard Output with the default verbose setting.

warm_start When fitting an estimator repeatedly on the same dataset, but for multiple parameter values (such as to find the value maximizing performance as in grid search), it may be possible to reuse aspects of the model learned from the previous parameter value, saving time. When warm_start is true, the existing fitted model attributes are used to initialize the new model in a subsequent call to fit.

Note that this is only applicable for some models and some parameters, and even some orders of parameter values. For example, warm_start may be used when building random forests to add more trees to the forest (increasing n_estimators) but not to reduce their number.

partial_fit also retains the model between calls, but differs: with warm_start the parameters change and the data is (more-or-less) constant across calls to fit; with partial_fit, the mini-batch of data changes and model parameters stay fixed.

There are cases where you want to use warm_start to fit on different, but closely related data. For example, one may initially fit to a subset of the data, then fine-tune the parameter search on the full dataset. For classification, all data in a sequence of warm_start calls to fit must include samples from each class.

5.5. Parameters
5.6 Attributes

See concept attribute.

**classes_** A list of class labels known to the classifier, mapping each label to a numerical index used in the model representation our output. For instance, the array output from `predict_proba` has columns aligned with `classes_`. For multi-output classifiers, `classes_` should be a list of lists, with one class listing for each output. For each output, the classes should be sorted (numerically, or lexicographically for strings). `classes_` and the mapping to indices is often managed with `preprocessing.LabelEncoder`.

**components_** An affine transformation matrix of shape `(n_components, n_features)` used in many linear transformers where `n_components` is the number of output features and `n_features` is the number of input features.

See also `components_` which is a similar attribute for linear predictors.

**coef_** The weight/coefficient matrix of a generalised linear model `predictor`, of shape `(n_features,)` for binary classification and single-output regression, `(n_classes, n_features)` for multiclass classification and `(n_targets, n_features)` for multi-output regression. Note this does not include the intercept (or bias) term, which is stored in `intercept_`.

When available, `feature_importances_` is not usually provided as well, but can be calculated as the norm of each feature’s entry in `coef_`.

See also `components_` which is a similar attribute for linear transformers.

**embedding_** An embedding of the training data in manifold learning estimators, with shape `(n_samples, n_components)`, identical to the output of `fit_transform`. See also `labels_`.

**n_iter_** The number of iterations actually performed when fitting an iterative estimator that may stop upon convergence. See also `max_iter`.

**feature_importances_** A vector of shape `(n_features,)` available in some predictors to provide a relative measure of the importance of each feature in the predictions of the model.

**labels_** A vector containing a cluster label for each sample of the training data in clusterers, identical to the output of `fit_predict`. See also `embedding_`.

5.7 Data and sample properties

See concept sample property.

**groups** Used in cross-validation routines to identify samples that are correlated. Each value is an identifier such that, in a supporting CV splitter, samples from some `groups` value may not appear in both a training set and its corresponding test set. See Cross-validation iterators for grouped data.

**sample_weight** A relative weight for each sample. Intuitively, if all weights are integers, a weighted model or score should be equivalent to that calculated when repeating the sample the number of times specified in the weight. Weights may be specified as floats, so that sample weights are usually equivalent up to a constant positive scaling factor.

FIXME Is this interpretation always the case in practice? We have no common tests.

Some estimators, such as decision trees, support negative weights. FIXME: This feature or its absence may not be tested or documented in many estimators.

This is not entirely the case where other parameters of the model consider the number of samples in a region, as with `min_samples` in `cluster.DBSCAN`. In this case, a count of samples becomes to a sum of their weights.
In classification, sample weights can also be specified as a function of class with the `class_weight` estimator parameter.

\( X \) Denotes data that is observed at training and prediction time, used as independent variables in learning. The notation is uppercase to denote that it is ordinarily a matrix (see rectangular). When a matrix, each sample may be represented by a feature vector, or a vector of precomputed (dis)similarity with each training sample. \( X \) may also not be a matrix, and may require a feature extractor or a pairwise metric to turn it into one before learning a model.

\( X_t \) Shorthand for “transformed \( X \”).

\( y \)

\( Y \) Denotes data that may be observed at training time as the dependent variable in learning, but which is unavailable at prediction time, and is usually the target of prediction. The notation may be uppercase to denote that it is a matrix, representing multi-output targets, for instance; but usually we use \( y \) and sometimes do so even when multiple outputs are assumed.
EXAMPLES

6.1 Scalable learning with polynomial kernel approximation

This example illustrates the use of \texttt{PolynomialCountSketch} to efficiently generate polynomial kernel feature-space approximations. This is used to train linear classifiers that approximate the accuracy of kernelized ones.

We use the Covtype dataset [2], trying to reproduce the experiments on the original paper of Tensor Sketch [1], i.e. the algorithm implemented by \texttt{PolynomialCountSketch}.

First, we compute the accuracy of a linear classifier on the original features. Then, we train linear classifiers on different numbers of features (\texttt{n\_components}) generated by \texttt{PolynomialCountSketch}, approximating the accuracy of a kernelized classifier in a scalable manner.

```python
print(__doc__)

# Author: Daniel Lopez-Sanchez <lope@usal.es>
# License: BSD 3 clause
import matplotlib.pyplot as plt
from sklearn.datasets import fetch_covtype
from sklearn.model_selection import train_test_split
from sklearn.preprocessing import MinMaxScaler, Normalizer
from sklearn.svm import LinearSVC
from sklearn.kernel_approximation import PolynomialCountSketch
from sklearn.pipeline import Pipeline, make_pipeline
import time

# Load the Covtype dataset, which contains 581,012 samples with 54 features each, distributed among 6 classes. The goal of this dataset is to predict forest cover type from cartographic variables only (no remotely sensed data). After loading, we transform it into a binary classification problem to match the version of the dataset in the LIBSVM webpage [2], which was the one used in [1].

X, y = fetch_covtype(return_X_y=True)
y[y != 2] = 0
y[y == 2] = 1  # We will try to separate class 2 from the other 6 classes.

# Here we select 5,000 samples for training and 10,000 for testing. To actually reproduce the results in the original Tensor Sketch paper, select 100,000 for training.

x_train, X_test, y_train, y_test = train_test_split(X, y, train_size=5_000,
                                                        test_size=10_000,
                                                        random_state=42)
```

---

701
Now scale features to the range $[0, 1]$ to match the format of the dataset in the LIBSVM webpage, and then normalize
to unit length as done in the original Tensor Sketch paper [1].

```python
mm = make_pipeline(MinMaxScaler(), Normalizer())
X_train = mm.fit_transform(X_train)
X_test = mm.transform(X_test)
```

As a baseline, train a linear SVM on the original features and print the accuracy. We also measure and store accuracies
and training times to plot them latter.

```python
results = {}
lsvm = LinearSVC()
start = time.time()
lsvm.fit(X_train, y_train)
lsvm_time = time.time() - start
lsvm_score = 100 * lsvm.score(X_test, y_test)
results["LSVM"] = {"time": lsvm_time, "score": lsvm_score}
print(f"Linear SVM score on raw features: {lsvm_score:.2f}%")
```

Out:

```
Linear SVM score on raw features: 75.62%
```

Then we train linear SVMs on the features generated by `PolynomialCountSketch` with different values for
.n_components, showing that these kernel feature approximations improve the accuracy of linear classification. In
typical application scenarios, .n_components should be larger than the number of features in the input representation
in order to achieve an improvement with respect to linear classification. As a rule of thumb, the optimum of evaluation
score / run time cost is typically achieved at around .n_components = 10 * .n_features, though this might depend
on the specific dataset being handled. Note that, since the original samples have 54 features, the explicit feature map
of the polynomial kernel of degree four would have approximately 8.5 million features (precisely, 54^4). Thanks to
`PolynomialCountSketch`, we can condense most of the discriminative information of that feature space into
a much more compact representation. We repeat the experiment 5 times to compensate for the stochastic nature of
`PolynomialCountSketch`.

```python
n_runs = 3
for n_components in [250, 500, 1000, 2000]:
    ps_lsvm_time = 0
    ps_lsvm_score = 0
    for _ in range(n_runs):
        pipeline = Pipeline(steps=[
            "kernel_approximator",
            PolynomialCountSketch(n_components=n_components,
            degree=4)),
            "linear_classifier", LinearSVC())]

    start = time.time()
    pipeline.fit(X_train, y_train)
    ps_lsvm_time += time.time() - start
    ps_lsvm_score += 100 * pipeline.score(X_test, y_test)

    ps_lsvm_time /= n_runs
    ps_lsvm_score /= n_runs
```

(continues on next page)
results[f"LSVM + PS({n_components})"] = {
    "time": ps_lsvm_time, "score": ps_lsvm_score
}
print(f"Linear SVM score on {n_components} PolynomialCountSketch features: {ps_lsvm_score:.2f}%")

Out:
Linear SVM score on 250 PolynomialCountSketch features: 75.91%
Linear SVM score on 500 PolynomialCountSketch features: 77.45%
Linear SVM score on 1000 PolynomialCountSketch features: 77.87%
Linear SVM score on 2000 PolynomialCountSketch features: 78.08%

Train a kernelized SVM to see how well PolynomialCountSketch is approximating the performance of the kernel. This, of course, may take some time, as the SVC class has a relatively poor scalability. This is the reason why kernel approximators are so useful:

```python
from sklearn.svm import SVC
ksvm = SVC(C=500., kernel="poly", degree=4, coef0=0, gamma=1.)
start = time.time()
ksvm.fit(X_train, y_train)
ksvm_time = time.time() - start
ksvm_score = 100 * ksvm.score(X_test, y_test)
results["KSVM"] = {"time": ksvm_time, "score": ksvm_score}
print(f"Kernel-SVM score on raw features: {ksvm_score:.2f}%")
```

Out:
Kernel-SVM score on raw features: 79.77%

Finally, plot the results of the different methods against their training times. As we can see, the kernelized SVM achieves a higher accuracy, but its training time is much larger and, most importantly, will grow much faster if the number of training samples increases.

```python
N_COMPONENTS = [250, 500, 1000, 2000]
fig, ax = plt.subplots(figsize=(7, 7))
ax.scatter([results["LSVM"]['time'], ], [results["LSVM"]['score'], ], label="Linear SVM", c="green", marker="^")
ax.scatter([results["LSVM + PS(250)"]['time'], ], [results["LSVM + PS(250)"]['score'], ], label="Linear SVM + PolynomialCountSketch", c="blue")
for n_components in N_COMPONENTS:
    ax.scatter([results[f"LSVM + PS({n_components})"]['time'], ], [results[f"LSVM + PS({n_components})"]['score'], ], c="blue")
    ax.annotate(f"n_comp.={n_components}",
                (results[f"LSVM + PS({n_components})"]['time'],
                 results[f"LSVM + PS({n_components})"]['score']),
                xytext=(-30, 10), textcoords="offset pixels")
ax.scatter([results["KSVM"]['time'], ], [results["KSVM"]['score'], ],
```

(continues on next page)
ax.set_xlabel("Training time (s)")
ax.set_ylabel("Accuracy (%)")
ax.legend()
plt.show()

6.2 Release Highlights

These examples illustrate the main features of the releases of scikit-learn.

6.2.1 Release Highlights for scikit-learn 0.23

We are pleased to announce the release of scikit-learn 0.23! Many bug fixes and improvements were added, as well as some new key features. We detail below a few of the major features of this release. For an exhaustive list of all the changes, please refer to the release notes.

To install the latest version (with pip):

```bash
pip install --upgrade scikit-learn
```

or with conda:

```bash
conda install -c conda-forge scikit-learn
```

Generalized Linear Models, and Poisson loss for gradient boosting

Long-awaited Generalized Linear Models with non-normal loss functions are now available. In particular, three new regressors were implemented: PoissonRegressor, GammaRegressor, and TweedieRegressor. The Poisson regressor can be used to model positive integer counts, or relative frequencies. Read more in the User Guide. Additionally, HistGradientBoostingRegressor supports a new ‘poisson’ loss as well.

```python
import numpy as np
from sklearn.model_selection import train_test_split
from sklearn.linear_model import PoissonRegressor
from sklearn.experimental import enable_hist_gradient_boosting # noqa
from sklearn.ensemble import HistGradientBoostingRegressor

n_samples, n_features = 1000, 20
rng = np.random.RandomState(0)
X = rng.randn(n_samples, n_features)
# positive integer target correlated with X[:, 5] with many zeros:
y = rng.poisson(lam=np.exp(X[:, 5]) / 2)
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=rng)
glm = PoissonRegressor()
gbdt = HistGradientBoostingRegressor(loss='poisson', learning_rate=.01)
glm.fit(X_train, y_train)
gbdt.fit(X_train, y_train)
print(glm.score(X_test, y_test))
print(gbdt.score(X_test, y_test))
```

Out:
Rich visual representation of estimators

Estimators can now be visualized in notebooks by enabling the `display='diagram'` option. This is particularly useful to summarise the structure of pipelines and other composite estimators, with interactivity to provide detail. Click on the example image below to expand Pipeline elements. See `Visualizing Composite Estimators` for how you can use this feature.

```python
from sklearn import set_config
from sklearn.pipeline import make_pipeline
from sklearn.preprocessing import OneHotEncoder, StandardScaler
from sklearn.impute import SimpleImputer
from sklearn.compose import make_column_transformer
from sklearn.linear_model import LogisticRegression
set_config(display='diagram')

num_proc = make_pipeline(SimpleImputer(strategy='median'), StandardScaler())
cat_proc = make_pipeline(SimpleImputer(strategy='constant', fill_value='missing'),
                         OneHotEncoder(handle_unknown='ignore'))

preprocessor = make_column_transformer((num_proc, ('feat1', 'feat3')),
                                        (cat_proc, ('feat0', 'feat2')))

clf = make_pipeline(preprocessor, LogisticRegression())
clf
```

Scalability and stability improvements to KMeans

The `KMeans` estimator was entirely re-worked, and it is now significantly faster and more stable. In addition, the Elkan algorithm is now compatible with sparse matrices. The estimator uses OpenMP based parallelism instead of relying on joblib, so the `n_jobs` parameter has no effect anymore. For more details on how to control the number of threads, please refer to our `Parallelism` notes.

```python
import scipy
import numpy as np
from sklearn.model_selection import train_test_split
from sklearn.cluster import KMeans
from sklearn.datasets import make_blobs
from sklearn.metrics import completeness_score

rng = np.random.RandomState(0)
X, y = make_blobs(random_state=rng)
X = scipy.sparse.csr_matrix(X)
X_train, X_test, _, y_test = train_test_split(X, y, random_state=rng)
kmeans = KMeans(algorithm='elkan').fit(X_train)
print(completeness_score(kmeans.predict(X_test), y_test))
```

Out:
Improvements to the histogram-based Gradient Boosting estimators

Various improvements were made to HistGradientBoostingClassifier and HistGradientBoostingRegressor. On top of the Poisson loss mentioned above, these estimators now support sample weights. Also, an automatic early-stopping criterion was added: early-stopping is enabled by default when the number of samples exceeds 10k. Finally, users can now define monotonic constraints to constrain the predictions based on the variations of specific features. In the following example, we construct a target that is generally positively correlated with the first feature, with some noise. Applying monotonic constraints allows the prediction to capture the global effect of the first feature, instead of fitting the noise.

```python
import numpy as np
from matplotlib import pyplot as plt
from sklearn.model_selection import train_test_split
from sklearn.inspection import plot_partial_dependence
from sklearn.experimental import enable_hist_gradient_boosting  # noqa
from sklearn.ensemble import HistGradientBoostingRegressor

n_samples = 500
rng = np.random.RandomState(0)
X = rng.randn(n_samples, 2)
noise = rng.normal(loc=0.0, scale=0.01, size=n_samples)
y = (5 * X[:, 0] + np.sin(10 * np.pi * X[:, 0]) - noise)

gbdt_no_cst = HistGradientBoostingRegressor().fit(X, y)
gbdt_cst = HistGradientBoostingRegressor(monotonic_cst=[1, 0]).fit(X, y)

disp = plot_partial_dependence(gbdt_no_cst, X, features=[0], feature_names=['feature 0'], line_kw={'linewidth': 4, 'label': 'unconstrained'})
plot_partial_dependence(gbdt_cst, X, features=[0], line_kw={'linewidth': 4, 'label': 'constrained'}, ax=disp.axes_)
disp.axes_[0, 0].plot(X[:, 0], y, 'o', alpha=.5, zorder=-1, label='samples')
disp.axes_[0, 0].set_xlim(-1, 1)
plt.legend()
plt.show()
```
Sample-weight support for Lasso and ElasticNet

The two linear regressors *Lasso* and *ElasticNet* now support sample weights.

```python
from sklearn.model_selection import train_test_split
from sklearn.datasets import make_regression
from sklearn.linear_model import Lasso
import numpy as np

n_samples, n_features = 1000, 20
rng = np.random.RandomState(0)
X, y = make_regression(n_samples, n_features, random_state=rng)
sample_weight = rng.rand(n_samples)
X_train, X_test, y_train, y_test, sw_train, sw_test = train_test_split(X, y, sample_weight, random_state=rng)
reg = Lasso()
reg.fit(X_train, y_train, sample_weight=sw_train)
print(reg.score(X_test, y_test, sw_test))
```

Out:

```
0.999791942438998
```

**Total running time of the script:** ( 0 minutes 0.764 seconds)
6.2.2 Release Highlights for scikit-learn 0.22

We are pleased to announce the release of scikit-learn 0.22, which comes with many bug fixes and new features! We detail below a few of the major features of this release. For an exhaustive list of all the changes, please refer to the release notes.

To install the latest version (with pip):

```
pip install --upgrade scikit-learn
```

or with conda:

```
conda install -c conda-forge scikit-learn
```

New plotting API

A new plotting API is available for creating visualizations. This new API allows for quickly adjusting the visuals of a plot without involving any recomputation. It is also possible to add different plots to the same figure. The following example illustrates `plot_roc_curve`, but other plots utilities are supported like `plot_partial_dependence`, `plot_precision_recall_curve`, and `plot_confusion_matrix`. Read more about this new API in the User Guide.

```
from sklearn.model_selection import train_test_split
from sklearn.svm import SVC
from sklearn.metrics import plot_roc_curve
from sklearn.ensemble import RandomForestClassifier
from sklearn.datasets import make_classification
import matplotlib.pyplot as plt

X, y = make_classification(random_state=0)
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=42)

svc = SVC(random_state=42)
svc.fit(X_train, y_train)

rfc = RandomForestClassifier(random_state=42)
rfc.fit(X_train, y_train)

svc_disp = plot_roc_curve(svc, X_test, y_test)
rfc_disp = plot_roc_curve(rfc, X_test, y_test, ax=svc_disp.ax_)
rfc_disp.figure_.suptitle("ROC curve comparison")

plt.show()
```
Stacking Classifier and Regressor

StackingClassifier and StackingRegressor allow you to have a stack of estimators with a final classifier or a regressor. Stacked generalization consists in stacking the output of individual estimators and use a classifier to compute the final prediction. Stacking allows to use the strength of each individual estimator by using their output as input of a final estimator. Base estimators are fitted on the full $X$ while the final estimator is trained using cross-validated predictions of the base estimators using cross_val_predict.

Read more in the User Guide.

```python
from sklearn.datasets import load_iris
from sklearn.svm import LinearSVC
from sklearn.linear_model import LogisticRegression
from sklearn.preprocessing import StandardScaler
from sklearn.pipeline import make_pipeline
from sklearn.ensemble import StackingClassifier
from sklearn.model_selection import train_test_split

X, y = load_iris(return_X_y=True)
estimators = [
    ('rf', RandomForestClassifier(n_estimators=10, random_state=42)),
    ('svr', make_pipeline(StandardScaler(), LinearSVC(random_state=42)))
]  
```
clf = StackingClassifier(  
estimators=estimators, final_estimator=LogisticRegression()  
)  
X_train, X_test, y_train, y_test = train_test_split(  
    X, y, stratify=y, random_state=42  
)  
clf.fit(X_train, y_train).score(X_test, y_test)

Out:

0.9473684210526315

Permutation-based feature importance

The `inspection.permutation_importance` can be used to get an estimate of the importance of each feature, for any fitted estimator:

```python
import numpy as np
import matplotlib.pyplot as plt
from sklearn.datasets import make_classification
from sklearn.ensemble import RandomForestClassifier
from sklearn.inspection import permutation_importance

X, y = make_classification(random_state=0, n_features=5, n_informative=3)
feature_names = np.array([f'x_{i}' for i in range(X.shape[1])])

rf = RandomForestClassifier(random_state=0).fit(X, y)
result = permutation_importance(rf, X, y, n_repeats=10, random_state=0, n_jobs=-1)

fig, ax = plt.subplots()
sorted_idx = result.importances_mean.argsort()
ax.boxplot(result.importances[sorted_idx].T, vert=False, labels=feature_names[sorted_idx])
ax.set_title("Permutation Importance of each feature")
ax.set_ylabel("Features")
fig.tight_layout()
plt.show()
```
Native support for missing values for gradient boosting

The `ensemble.HistGradientBoostingClassifier` and `ensemble.HistGradientBoostingRegressor` now have native support for missing values (NaNs). This means that there is no need for imputing data when training or predicting.

```python
from sklearn.experimental import enable_hist_gradient_boosting  # noqa
from sklearn.ensemble import HistGradientBoostingClassifier

X = np.array([0, 1, 2, np.nan]).reshape(-1, 1)
y = [0, 0, 1, 1]

gbdt = HistGradientBoostingClassifier(min_samples_leaf=1).fit(X, y)
print(gbdt.predict(X))
```

Out:

```
[0 0 1 1]
```
Precomputed sparse nearest neighbors graph

Most estimators based on nearest neighbors graphs now accept precomputed sparse graphs as input, to reuse the same graph for multiple estimator fits. To use this feature in a pipeline, one can use the `memory` parameter, along with one of the two new transformers, `neighbors.KNeighborsTransformer` and `neighbors.RadiusNeighborsTransformer`. The precomputation can also be performed by custom estimators to use alternative implementations, such as approximate nearest neighbors methods. See more details in the User Guide.

```python
from tempfile import TemporaryDirectory
from sklearn.neighbors import KNeighborsTransformer
from sklearn.manifold import Isomap
from sklearn.pipeline import make_pipeline

X, y = make_classification(random_state=0)

with TemporaryDirectory(prefix="sklearn_cache_") as tmpdir:
    estimator = make_pipeline(
        KNeighborsTransformer(n_neighbors=10, mode='distance'),
        Isomap(n_neighbors=10, metric='precomputed'),
        memory=tmpdir)
    estimator.fit(X)

    # We can decrease the number of neighbors and the graph will not be recomputed.
    estimator.set_params(isomap__n_neighbors=5)
    estimator.fit(X)
```

KNN Based Imputation

We now support imputation for completing missing values using k-Nearest Neighbors.

Each sample's missing values are imputed using the mean value from `n_neighbors` nearest neighbors found in the training set. Two samples are close if the features that neither is missing are close. By default, a euclidean distance metric that supports missing values, `nan_euclidean_distances`, is used to find the nearest neighbors.

Read more in the User Guide.

```python
from sklearn.impute import KNNImputer

X = [[1, 2, np.nan], [3, 4, 3], [np.nan, 6, 5], [8, 8, 7]]
imputer = KNNImputer(n_neighbors=2)
print(imputer.fit_transform(X))
```

Out:

```
[[1. 2. 4.]
 [3. 4. 3.]
 [5.5 6. 5.]
 [8. 8. 7.]]
```
### Tree pruning

It is now possible to prune most tree-based estimators once the trees are built. The pruning is based on minimal cost-complexity. Read more in the *User Guide* for details.

```python
X, y = make_classification(random_state=0)
rf = RandomForestClassifier(random_state=0, ccp_alpha=0).fit(X, y)
print("Average number of nodes without pruning {:.1f}".format(
    np.mean([e.tree_.node_count for e in rf.estimators_])))

rf = RandomForestClassifier(random_state=0, ccp_alpha=0.05).fit(X, y)
print("Average number of nodes with pruning {:.1f}".format(
    np.mean([e.tree_.node_count for e in rf.estimators_])))
```

Out:
```
Average number of nodes without pruning 22.3
Average number of nodes with pruning 6.4
```

### Retrieve dataframes from OpenML

*datasets.fetch_openml* can now return pandas dataframe and thus properly handle datasets with heterogeneous data:

```python
from sklearn.datasets import fetch_openml
titanic = fetch_openml('titanic', version=1, as_frame=True)
print(titanic.data.head()[['pclass', 'embarked']])
```

Out:
```
pclass embarked
 0  1.0   S
 1  1.0   S
 2  1.0   S
 3  1.0   S
 4  1.0   S
```

### Checking scikit-learn compatibility of an estimator

Developers can check the compatibility of their scikit-learn compatible estimators using *check_estimator*. For instance, the `check_estimator(LinearSVC())` passes.

We now provide a pytest specific decorator which allows pytest to run all checks independently and report the checks that are failing.

```
..note:: This entry was slightly updated in version 0.24, where passing classes isn’t supported anymore: pass instances instead.
```

```python
from sklearn.linear_model import LogisticRegression
from sklearn.tree import DecisionTreeRegressor
from sklearn.utils.estimator_checks import parametrize_with_checks
```

(continues on next page)
ROC AUC now supports multiclass classification

The `roc_auc_score` function can also be used in multi-class classification. Two averaging strategies are currently supported: the one-vs-one algorithm computes the average of the pairwise ROC AUC scores, and the one-vs-rest algorithm computes the average of the ROC AUC scores for each class against all other classes. In both cases, the multiclass ROC AUC scores are computed from the probability estimates that a sample belongs to a particular class according to the model. The OvO and OvR algorithms support weighting uniformly (average='macro') and weighting by the prevalence (average='weighted').

Read more in the User Guide.

```python
from sklearn.datasets import make_classification
from sklearn.svm import SVC
from sklearn.metrics import roc_auc_score

X, y = make_classification(n_classes=4, n_informative=16)
clf = SVC(decision_function_shape='ovo', probability=True).fit(X, y)
print(roc_auc_score(y, clf.predict_proba(X), multi_class='ovo'))
```

Out:

```
0.9956
```

Total running time of the script: 0 minutes 2.110 seconds

### 6.3 Biclustering

Examples concerning the `sklearn.cluster.bicluster` module.

#### 6.3.1 A demo of the Spectral Co-Clustering algorithm

This example demonstrates how to generate a dataset and bicluster it using the Spectral Co-Clustering algorithm.

The dataset is generated using the `make_biclusters` function, which creates a matrix of small values and implants bicluster with large values. The rows and columns are then shuffled and passed to the Spectral Co-Clustering algorithm. Rearranging the shuffled matrix to make biclusters contiguous shows how accurately the algorithm found the biclusters.
from sklearn.datasets import make_biclusters
from sklearn.cluster import SpectralCoclustering
from sklearn.metrics import consensus_score

data, rows, columns = make_biclusters(
    shape=(300, 300), n_clusters=5, noise=5,
    shuffle=False, random_state=0)
plt.matshow(data, cmap=plt.cm.Blues)
plt.title("Original dataset")

# shuffle clusters
rng = np.random.RandomState(0)
row_idx = rng.permutation(data.shape[0])
col_idx = rng.permutation(data.shape[1])
data = data[row_idx][:, col_idx]

plt.matshow(data, cmap=plt.cm.Blues)
plt.title("Shuffled dataset")

model = SpectralCoclustering(n_clusters=5, random_state=0)
model.fit(data)
score = consensus_score(model.biclusters_,
                        {rows[:, row_idx], columns[:, col_idx]})

print("consensus score: {:.3f}"
      .format(score))

fit_data = data[np.argsort(model.row_labels_)]
fit_data = fit_data[:, np.argsort(model.column_labels_)]

plt.matshow(fit_data, cmap=plt.cm.Blues)
plt.title("After biclustering; rearranged to show biclusters")

plt.show()

Total running time of the script: ( 0 minutes 0.369 seconds)

6.3.2 A demo of the Spectral Biclustering algorithm

This example demonstrates how to generate a checkerboard dataset and bicluster it using the Spectral Biclustering algorithm.

The data is generated with the make_checkerboard function, then shuffled and passed to the Spectral Biclustering algorithm. The rows and columns of the shuffled matrix are rearranged to show the biclusters found by the algorithm. The outer product of the row and column label vectors shows a representation of the checkerboard structure.
Out:

consensus score: 1.0

print(__doc__)

# Author: Kemal Eren <kemal@kemaleren.com>
# License: BSD 3 clause

import numpy as np
from matplotlib import pyplot as plt

from sklearn.datasets import make_checkerboard
from sklearn.cluster import SpectralBiclustering
from sklearn.metrics import consensus_score

n_clusters = (4, 3)
data, rows, columns = make_checkerboard(
    shape=(300, 300), n_clusters=n_clusters, noise=10,
shuffle=False, random_state=0)

plt.matshow(data, cmap=pl.cm.Blues)
plt.title("Original dataset")

# shuffle clusters
rng = np.random.RandomState(0)
row_idx = rng.permutation(data.shape[0])
col_idx = rng.permutation(data.shape[1])
data = data[row_idx][:, col_idx]

plt.matshow(data, cmap=pl.cm.Blues)
plt.title("Shuffled dataset")

model = SpectralBiclustering(n_clusters=n_clusters, method='log',
random_state=0)
model.fit(data)
score = consensus_score(model.biclusters_,
(rows[:, row_idx], columns[:, col_idx]))

print("consensus score: {:.1f}".format(score))

fit_data = data[np.argsort(model.row_labels_)]
fit_data = fit_data[:, np.argsort(model.column_labels_)]

plt.matshow(fit_data, cmap=pl.cm.Blues)
plt.title("After biclustering; rearranged to show biclusters")

plt.matshow(np.outer(np.sort(model.row_labels_) + 1,
np.sort(model.column_labels_) + 1),
cmap=pl.cm.Blues)
plt.title("Checkerboard structure of rearranged data")

plt.show()

Total running time of the script: ( 0 minutes 0.667 seconds)

6.3.3 Biclustering documents with the Spectral Co-clustering algorithm

This example demonstrates the Spectral Co-clustering algorithm on the twenty newsgroups dataset. The ‘comp.os.ms-
windows.misc’ category is excluded because it contains many posts containing nothing but data.

The TF-IDF vectorized posts form a word frequency matrix, which is then biclustered using Dhillon’s Spectral Co-
Clustering algorithm. The resulting document-word biclusters indicate subsets words used more often in those subsets
documents.

For a few of the best biclusters, its most common document categories and its ten most important words get printed.
The best biclusters are determined by their normalized cut. The best words are determined by comparing their sums
inside and outside the bicluster.

For comparison, the documents are also clustered using MiniBatchKMeans. The document clusters derived from the
biclusters achieve a better V-measure than clusters found by MiniBatchKMeans.

Out:
Vectorizing...
Coclustering...
Done in 1.61s. V-measure: 0.4431
MiniBatchKMeans...
Done in 4.83s. V-measure: 0.3344

6.3. Biclustering 727
6.4 Calibration

Examples illustrating the calibration of predicted probabilities of classifiers.

6.4.1 Comparison of Calibration of Classifiers

Well calibrated classifiers are probabilistic classifiers for which the output of the predict_proba method can be directly interpreted as a confidence level. For instance a well calibrated (binary) classifier should classify the samples such that among the samples to which it gave a predict_proba value close to 0.8, approx. 80% actually belong to the positive class.

LogisticRegression returns well calibrated predictions as it directly optimizes log-loss. In contrast, the other methods return biased probabilities, with different biases per method:

- GaussianNaiveBayes tends to push probabilities to 0 or 1 (note the counts in the histograms). This is mainly because it makes the assumption that features are conditionally independent given the class, which is not the case in this dataset which contains 2 redundant features.

- RandomForestClassifier shows the opposite behavior: the histograms show peaks at approx. 0.2 and 0.9 probability, while probabilities close to 0 or 1 are very rare. An explanation for this is given by Niculescu-Mizil and Caruana¹: “Methods such as bagging and random forests that average predictions from a base set of models can have difficulty making predictions near 0 and 1 because variance in the underlying base models will bias predictions that should be near zero or one away from these values. Because predictions are restricted to the interval [0,1], errors caused by variance tend to be one-sided near zero and one. For example, if a model should predict p = 0 for a case, the only way bagging can achieve this is if all bagged trees predict zero. If we add noise to the trees that bagging is averaging over, this noise will cause some trees to predict values larger than 0 for this case, thus moving the average prediction of the bagged ensemble away from 0. We observe this effect most strongly with random forests because the base-level trees trained with random forests have relatively high variance due to feature subsetting.” As a result, the calibration curve shows a characteristic sigmoid shape, indicating that the classifier could trust its “intuition” more and return probabilities closer to 0 or 1 typically.

- Support Vector Classification (SVC) shows an even more sigmoid curve as the RandomForestClassifier, which is typical for maximum-margin methods (compare Niculescu-Mizil and Caruana¹), which focus on hard samples that are close to the decision boundary (the support vectors).

Chapter 6. Examples


6.4.2 Probability Calibration curves

When performing classification one often wants to predict not only the class label, but also the associated probability. This probability gives some kind of confidence on the prediction. This example demonstrates how to display how well calibrated the predicted probabilities are and how to calibrate an uncalibrated classifier.

The experiment is performed on an artificial dataset for binary classification with 100,000 samples (1,000 of them are used for model fitting) with 20 features. Of the 20 features, only 2 are informative and 10 are redundant. The first figure shows the estimated probabilities obtained with logistic regression, Gaussian naive Bayes, and Gaussian naive Bayes with both isotonic calibration and sigmoid calibration. The calibration performance is evaluated with Brier score, reported in the legend (the smaller the better). One can observe here that logistic regression is well calibrated while raw Gaussian naive Bayes performs very badly. This is because of the redundant features which violate the assumption of feature-independence and result in an overly confident classifier, which is indicated by the typical transposed-sigmoid curve.

Calibration of the probabilities of Gaussian naive Bayes with isotonic regression can fix this issue as can be seen from the nearly diagonal calibration curve. Sigmoid calibration also improves the brier score slightly, albeit not as strongly as the non-parametric isotonic regression. This can be attributed to the fact that we have plenty of calibration data such that the greater flexibility of the non-parametric model can be exploited.

The second figure shows the calibration curve of a linear support-vector classifier (LinearSVC). LinearSVC shows the opposite behavior as Gaussian naive Bayes: the calibration curve has a sigmoid curve, which is typical for an under-confident classifier. In the case of LinearSVC, this is caused by the margin property of the hinge loss, which lets the model focus on hard samples that are close to the decision boundary (the support vectors).

Both kinds of calibration can fix this issue and yield nearly identical results. This shows that sigmoid calibration can deal with situations where the calibration curve of the base classifier is sigmoid (e.g., for LinearSVC) but not where it is transposed-sigmoid (e.g., Gaussian naive Bayes).

6.4.3 Probability calibration of classifiers

When performing classification you often want to predict not only the class label, but also the associated probability. This probability gives you some kind of confidence on the prediction. However, not all classifiers provide well-calibrated probabilities, some being over-confident while others being under-confident. Thus, a separate calibration of predicted probabilities is often desirable as a postprocessing. This example illustrates two different methods for this calibration and evaluates the quality of the returned probabilities using Brier’s score (see https://en.wikipedia.org/wiki/Brier_score).

Compared are the estimated probability using a Gaussian naive Bayes classifier without calibration, with a sigmoid calibration, and with a non-parametric isotonic calibration. One can observe that only the non-parametric model is able to provide a probability calibration that returns probabilities close to the expected 0.5 for most of the samples belonging to the middle cluster with heterogeneous labels. This results in a significantly improved Brier score.

Probability Calibration for 3-class classification

This example illustrates how sigmoid calibration changes predicted probabilities for a 3-class classification problem. Illustrated is the standard 2-simplex, where the three corners correspond to the three classes. Arrows point from the probability vectors predicted by an uncalibrated classifier to the probability vectors predicted by the same classifier after sigmoid calibration on a hold-out validation set. Colors indicate the true class of an instance (red: class 1, green: class 2, blue: class 3).

The base classifier is a random forest classifier with 25 base estimators (trees). If this classifier is trained on all 800 training datapoints, it is overly confident in its predictions and thus incurs a large log-loss. Calibrating an identical classifier, which was trained on 600 datapoints, with method='sigmoid' on the remaining 200 datapoints reduces the confidence of the predictions, i.e., moves the probability vectors from the edges of the simplex towards the center. This calibration results in a lower log-loss. Note that an alternative would have been to increase the number of base estimators which would have resulted in a similar decrease in log-loss.

6.5 Classification

General examples about classification algorithms.

6.5.1 Recognizing hand-written digits

This example shows how scikit-learn can be used to recognize images of hand-written digits, from 0-9.

from sklearn import datasets, svm, metrics
from sklearn.model_selection import train_test_split

Digits dataset

The digits dataset consists of 8x8 pixel images of digits. The images attribute of the dataset stores 8x8 arrays of grayscale values for each image. We will use these arrays to visualize the first 4 images. The target attribute of the dataset stores the digit each image represents and this is included in the title of the 4 plots below.

Note: if we were working from image files (e.g., ‘png’ files), we would load them using matplotlib.pyplot.imread.

digits = datasets.load_digits()

_, axes = plt.subplots(nrows=1, ncols=4, figsize=(10, 3))
for ax, image, label in zip(axes, digits.images, digits.target):
    ax.set_axis_off()
Classification

To apply a classifier on this data, we need to flatten the images, turning each 2-D array of grayscale values from shape (8, 8) into shape (64,). Subsequently, the entire dataset will be of shape (n_samples, n_features), where n_samples is the number of images and n_features is the total number of pixels in each image.

We can then split the data into train and test subsets and fit a support vector classifier on the train samples. The fitted classifier can subsequently be used to predict the value of the digit for the samples in the test subset.

```python
# flatten the images
data = digits.images.reshape((n_samples, -1))

# Create a classifier: a support vector classifier
clf = svm.SVC(gamma=0.001)

# Split data into 50% train and 50% test subsets
X_train, X_test, y_train, y_test = train_test_split(data, digits.target, test_size=0.5, shuffle=False)

# Learn the digits on the train subset
clf.fit(X_train, y_train)

# Predict the value of the digit on the test subset
predicted = clf.predict(X_test)
```

Below we visualize the first 4 test samples and show their predicted digit value in the title.

```python
for ax, image, prediction in zip(axes, digits.images, predicted):
    ax.set_axis_off()
    ax.imshow(image, cmap=plt.cm.gray_r, interpolation='nearest')
    ax.set_title(f'Prediction: {prediction}')
```
classification_report builds a text report showing the main classification metrics.

```python
print(f"Classification report for classifier {clf}:

{metrics.classification_report(y_test, predicted)}")
```

Out:

```
Classification report for classifier SVC(gamma=0.001):

6.5.2 Normal, Ledoit-Wolf and OAS Linear Discriminant Analysis for classification

This example illustrates how the Ledoit-Wolf and Oracle Shrinkage Approximating (OAS) estimators of covariance can improve classification.

```python
import numpy as np
import matplotlib.pyplot as plt
from sklearn.datasets import make_blobs
from sklearn.discriminant_analysis import LinearDiscriminantAnalysis
from sklearn.covariance import OAS

n_train = 20  # samples for training
n_test = 200  # samples for testing
n_averages = 50  # how often to repeat classification
n_features_max = 75  # maximum number of features
step = 4  # step size for the calculation

def generate_data(n_samples, n_features):
    """Generate random blob-ish data with noisy features.

    This returns an array of input data with shape `(n_samples, n_features)`
    and an array of `n_samples` target labels.
    """
```

(continues on next page)
Only one feature contains discriminative information, the other features contain only noise.

```
X, y = make_blobs(n_samples=n_samples, n_features=1, centers=[[-2], [2]])

# add non-discriminative features
if n_features > 1:
    X = np.hstack([X, np.random.randn(n_samples, n_features - 1)])
return X, y
```

```
acc_clf1, acc_clf2, acc_clf3 = [], [], []
n_features_range = range(1, n_features_max + 1, step)
for n_features in n_features_range:
    score_clf1, score_clf2, score_clf3 = 0, 0, 0
    for _ in range(n_averages):
        X, y = generate_data(n_train, n_features)
        clf1 = LinearDiscriminantAnalysis(solver='lsqr',
                                          shrinkage='auto').fit(X, y)
        clf2 = LinearDiscriminantAnalysis(solver='lsqr',
                                          shrinkage=None).fit(X, y)
        oa = OAS(store_precision=False, assume_centered=False)
        clf3 = LinearDiscriminantAnalysis(solver='lsqr',
                                           covariance_estimator=oa).fit(X, y)
        X, y = generate_data(n_test, n_features)
        score_clf1 += clf1.score(X, y)

6.5.3 Plot classification probability

Plot the classification probability for different classifiers. We use a 3 class dataset, and we classify it with a Support Vector classifier, L1 and L2 penalized logistic regression with either a One-Vs-Rest or multinomial setting, and Gaussian process classification.

Linear SVC is not a probabilistic classifier by default but it has a built-in calibration option enabled in this example (probability=True).

The logistic regression with One-Vs-Rest is not a multiclass classifier out of the box. As a result it has more trouble in separating class 2 and 3 than the other estimators.
Accuracy (train) for L1 logistic: 83.3%
Accuracy (train) for L2 logistic (Multinomial): 82.7%
Accuracy (train) for L2 logistic (OvR): 79.3%
Accuracy (train) for Linear SVC: 82.0%
Accuracy (train) for GPC: 82.7%

# Create different classifiers.
classifiers = {
    'L1 logistic': LogisticRegression(C=C, penalty='l1',
                                      solver='saga',
                                      multi_class='multinomial',
                                      max_iter=10000),
    'L2 logistic (Multinomial)': LogisticRegression(C=C, penalty='l2',
                                                    solver='saga',
                                                    multi_class='multinomial',
                                                    max_iter=10000),
    'L2 logistic (OvR)': LogisticRegression(C=C, penalty='l2',
                                             solver='saga',
                                             multi_class='ovr',
                                             max_iter=10000),
    'Linear SVC': SVC(kernel='linear', C=C, probability=True,
                       random_state=0),
    'GPC': GaussianProcessClassifier(kernel)
}
n_classifiers = len(classifiers)
A comparison of several classifiers in scikit-learn on synthetic datasets. The point of this example is to illustrate
the nature of decision boundaries of different classifiers. This should be taken with a grain of salt, as the intuition
conveyed by these examples does not necessarily carry over to real datasets.

Particularly in high-dimensional spaces, data can more easily be separated linearly and the simplicity of classifiers
such as naive Bayes and linear SVMs might lead to better generalization than is achieved by other classifiers.

The plots show training points in solid colors and testing points semi-transparent. The lower right shows the classifi-
cation accuracy on the test set.

## 6.6 Clustering

Examples concerning the `sklearn.cluster` module.
6.6.1 Plot Hierarchical Clustering Dendrogram

This example plots the corresponding dendrogram of a hierarchical clustering using AgglomerativeClustering and the dendrogram method available in scipy.

```python
import numpy as np
from matplotlib import pyplot as plt
from scipy.cluster.hierarchy import dendrogram
from sklearn.datasets import load_iris
from sklearn.cluster import AgglomerativeClustering

def plot_dendrogram(model, **kwargs):
    # Create linkage matrix and then plot the dendrogram

    # create the counts of samples under each node
    counts = np.zeros(model.children_.shape[0])
    n_samples = len(model.labels_)
    for i, merge in enumerate(model.children_):
        current_count = 0
        for child_idx in merge:
            if child_idx < n_samples:
                current_count += 1  # leaf node
            else:
                current_count += counts[child_idx]
        counts[i] = current_count

    indices = np.arange(model.n_samples, dtype=int)
    if 'colorbar' not in kwargs:
        kwargs['colorbar'] = True
    dendrogram(model, labels=indices, orientation='left', **kwargs)

if __name__ == '__main__':
    iris = load_iris()
    X = iris.data
    model = AgglomerativeClustering(distance_threshold=1.0, n_clusters=3)
    model.fit(X)
    plot_dendrogram(model)
```

### 6.6.5 Online learning of a dictionary of parts of faces

This example uses a large dataset of faces to learn a set of 20 x 20 images patches that constitute faces.

From the programming standpoint, it is interesting because it shows how to use the online API of the scikit-learn to process a very large dataset by chunks. The way we proceed is that we load an image at a time and extract randomly 50 patches from this image. Once we have accumulated 500 of these patches (using 10 images), we run the `partial_fit` method of the online KMeans object, MiniBatchKMeans.

The verbose setting on the MiniBatchKMeans enables us to see that some clusters are reassigned during the successive calls to partial-fit. This is because the number of patches that they represent has become too low, and it is better to choose a random new cluster.
Patches of faces
Train time 1.5s on 3200 patches

6.6.8 Agglomerative clustering with and without structure

This example shows the effect of imposing a connectivity graph to capture local structure in the data. The graph is simply the graph of 20 nearest neighbors.

Two consequences of imposing a connectivity can be seen. First clustering with a connectivity matrix is much faster. Second, when using a connectivity matrix, single, average and complete linkage are unstable and tend to create a few clusters that grow very quickly. Indeed, average and complete linkage fight this percolation behavior by considering all the distances between two clusters when merging them (while single linkage exaggerates the behavior by considering only the shortest distance between clusters). The connectivity graph breaks this mechanism for average and complete linkage, making them resemble the more brittle single linkage. This effect is more pronounced for very sparse graphs (try decreasing the number of neighbors in kneighbors_graph) and with complete linkage. In particular, having a very small number of neighbors in the graph, imposes a geometry that is close to that of single linkage, which is well known to have this percolation instability.
import time
import matplotlib.pyplot as plt
import numpy as np
from sklearn.cluster import AgglomerativeClustering
from sklearn.neighbors import kneighbors_graph

# Generate sample data
n_samples = 1500
np.random.seed(0)

6.6.9 Various Agglomerative Clustering on a 2D embedding of digits

An illustration of various linkage option for agglomerative clustering on a 2D embedding of the digits dataset.

The goal of this example is to show intuitively how the metrics behave, and not to find good clusters for the digits. This is why we work on a 2D embedding.

What this example shows us is the behavior “rich getting richer” of agglomerative clustering that tends to create uneven cluster sizes. This behavior is pronounced for the average linkage strategy, that ends up with a couple of singleton clusters, while in the case of single linkage we get a single central cluster with all other clusters being drawn from noise points around the fringes.

6.6.10 Segmenting the picture of greek coins in regions

This example uses Spectral clustering on a graph created from voxel-to-voxel difference on an image to break this image into multiple partly-homogeneous regions.

This procedure (spectral clustering on an image) is an efficient approximate solution for finding normalized graph cuts.

There are two options to assign labels:

- with ‘kmeans’ spectral clustering will cluster samples in the embedding space using a kmeans algorithm
- whereas ‘discrete’ will iteratively search for the closest partition space to the embedding space.

### 6.6.11 K-means Clustering

The plots display firstly what a K-means algorithm would yield using three clusters. It is then shown what the effect of a bad initialization is on the classification process: By setting n_init to only 1 (default is 10), the amount of times that the algorithm will be run with different centroid seeds is reduced. The next plot displays what using eight clusters would deliver and finally the ground truth.

6.6.12 Spectral clustering for image segmentation

In this example, an image with connected circles is generated and spectral clustering is used to separate the circles.

In these settings, the **Spectral clustering** approach solves the problem known as ‘normalized graph cuts’: the image is seen as a graph of connected voxels, and the spectral clustering algorithm amounts to choosing graph cuts defining regions while minimizing the ratio of the gradient along the cut, and the volume of the region.

As the algorithm tries to balance the volume (i.e., balance the region sizes), if we take circles with different sizes, the segmentation fails.

In addition, as there is no useful information in the intensity of the image, or its gradient, we choose to perform the spectral clustering on a graph that is only weakly informed by the gradient. This is close to performing a Voronoi partition of the graph.

In addition, we use the mask of the objects to restrict the graph to the outline of the objects. In this example, we are interested in separating the objects one from the other, and not from the background.
```python
import numpy as np
import matplotlib.pyplot as plt
from sklearn.feature_extraction import image
from sklearn.cluster import spectral_clustering

l = 100
x, y = np.indices((l, l))

center1 = (28, 24)
center2 = (40, 50)
center3 = (67, 58)
center4 = (24, 70)

radius1, radius2, radius3, radius4 = 16, 14, 15, 14

circle1 = (x - center1[0]) ** 2 + (y - center1[1]) ** 2 < radius1 ** 2
circle2 = (x - center2[0]) ** 2 + (y - center2[1]) ** 2 < radius2 ** 2
circle3 = (x - center3[0]) ** 2 + (y - center3[1]) ** 2 < radius3 ** 2
```

(continues on next page)
circle4 = (x - center4[0]) ** 2 + (y - center4[1]) ** 2 < radius4 ** 2

# 4 circles
img = circle1 + circle2 + circle3 + circle4

# We use a mask that limits to the foreground: the problem that we are
# interested in here is not separating the objects from the background,
# but separating them one from the other.
mask = img.astype(bool)

img = img.astype(float)
img += 1 + 0.2 * np.random.randn(*img.shape)

# Convert the image into a graph with the value of the gradient on the
# edges.
graph = image.img_to_graph(img, mask=mask)

# Take a decreasing function of the gradient: we take it weakly
# dependent from the gradient the segmentation is close to a voronoi
graph.data = np.exp(-graph.data / graph.data.std())

# Force the solver to be arpack, since amg is numerically
# unstable on this example
labels = spectral_clustering(graph, n_clusters=4, eigen_solver='arpack')
label_im = np.full(mask.shape, -1.)
label_im[mask] = labels

plt.matshow(img)
plt.matshow(label_im)

# 2 circles
img = circle1 + circle2
mask = img.astype(bool)
img = img.astype(float)

img += 1 + 0.2 * np.random.randn(*img.shape)

6.6.15 Color Quantization using K-Means

Performs a pixel-wise Vector Quantization (VQ) of an image of the summer palace (China), reducing the number of colors required to show the image from 96,615 unique colors to 64, while preserving the overall appearance quality.

In this example, pixels are represented in a 3D-space and K-means is used to find 64 color clusters. In the image processing literature, the codebook obtained from K-means (the cluster centers) is called the color palette. Using a single byte, up to 256 colors can be addressed, whereas an RGB encoding requires 3 bytes per pixel. The GIF file format, for example, uses such a palette.

For comparison, a quantized image using a random codebook (colors picked up randomly) is also shown.

Original image (96,615 colors)
Quantized image (64 colors, K-Means)
Quantized image (64 colors, Random)

### 6.6.16 Hierarchical clustering: structured vs unstructured ward

Example builds a swiss roll dataset and runs hierarchical clustering on their position.

For more information, see *Hierarchical clustering*.

In a first step, the hierarchical clustering is performed without connectivity constraints on the structure and is solely based on distance, whereas in a second step the clustering is restricted to the k-Nearest Neighbors graph: it’s a hierarchical clustering with structure prior.

Some of the clusters learned without connectivity constraints do not respect the structure of the swiss roll and extend across different folds of the manifolds. On the opposite, when opposing connectivity constraints, the clusters form a nice parcellation of the swiss roll.

6.6.17 Agglomerative clustering with different metrics

Demonstrates the effect of different metrics on the hierarchical clustering.

The example is engineered to show the effect of the choice of different metrics. It is applied to waveforms, which can be seen as high-dimensional vector. Indeed, the difference between metrics is usually more pronounced in high dimension (in particular for euclidean and cityblock).

We generate data from three groups of waveforms. Two of the waveforms (waveform 1 and waveform 2) are proportional one to the other. The cosine distance is invariant to a scaling of the data, as a result, it cannot distinguish these two waveforms. Thus even with no noise, clustering using this distance will not separate out waveform 1 and 2.

We add observation noise to these waveforms. We generate very sparse noise: only 6% of the time points contain noise. As a result, the 11 norm of this noise (ie “cityblock” distance) is much smaller than it’s 12 norm (“euclidean” distance). This can be seen on the inter-class distance matrices: the values on the diagonal, that characterize the spread of the class, are much bigger for the Euclidean distance than for the cityblock distance.

When we apply clustering to the data, we find that the clustering reflects what was in the distance matrices. Indeed, for the Euclidean distance, the classes are ill-separated because of the noise, and thus the clustering does not separate the waveforms. For the cityblock distance, the separation is good and the waveform classes are recovered. Finally, the cosine distance does not separate at all waveform 1 and 2, thus the clustering puts them in the same cluster.

### 6.6.18 Inductive Clustering

Clustering can be expensive, especially when our dataset contains millions of datapoints. Many clustering algorithms are not inductive and so cannot be directly applied to new data samples without recomputing the clustering, which may be intractable. Instead, we can use clustering to then learn an inductive model with a classifier, which has several benefits:

- it allows the clusters to scale and apply to new data
- unlike re-fitting the clusters to new samples, it makes sure the labelling procedure is consistent over time
- it allows us to use the inferential capabilities of the classifier to describe or explain the clusters

This example illustrates a generic implementation of a meta-estimator which extends clustering by inducing a classifier from the cluster labels.

```python

### 6.6.19 Demo of OPTICS clustering algorithm

Finds core samples of high density and expands clusters from them. This example uses data that is generated so that the clusters have different densities. The OPTICS is first used with its XI cluster detection method, and then setting specific thresholds on the reachability, which corresponds to DBSCAN. We can see that the different clusters of OPTICS’s XI method can be recovered with different choices of thresholds in DBSCAN.
from sklearn.cluster import OPTICS, cluster_optics_dbscan
import matplotlib.gridspec as gridspec
import matplotlib.pyplot as plt
import numpy as np

# Generate sample data

6.6.20 Compare BIRCH and MiniBatchKMeans

This example compares the timing of Birch (with and without the global clustering step) and MiniBatchKMeans on a synthetic dataset having 100,000 samples and 2 features generated using make_blobs.

If `n_clusters` is set to None, the data is reduced from 100,000 samples to a set of 158 clusters. This can be viewed as a preprocessing step before the final (global) clustering step that further reduces these 158 clusters to 100 clusters.

```
Birch without global clustering as the final step took 2.90 seconds
n_clusters : 158
Birch with global clustering as the final step took 3.06 seconds
n_clusters : 100
Time taken to run MiniBatchKMeans 2.96 seconds
```

```

6.6.21 Empirical evaluation of the impact of k-means initialization

Evaluate the ability of k-means initializations strategies to make the algorithm convergence robust as measured by the relative standard deviation of the inertia of the clustering (i.e. the sum of squared distances to the nearest cluster center).

The first plot shows the best inertia reached for each combination of the model (KMeans or MiniBatchKMeans) and the init method (init="random" or init="kmeans++") for increasing values of the n_init parameter that controls the number of initializations.

The second plot demonstrate one single run of the MiniBatchKMeans estimator using a init="random" and n_init=1. This run leads to a bad convergence (local optimum) with estimated centers stuck between ground truth clusters.

The dataset used for evaluation is a 2D grid of isotropic Gaussian clusters widely spaced.

### 6.6.22 Adjustment for chance in clustering performance evaluation

The following plots demonstrate the impact of the number of clusters and number of samples on various clustering performance evaluation metrics. Non-adjusted measures such as the V-Measure show a dependency between the number of clusters and the number of samples: the mean V-Measure of random labeling increases significantly as the number of clusters is closer to the total number of samples used to compute the measure.

Adjusted for chance measure such as ARI display some random variations centered around a mean score of 0.0 for any number of samples and clusters.

Only adjusted measures can hence safely be used as a consensus index to evaluate the average stability of clustering algorithms for a given value of $k$ on various overlapping sub-samples of the dataset.

6.6.23 Comparison of the K-Means and MiniBatchKMeans clustering algorithms

We want to compare the performance of the MiniBatchKMeans and KMeans: the MiniBatchKMeans is faster, but
gives slightly different results (see Mini Batch K-Means).

We will cluster a set of data, first with KMeans and then with MiniBatchKMeans, and plot the results. We will also
plot the points that are labelled differently between the two algorithms.

```python
print(__doc__)

import time
import numpy as np
import matplotlib.pyplot as plt
from sklearn.cluster import MiniBatchKMeans, KMeans
from sklearn.metrics.pairwise import pairwise_distances_argmin
from sklearn.datasets import make_blobs

# #############################################################################
# Generate sample data
np.random.seed(0)

batch_size = 45
centers = [[1, 1], [-1, -1], [1, -1]]
n_clusters = len(corners)
X, labels_true = make_blobs(n_samples=3000, centers=centers, cluster_std=0.7)

# #############################################################################
# Compute clustering with Means
k_means = KMeans(init='k-means++', n_clusters=3, n_init=10)
t0 = time.time()
k_means.fit(X)
t_train = time.time() - t0

# #############################################################################
# Compute clustering with MiniBatchKMeans
mbk = MiniBatchKMeans(init='k-means++', n_clusters=3, batch_size=batch_size,
                       n_init=10, max_no_improvement=10, verbose=0)
```

### 6.6.24 Feature agglomeration vs. univariate selection

This example compares 2 dimensionality reduction strategies:
- univariate feature selection with Anova
- feature agglomeration with Ward hierarchical clustering

Both methods are compared in a regression problem using a BayesianRidge as supervised estimator.

### 6.6.25 A demo of K-Means clustering on the handwritten digits data

In this example we compare the various initialization strategies for K-means in terms of runtime and quality of the results.

As the ground truth is known here, we also apply different cluster quality metrics to judge the goodness of fit of the cluster labels to the ground truth.

Cluster quality metrics evaluated (see *Clustering performance evaluation* for definitions and discussions of the metrics):

6.6.26 Comparing different hierarchical linkage methods on toy datasets

This example shows characteristics of different linkage methods for hierarchical clustering on datasets that are “interesting” but still in 2D.

The main observations to make are:

- single linkage is fast, and can perform well on non-globular data, but it performs poorly in the presence of noise.
- average and complete linkage perform well on cleanly separated globular clusters, but have mixed results otherwise.
- Ward is the most effective method for noisy data.

While these examples give some intuition about the algorithms, this intuition might not apply to very high dimensional data.

print(__doc__)

import time
import warnings
Generate datasets. We choose the size big enough to see the scalability of the algorithms, but not too big to avoid too long running times

```python
n_samples = 1500
noisy_circles = datasets.make_circles(n_samples=n_samples, factor=.5,
                                        noise=.05)

---

**Total running time of the script:** (0 minutes 2.417 seconds)
Silhouette analysis can be used to study the separation distance between the resulting clusters. The silhouette plot displays a measure of how close each point in one cluster is to points in the neighboring clusters and thus provides a way to assess parameters like number of clusters visually. This measure has a range of [-1, 1].

Silhouette coefficients (as these values are referred to as) near +1 indicate that the sample is far away from the neighboring clusters. A value of 0 indicates that the sample is on or very close to the decision boundary between two neighboring clusters and negative values indicate that those samples might have been assigned to the wrong cluster.

In this example the silhouette analysis is used to choose an optimal value for \( n\_clusters \). The silhouette plot shows that the \( n\_clusters \) value of 3, 5 and 6 are a bad pick for the given data due to the presence of clusters with below average silhouette scores and also due to wide fluctuations in the size of the silhouette plots. Silhouette analysis is more ambivalent in deciding between 2 and 4.

Also from the thickness of the silhouette plot the cluster size can be visualized. The silhouette plot for cluster 0 when \( n\_clusters \) is equal to 2, is bigger in size owing to the grouping of the 3 sub clusters into one big cluster. However when the \( n\_clusters \) is equal to 4, all the plots are more or less of similar thickness and hence are of similar sizes as can be also verified from the labelled scatter plot on the right.
For $n\_clusters = 2$ The average silhouette_score is : 0.7049787496083262
For $n\_clusters = 3$ The average silhouette_score is : 0.5882004012129721
For $n\_clusters = 4$ The average silhouette_score is : 0.6505186632729437
For $n\_clusters = 5$ The average silhouette_score is : 0.56376469026194
For $n\_clusters = 6$ The average silhouette_score is : 0.4504666294372765

6.6.28 Comparing different clustering algorithms on toy datasets

This example shows characteristics of different clustering algorithms on datasets that are “interesting” but still in 2D. With the exception of the last dataset, the parameters of each of these dataset-algorithm pairs has been tuned to produce good clustering results. Some algorithms are more sensitive to parameter values than others.

The last dataset is an example of a ‘null’ situation for clustering: the data is homogeneous, and there is no good clustering. For this example, the null dataset uses the same parameters as the dataset in the row above it, which represents a mismatch in the parameter values and the data structure.

While these examples give some intuition about the algorithms, this intuition might not apply to very high dimensional data.

6.7.2 Sparse inverse covariance estimation

Using the GraphicalLasso estimator to learn a covariance and sparse precision from a small number of samples.

To estimate a probabilistic model (e.g. a Gaussian model), estimating the precision matrix, that is the inverse covariance matrix, is as important as estimating the covariance matrix. Indeed a Gaussian model is parametrized by the precision matrix.

To be in favorable recovery conditions, we sample the data from a model with a sparse inverse covariance matrix. In addition, we ensure that the data is not too much correlated (limiting the largest coefficient of the precision matrix) and that there are no small coefficients in the precision matrix that cannot be recovered. In addition, with a small number of observations, it is easier to recover a correlation matrix rather than a covariance, thus we scale the time series.

Here, the number of samples is slightly larger than the number of dimensions, thus the empirical covariance is still invertible. However, as the observations are strongly correlated, the empirical covariance matrix is ill-conditioned and as a result its inverse—the empirical precision matrix—is very far from the ground truth.

If we use l2 shrinkage, as with the Ledoit-Wolf estimator, as the number of samples is small, we need to shrink a lot. As a result, the Ledoit-Wolf precision is fairly close to the ground truth precision, that is not far from being diagonal, but the off-diagonal structure is lost.

The l1-penalized estimator can recover part of this off-diagonal structure. It learns a sparse precision. It is not able to recover the exact sparsity pattern: it detects too many non-zero coefficients. However, the highest non-zero coefficients of the l1 estimated correspond to the non-zero coefficients in the ground truth. Finally, the coefficients of
the l1 precision estimate are biased toward zero: because of the penalty, they are all smaller than the corresponding ground truth value, as can be seen on the figure.

Note that, the color range of the precision matrices is tweaked to improve readability of the figure. The full range of values of the empirical precision is not displayed.

The alpha parameter of the GraphicalLasso setting the sparsity of the model is set by internal cross-validation in the GraphicalLassoCV. As can be seen on figure 2, the grid to compute the cross-validation score is iteratively refined in the neighborhood of the maximum.

6.7.3 Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood

When working with covariance estimation, the usual approach is to use a maximum likelihood estimator, such as the
`EmpiricalCovariance`. It is unbiased, i.e. it converges to the true (population) covariance when given many
observations. However, it can also be beneficial to regularize it, in order to reduce its variance; this, in turn, introduces
some bias. This example illustrates the simple regularization used in `Shrunk Covariance` estimators. In particular, it
focuses on how to set the amount of regularization, i.e. how to choose the bias-variance trade-off.

Here we compare 3 approaches:

- Setting the parameter by cross-validating the likelihood on three folds according to a grid of potential shrinkage
  parameters.

- A close formula proposed by Ledoit and Wolf to compute the asymptotically optimal regularization parameter
  (minimizing a MSE criterion), yielding the `LedoitWolf` covariance estimate.

- An improvement of the Ledoit-Wolf shrinkage, the `OAS`, proposed by Chen et al. Its convergence is significantly
  better under the assumption that the data are Gaussian, in particular for small samples.

To quantify estimation error, we plot the likelihood of unseen data for different values of the shrinkage parameter. We
also show the choices by cross-validation, or with the LedoitWolf and OAS estimates.

Note that the maximum likelihood estimate corresponds to no shrinkage, and thus performs poorly. The Ledoit-Wolf
estimate performs really well, as it is close to the optimal and is computational not costly. In this example, the OAS
estimate is a bit further away. Interestingly, both approaches outperform cross-validation, which is significantly most
computationally costly.

6.7.4 Robust covariance estimation and Mahalanobis distances relevance

This example shows covariance estimation with Mahalanobis distances on Gaussian distributed data.

For Gaussian distributed data, the distance of an observation \( x_i \) to the mode of the distribution can be computed using its Mahalanobis distance:

\[
d((\mu, \Sigma), x_i)^2 = (x_i - \mu)^T \Sigma^{-1} (x_i - \mu)
\]

where \( \mu \) and \( \Sigma \) are the location and the covariance of the underlying Gaussian distributions.

In practice, \( \mu \) and \( \Sigma \) are replaced by some estimates. The standard covariance maximum likelihood estimate (MLE) is very sensitive to the presence of outliers in the data set and therefore, the downstream Mahalanobis distances also are.

It would be better to use a robust estimator of covariance to guarantee that the estimation is resistant to “erroneous” observations in the dataset and that the calculated Mahalanobis distances accurately reflect the true organization of the observations.

The Minimum Covariance Determinant estimator (MCD) is a robust, high-breakdown point (i.e. it can be used to estimate the covariance matrix of highly contaminated datasets, up to \( \frac{n_{\text{samples}} - n_{\text{features}} - 1}{2} \) outliers) estimator of covariance.

The idea behind the MCD is to find \( \frac{n_{\text{samples}} + n_{\text{features}} + 1}{2} \) observations whose empirical covariance has the smallest determinant, yielding a “pure” subset of observations from which to compute standards estimates of location and covariance. The MCD was introduced by P.J.Rousseeuw in\(^1\).

This example illustrates how the Mahalanobis distances are affected by outlying data. Observations drawn from a contaminating distribution are not distinguishable from the observations coming from the real, Gaussian distribution when using standard covariance MLE based Mahalanobis distances. Using MCD-based Mahalanobis distances, the two populations become distinguishable. Associated applications include outlier detection, observation ranking and clustering.

**Note:** See also *Robust vs Empirical covariance estimate*

---

**References:**

Generate data

First, we generate a dataset of 125 samples and 2 features. Both features are Gaussian distributed with mean of 0 but feature 1 has a standard deviation equal to 2 and feature 2 has a standard deviation equal to 1. Next, 25 samples are replaced with Gaussian outlier samples where feature 1 has a standard deviation equal to 1 and feature 2 has a standard deviation equal to 7.

```python
import numpy as np

# for consistent results
np.random.seed(7)

n_samples = 125
n_outliers = 25
n_features = 2

# generate Gaussian data of shape (125, 2)
gen_cov = np.eye(n_features)
gen_cov[0, 0] = 2.
X = np.dot(np.random.randn(n_samples, n_features), gen_cov)
# add some outliers
outliers_cov = np.eye(n_features)
outliers_cov[np.arange(1, n_features), np.arange(1, n_features)] = 7.
X[-n_outliers:] = np.dot(np.random.randn(n_outliers, n_features), outliers_cov)
```

Comparison of results

Below, we fit MCD and MLE based covariance estimators to our data and print the estimated covariance matrices. Note that the estimated variance of feature 2 is much higher with the MLE based estimator (7.5) than that of the MCD robust estimator (1.2). This shows that the MCD based robust estimator is much more resistant to the outlier samples, which were designed to have a much larger variance in feature 2.

```python
import matplotlib.pyplot as plt
from sklearn.covariance import EmpiricalCovariance, MinCovDet

# fit a MCD robust estimator to data
robust_cov = MinCovDet().fit(X)
# fit a MLE estimator to data
emp_cov = EmpiricalCovariance().fit(X)
print('Estimated covariance matrix:
      MCD (Robust):
         \[
         \begin{bmatrix}
         3.26253567 & -0.0306695631e+03 \\
         -0.0306695631e+03 & 1.22747343e+00
         \end{bmatrix}
      \]
      MLE:
         \[
         \begin{bmatrix}
         3.23773583 & -0.24640578 \\
         -0.24640578 & 7.51963999
         \end{bmatrix}
      \]
```

To better visualize the difference, we plot contours of the Mahalanobis distances calculated by both methods. Notice that the robust MCD based Mahalanobis distances fit the inlier black points much better, whereas the MLE based distances are more influenced by the outlier red points.
Finally, we highlight the ability of MCD based Mahalanobis distances to distinguish outliers. We take the cubic root of the Mahalanobis distances, yielding approximately normal distributions (as suggested by Wilson and Hilferty\(^2\)), then

scikit-learn user guide, Release 0.24.dev0

plot the values of inlier and outlier samples with boxplots. The distribution of outlier samples is more separated from
the distribution of inlier samples for robust MCD based Mahalanobis distances.

Chapter 6. Examples


6.7.5 Robust vs Empirical covariance estimate

The usual covariance maximum likelihood estimate is very sensitive to the presence of outliers in the data set. In such a case, it would be better to use a robust estimator of covariance to guarantee that the estimation is resistant to “erroneous” observations in the data set.\(^1\)\(^2\)

Minimum Covariance Determinant Estimator

The Minimum Covariance Determinant estimator is a robust, high-breakdown point (i.e. it can be used to estimate the covariance matrix of highly contaminated datasets, up to \(n_{\text{samples}} - n_{\text{features}} - 1\) outliers) estimator of covariance. The idea is to find \(n_{\text{samples}} + n_{\text{features}} + 1\) observations whose empirical covariance has the smallest determinant, yielding a “pure” subset of observations from which to compute standards estimates of location and covariance. After a correction step aiming at compensating the fact that the estimates were learned from only a portion of the initial data, we end up with robust estimates of the data set location and covariance.

The Minimum Covariance Determinant estimator (MCD) has been introduced by P.J.Rousseeuw in\(^3\).

---

**Evaluation**

In this example, we compare the estimation errors that are made when using various types of location and covariance estimates on contaminated Gaussian distributed data sets:

- The mean and the empirical covariance of the full dataset, which break down as soon as there are outliers in the data set
- The robust MCD, that has a low error provided \( n_{\text{samples}} > 5n_{\text{features}} \)
- The mean and the empirical covariance of the observations that are known to be good ones. This can be considered as a "perfect" MCD estimation, so one can trust our implementation by comparing to this case.

6.8 Cross decomposition

Examples concerning the sklearn.cross_decomposition module.

6.8.1 Principal Component Regression vs Partial Least Squares Regression

This example compares Principal Component Regression (PCR) and Partial Least Squares Regression (PLS) on a toy dataset. Our goal is to illustrate how PLS can outperform PCR when the target is strongly correlated with some directions in the data that have a low variance.

PCR is a regressor composed of two steps: first, PCA is applied to the training data, possibly performing dimensionality reduction; then, a regressor (e.g. a linear regressor) is trained on the transformed samples. In PCA, the transformation is purely unsupervised, meaning that no information about the targets is used. As a result, PCR may perform poorly in some datasets where the target is strongly correlated with directions that have low variance. Indeed, the dimensionality reduction of PCA projects the data into a lower dimensional space where the variance of the projected data is greedily maximized along each axis. Despite them having the most predictive power on the target, the directions with a lower variance will be dropped, and the final regressor will not be able to leverage them.
PLS is both a transformer and a regressor, and it is quite similar to PCR: it also applies a dimensionality reduction to the samples before applying a linear regressor to the transformed data. The main difference with PCR is that the PLS transformation is supervised. Therefore, as we will see in this example, it does not suffer from the issue we just mentioned.

```python
print(__doc__)
```

### The data

We start by creating a simple dataset with two features. Before we even dive into PCR and PLS, we fit a PCA estimator to display the two principal components of this dataset, i.e. the two directions that explain the most variance in the data.

```python
import numpy as np
import matplotlib.pyplot as plt
from sklearn.decomposition import PCA
rng = np.random.RandomState(0)
n_samples = 500
cov = [[3, 3],
       [3, 4]]
X = rng.multivariate_normal(mean=[0, 0], cov=cov, size=n_samples)
pca = PCA(n_components=2).fit(X)
plt.scatter(X[:, 0], X[:, 1], alpha=.3, label='samples')
for i, (comp, var) in enumerate(zip(pca.components_, pca.explained_variance_)):
    comp = comp * var  # scale component by its variance explanation power
    plt.plot([0, comp[0]], [0, comp[1]], label=f'Component {i}', linewidth=5,
             color=f'C{i + 2}')
plt.gca().set(aspect='equal',
              title='2-dimensional dataset with principal components',
              xlabel='first feature', ylabel='second feature')
plt.legend()
plt.show()
```
For the purpose of this example, we now define the target $y$ such that it is strongly correlated with a direction that has a small variance. To this end, we will project $X$ onto the second component, and add some noise to it.

```python
y = X.dot(pca.components_[1]) + rng.normal(size=n_samples) / 2
fig, axes = plt.subplots(1, 2, figsize=(10, 3))
axes[0].scatter(X.dot(pca.components_[0]), y, alpha=.3)
axes[0].set(xlabel='Projected data onto first PCA component', ylabel='y')
axes[1].scatter(X.dot(pca.components_[1]), y, alpha=.3)
axes[1].set(xlabel='Projected data onto second PCA component', ylabel='y')
plt.tight_layout()
plt.show()
```
Projection on one component and predictive power

We now create two regressors: PCR and PLS, and for our illustration purposes we set the number of components to 1. Before feeding the data to the PCA step of PCR, we first standardize it, as recommended by good practice. The PLS estimator has built-in scaling capabilities.

For both models, we plot the projected data onto the first component against the target. In both cases, this projected data is what the regressors will use as training data.

```python
from sklearn.model_selection import train_test_split
from sklearn.pipeline import make_pipeline
from sklearn.linear_model import LinearRegression
from sklearn.preprocessing import StandardScaler
from sklearn.decomposition import PCA
from sklearn.cross_decomposition import PLSRegression

X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=rng)

pcr = make_pipeline(StandardScaler(), PCA(n_components=1), LinearRegression())
pcr.fit(X_train, y_train)

pls = PLSRegression(n_components=1)
pls.fit(X_train, y_train)

fig, axes = plt.subplots(1, 2, figsize=(10, 3))
axes[0].scatter(pca.transform(X_test), y_test, alpha=.3, label='ground truth')
axes[0].scatter(pca.transform(X_test), pcr.predict(X_test), alpha=.3, label='predictions')
axes[0].set(xlabel='Projected data onto first PCA component', ylabel='y', title='PCR / PCA')
axes[0].legend()

axes[1].scatter(pls.transform(X_test), y_test, alpha=.3, label='ground truth')
axes[1].scatter(pls.transform(X_test), pls.predict(X_test), alpha=.3, label='predictions')
axes[1].set(xlabel='Projected data onto first PLS component', ylabel='y', title='PLS')
axes[1].legend()
plt.tight_layout()
plt.show()
```

As expected, the unsupervised PCA transformation of PCR has dropped the second component, i.e. the direction with the lowest variance, despite it being the most predictive direction. This is because PCA is a completely unsupervised transformation, and results in the projected data having a low predictive power on the target.
On the other hand, the PLS regressor manages to capture the effect of the direction with the lowest variance, thanks to its use of target information during the transformation: it can recognize that this direction is actually the most predictive. We note that the first PLS component is negatively correlated with the target, which comes from the fact that the signs of eigenvectors are arbitrary.

We also print the R-squared scores of both estimators, which further confirms that PLS is a better alternative than PCR in this case. A negative R-squared indicates that PCR performs worse than a regressor that would simply predict the mean of the target.

```python
print(f"PCR r-squared {pcr.score(X_test, y_test):.3f}"
print(f"PLS r-squared {pls.score(X_test, y_test):.3f}"
```

Out:

```
PCR r-squared -0.026
PLS r-squared 0.658
```

As a final remark, we note that PCR with 2 components performs as well as PLS: this is because in this case, PCR was able to leverage the second component which has the most predictive power on the target.

```python
pca_2 = make_pipeline(PCA(n_components=2), LinearRegression())
pca_2.fit(X_train, y_train)
print(f"PCR r-squared with 2 components {pca_2.score(X_test, y_test):.3f}"
```

Out:

```
PCR r-squared with 2 components 0.673
```

Total running time of the script: (0 minutes 0.522 seconds)

### 6.8.2 Compare cross decomposition methods

Simple usage of various cross decomposition algorithms: - PLSCanonical - PLSRegression, with multivariate response, a.k.a. PLS2 - PLSRegression, with univariate response, a.k.a. PLS1 - CCA

Given 2 multivariate covarying two-dimensional datasets, X, and Y, PLS extracts the ‘directions of covariance’, i.e. the components of each datasets that explain the most shared variance between both datasets. This is apparent on the scatterplot matrix display: components 1 in dataset X and dataset Y are maximally correlated (points lie around the first diagonal). This is also true for components 2 in both dataset, however, the correlation across datasets for different components is weak: the point cloud is very spherical.
Out:

\[
\text{Corr}(X) = \begin{bmatrix}
1 & 0.52 & -0.06 & -0.03 \\
0.52 & 1 & -0.02 & -0.06 \\
-0.06 & -0.02 & 1 & 0.58 \\
-0.03 & -0.06 & 0.58 & 1
\end{bmatrix}
\]

\[
\text{Corr}(Y) = \begin{bmatrix}
1 & 0.56 & -0.02 & 0 \\
0.56 & 1 & -0.05 & 0.04 \\
-0.02 & -0.05 & 1 & 0.53 \\
0 & 0.04 & 0.53 & 1
\end{bmatrix}
\]

True \(B\) (such that: \(Y = XB + \text{Err}\))

\[
\begin{bmatrix}
1 & 1 & 1 \\

from sklearn import datasets

import matplotlib.pyplot as plt

# Load the digits dataset
digits = datasets.load_digits()

# Display the first digit
plt.figure(1, figsize=(3, 3))
plt.imshow(digits.images[-1], cmap=plt.cm.gray_r, interpolation='nearest')
plt.show()
```

Total running time of the script: ( 0 minutes 0.108 seconds)
6.9.2 The Iris Dataset

This data sets consists of 3 different types of irises’ (Setosa, Versicolour, and Virginica) petal and sepal length, stored in a 150x4 numpy.ndarray.

The rows being the samples and the columns being: Sepal Length, Sepal Width, Petal Length and Petal Width.

The below plot uses the first two features. See here for more information on this dataset.
import matplotlib.pyplot as plt
from mpl_toolkits.mplot3d import Axes3D
from sklearn import datasets
from sklearn.decomposition import PCA

# import some data to play with
iris = datasets.load_iris()
X = iris.data[:, :2]  # we only take the first two features.
y = iris.target

x_min, x_max = X[:, 0].min() - .5, X[:, 0].max() + .5
y_min, y_max = X[:, 1].min() - .5, X[:, 1].max() + .5

plt.figure(2, figsize=(8, 6))
plt.clf()

# Plot the training points
plt.scatter(X[:, 0], X[:, 1], c=y, cmap=plt.cm.Set1,
            edgecolor='k')
plt.xlabel('Sepal length')
plt.ylabel('Sepal width')
plt.title('Sepal length vs. Sepal width')

(continues on next page)
plt.ylabel('Sepal width')
plt.xlim(x_min, x_max)
plt.ylim(y_min, y_max)
plt.xticks(()
plt.yticks(()

# To get a better understanding of interaction of the dimensions
fig = plt.figure(1, figsize=(8, 6))
ax = Axes3D(fig, elev=-150, azim=110)
X_reduced = PCA(n_components=3).fit_transform(iris.data)
ax.scatter(X_reduced[:, 0], X_reduced[:, 1], X_reduced[:, 2], c=y,
            cmap=plt.cm.Set1, edgecolor='k', s=40)
ax.set_title("First three PCA directions")
ax.set_xlabel("1st eigenvector")
ax.w_xaxis.set_ticklabels([])

6.9.4 Plot randomly generated multilabel dataset

This illustrates the make_multilabel_classification dataset generator. Each sample consists of counts of two features (up to 50 in total), which are differently distributed in each of two classes.

Points are labeled as follows, where Y means the class is present:
A star marks the expected sample for each class; its size reflects the probability of selecting that class label.

The left and right examples highlight the `n_labels` parameter: more of the samples in the right plot have 2 or 3 labels.

Note that this two-dimensional example is very degenerate: generally the number of features would be much greater than the “document length”, while here we have much larger documents than vocabulary. Similarly, with `n_classes > n_features`, it is much less likely that a feature distinguishes a particular class.

6.10 Decision Trees

Examples concerning the `sklearn.tree` module.

6.10.1 Decision Tree Regression

A 1D regression with decision tree.

The decision trees is used to fit a sine curve with addition noisy observation. As a result, it learns local linear regressions approximating the sine curve.

We can see that if the maximum depth of the tree (controlled by the `max_depth` parameter) is set too high, the decision trees learn too fine details of the training data and learn from the noise, i.e. they overfit.

```python
print(__doc__)

# Import the necessary modules and libraries
import numpy as np
from sklearn.tree import DecisionTreeRegressor
import matplotlib.pyplot as plt

# Create a random dataset
rng = np.random.RandomState(1)
X = np.sort(5 * rng.rand(80, 1), axis=0)

# Fit regression model
regr_1 = DecisionTreeRegressor(max_depth=2)
regr_2 = DecisionTreeRegressor(max_depth=5)
regr_1.fit(X, y)
regr_2.fit(X, y)

# Predict
y_1 = regr_1.predict(X)
y_2 = regr_2.predict(X)

# Plot the results
plt.figure()
plt.scatter(X, y, s=20, edgecolor="black", c="blue", label="data")
plt.plot(X, y_1, color="g", label="max_depth=2")
plt.plot(X, y_2, color="k", label="max_depth=5")
plt.xlabel("data")
plt.ylabel("target")
plt.title("Decision Tree Regression")
plt.legend()
plt.show()
```
y = np.sin(X).ravel()
y[::5] += 3 * (0.5 - rng.rand(16))

# Fit regression model
regr_1 = DecisionTreeRegressor(max_depth=2)
regr_2 = DecisionTreeRegressor(max_depth=5)
regr_1.fit(X, y)
regr_2.fit(X, y)

# Predict
X_test = np.arange(0.0, 5.0, 0.01)[:, np.newaxis]
y_1 = regr_1.predict(X_test)
y_2 = regr_2.predict(X_test)

# Plot the results
plt.figure()
plt.scatter(X, y, s=20, edgecolor="black",
c="darkorange", label="data")
plt.plot(X_test, y_1, color="cornflowerblue",
label="max_depth=2", linewidth=2)
plt.plot(X_test, y_2, color="yellowgreen", label="max_depth=5", linewidth=2)
plt.xlabel("data")
plt.ylabel("target")
plt.title("Decision Tree Regression")
plt.legend()
plt.show()

Total running time of the script: ( 0 minutes 0.103 seconds)

6.10.2 Multi-output Decision Tree Regression

An example to illustrate multi-output regression with decision tree.

The decision trees is used to predict simultaneously the noisy x and y observations of a circle given a single underlying feature. As a result, it learns local linear regressions approximating the circle.

We can see that if the maximum depth of the tree (controlled by the max_depth parameter) is set too high, the decision trees learn too fine details of the training data and learn from the noise, i.e. they overfit.
# Create a random dataset
rng = np.random.RandomState(1)
X = np.sort(200 * rng.rand(100, 1) - 100, axis=0)
y = np.array([np.pi * np.sin(X).ravel(), np.pi * np.cos(X).ravel()]).T
y[::5, :] += (0.5 - rng.rand(20, 2))

# Fit regression model
regr_1 = DecisionTreeRegressor(max_depth=2)
regr_2 = DecisionTreeRegressor(max_depth=5)
regr_3 = DecisionTreeRegressor(max_depth=8)
regr_1.fit(X, y)
regr_2.fit(X, y)
regr_3.fit(X, y)

# Predict
X_test = np.arange(-100.0, 100.0, 0.01)[:, np.newaxis]
y_1 = regr_1.predict(X_test)
y_2 = regr_2.predict(X_test)
y_3 = regr_3.predict(X_test)
# Plot the results

```python
plt.figure()
s = 25
plt.scatter(y[:, 0], y[:, 1], c="navy", s=s,
edgelcolor="black", label="data")
plt.scatter(y_1[:, 0], y_1[:, 1], c="cornflowerblue", s=s,
edgelcolor="black", label="max_depth=2")
plt.scatter(y_2[:, 0], y_2[:, 1], c="red", s=s,
edgelcolor="black", label="max_depth=5")
plt.scatter(y_3[:, 0], y_3[:, 1], c="orange", s=s,
edgelcolor="black", label="max_depth=8")
plt.xlim([-6, 6])
plt.xlabel("target 1")
plt.ylabel("target 2")
plt.title("Multi-output Decision Tree Regression")
plt.legend(loc="best")
plt.show()
```

Total running time of the script: ( 0 minutes 0.294 seconds)

## 6.10.3 Plot the decision surface of a decision tree on the iris dataset

Plot the decision surface of a decision tree trained on pairs of features of the iris dataset.

See [decision tree](#) for more information on the estimator.

For each pair of iris features, the decision tree learns decision boundaries made of combinations of simple thresholding rules inferred from the training samples.

We also show the tree structure of a model built on all of the features.
Decision surface of a decision tree using paired features
import numpy as np
import matplotlib.pyplot as plt
from sklearn.datasets import load_iris
from sklearn.tree import DecisionTreeClassifier, plot_tree

# Parameters
n_classes = 3
plot_colors = "ryb"
plot_step = 0.02

# Load data
iris = load_iris()

for pairidx, pair in enumerate(
    [[0, 1], [0, 2], [0, 3],
     [1, 2], [1, 3], [2, 3]]):

    # We only take the two corresponding features
    X = iris.data[:, pair]
y = iris.target

    # Train
    clf = DecisionTreeClassifier().fit(X, y)

    # Plot the decision boundary
    plt.subplot(2, 3, pairidx + 1)
x_min, x_max = X[:, 0].min() - 1, X[:, 0].max() + 1
y_min, y_max = X[:, 1].min() - 1, X[:, 1].max() + 1
xx, yy = np.meshgrid(np.arange(x_min, x_max, plot_step),
np.arange(y_min, y_max, plot_step))
plt.tight_layout(h_pad=0.5, w_pad=0.5, pad=2.5)
Z = clf.predict(np.c_[xx.ravel(), yy.ravel()])
Z = Z.reshape(xx.shape)
cs = plt.contourf(xx, yy, Z, cmap=plt.cm.RdYlBu)
plt.xlabel(iris.feature_names[pair[0]])
plt.ylabel(iris.feature_names[pair[1]])
# Plot the training points
for i, color in zip(range(n_classes), plot_colors):
    idx = np.where(y == i)
    plt.scatter(X[idx, 0], X[idx, 1], c=color, label=iris.target_names[i],
cmap=plt.cm.RdYlBu, edgecolor='black', s=15)
plt.suptitle("Decision surface of a decision tree using paired features")
plt.legend(loc='lower right', borderpad=0, handletextpad=0)
plt.axis("tight")
plt.figure()
clf = DecisionTreeClassifier().fit(iris.data, iris.target)
plot_tree(clf, filled=True)
plt.show()
Total impurity of leaves vs effective alphas of pruned tree

Minimal cost complexity pruning recursively finds the node with the “weakest link”. The weakest link is characterized by an effective alpha, where the nodes with the smallest effective alpha are pruned first. To get an idea of what values of `ccp_alpha` could be appropriate, scikit-learn provides `DecisionTreeClassifier.cost_complexity_pruning_path` that returns the effective alphas and the corresponding total leaf impurities at each step of the pruning process. As alpha increases, more of the tree is pruned, which increases the total impurity of its leaves.

```python
X, y = load_breast_cancer(return_X_y=True)
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
clf = DecisionTreeClassifier(random_state=0)
path = clf.cost_complexity_pruning_path(X_train, y_train)
ccp_alphas, impurities = path.ccp_alphas, path.impurities
```

In the following plot, the maximum effective alpha value is removed, because it is the trivial tree with only one node.

```python
fig, ax = plt.subplots()
an.plot(ccp_alphas[:-1], impurities[:-1], marker='o', drawstyle="steps-post")
an.set_xlabel("effective alpha")
an.set_ylabel("total impurity of leaves")
an.set_title("Total Impurity vs effective alpha for training set")
```

Out:
Next, we train a decision tree using the effective alphas. The last value in `ccp_alphas` is the alpha value that prunes the whole tree, leaving the tree, `clfs[-1]`, with one node.

```python
clfs = []
for ccp_alpha in ccp_alphas:
    clf = DecisionTreeClassifier(random_state=0, ccp_alpha=ccp_alpha)
    clf.fit(X_train, y_train)
    clfs.append(clf)
print("Number of nodes in the last tree is: {} with ccp_alpha: {}\n".format(clfs[-1].tree_.node_count, ccp_alphas[-1]))
```

Out:

```
Number of nodes in the last tree is: 1 with ccp_alpha: 0.3272984419327777
```

For the remainder of this example, we remove the last element in `clfs` and `ccp_alphas`, because it is the trivial tree with only one node. Here we show that the number of nodes and tree depth decreases as alpha increases.

```python
clfs = clfs[:-1]
ccp_alphas = ccp_alphas[:-1]

node_counts = [clf.tree_.node_count for clf in clfs]
depth = [clf.tree_.max_depth for clf in clfs]
fig, ax = plt.subplots(2, 1)
ax[0].plot(ccp_alphas, node_counts, marker='o', drawstyle="steps-post")
ax[0].set_xlabel("alpha")
ax[0].set_ylabel("number of nodes")
ax[0].set_title("Number of nodes vs alpha")
ax[1].plot(ccp_alphas, depth, marker='o', drawstyle="steps-post")
ax[1].set_xlabel("alpha")
ax[1].set_ylabel("depth of tree")
ax[1].set_title("Depth vs alpha")
fig.tight_layout()
```
Accuracy vs alpha for training and testing sets

When `ccp_alpha` is set to zero and keeping the other default parameters of `DecisionTreeClassifier`, the tree overfits, leading to a 100% training accuracy and 88% testing accuracy. As alpha increases, more of the tree is pruned, thus creating a decision tree that generalizes better. In this example, setting `ccp_alpha=0.015` maximizes the testing accuracy.

```python
train_scores = [clf.score(X_train, y_train) for clf in clfs]
test_scores = [clf.score(X_test, y_test) for clf in clfs]

fig, ax = plt.subplots()
ax.set_xlabel("alpha")
ax.set_ylabel("accuracy")
ax.set_title("Accuracy vs alpha for training and testing sets")
ax.plot(ccp_alphas, train_scores, marker='o', label="train",
        drawstyle="steps-post")
ax.plot(ccp_alphas, test_scores, marker='o', label="test",
        drawstyle="steps-post")
ax.legend()
plt.show()
```
6.10.5 Understanding the decision tree structure

The decision tree structure can be analysed to gain further insight on the relation between the features and the target to predict. In this example, we show how to retrieve:

- the binary tree structure;
- the depth of each node and whether or not it’s a leaf;
- the nodes that were reached by a sample using the `decision_path` method;
- the leaf that was reached by a sample using the apply method;
- the rules that were used to predict a sample;
- the decision path shared by a group of samples.

```python
import numpy as np
from matplotlib import pyplot as plt
from sklearn.model_selection import train_test_split
from sklearn.datasets import load_iris
from sklearn.tree import DecisionTreeClassifier
from sklearn import tree
```
Train tree classifier

First, we fit a `DecisionTreeClassifier` using the `load_iris` dataset.

```python
iris = load_iris()
X = iris.data
y = iris.target
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)

clf = DecisionTreeClassifier(max_leaf_nodes=3, random_state=0)
clf.fit(X_train, y_train)
```

Tree structure

The decision classifier has an attribute called `tree_` which allows access to low level attributes such as `node_count`, the total number of nodes, and `max_depth`, the maximal depth of the tree. It also stores the entire binary tree structure, represented as a number of parallel arrays. The i-th element of each array holds information about the node i. Node 0 is the tree’s root. Some of the arrays only apply to either leaves or split nodes. In this case the values of the nodes of the other type is arbitrary. For example, the arrays `feature` and `threshold` only apply to split nodes. The values for leaf nodes in these arrays are therefore arbitrary.

Among these arrays, we have:

- `children_left[i]`: id of the left child of node i or -1 if leaf node
- `children_right[i]`: id of the right child of node i or -1 if leaf node
- `feature[i]`: feature used for splitting node i
- `threshold[i]`: threshold value at node i
- `n_node_samples[i]`: the number of of training samples reaching node i
- `impurity[i]`: the impurity at node i

Using the arrays, we can traverse the tree structure to compute various properties. Below, we will compute the depth of each node and whether or not it is a leaf.

```python
n_nodes = clf.tree_.node_count
children_left = clf.tree_.children_left
children_right = clf.tree_.children_right
feature = clf.tree_.feature
threshold = clf.tree_.threshold

node_depth = np.zeros(shape=n_nodes, dtype=np.int64)
is_leaves = np.zeros(shape=n_nodes, dtype=bool)
stack = [(0, 0)]  # start with the root node id (0) and its depth (0)
while len(stack) > 0:
    node_id, depth = stack.pop()
    node_depth[node_id] = depth

    is_split_node = children_left[node_id] != children_right[node_id]
    if is_split_node:
        stack.append((children_left[node_id], depth + 1))
        stack.append((children_right[node_id], depth + 1))
```

(continues on next page)
stack.append((children_right[node_id], depth + 1))
    else:
        is_leaves[node_id] = True

print("The binary tree structure has {n} nodes and has ",
    "the following tree structure:

{string}").format(n=n_nodes))
for i in range(n_nodes):
    if is_leaves[i]:
        print("{space}node={node} is a leaf node.").format(
            space=node_depth[i] * "\t",
            node=i)
    else:
        print("{space}node={node} is a split node: ",
            "go to node (left) if X[:, {feature}] <= {threshold} ",
            "else to node (right): ").format(
                space=node_depth[i] * "\t",
                node=i,
                left=children_left[i],
                feature=feature[i],
                threshold=threshold[i],
                right=children_right[i]))

Out:

The binary tree structure has 5 nodes and has the following tree structure:

node=0 is a split node: go to node 1 if X[:, 3] <= 0.800000011920929 else to node 2.
    node=1 is a leaf node.
    node=2 is a split node: go to node 3 if X[:, 2] <= 4.950000047683716 else to
    →node 4.
        node=3 is a leaf node.
        node=4 is a leaf node.

We can compare the above output to the plot of the decision tree.

tree.plot_tree(clf)
plt.show()
Decision path

We can also retrieve the decision path of samples of interest. The `decision_path` method outputs an indicator matrix that allows us to retrieve the nodes the samples of interest traverse through. A non zero element in the indicator matrix at position \((i, j)\) indicates that the sample \(i\) goes through the node \(j\). Or, for one sample \(i\), the positions of the non zero elements in row \(i\) of the indicator matrix designate the ids of the nodes that sample goes through.

The leaf ids reached by samples of interest can be obtained with the `apply` method. This returns an array of the node ids of the leaves reached by each sample of interest. Using the leaf ids and the `decision_path` we can obtain the splitting conditions that were used to predict a sample or a group of samples. First, let's do it for one sample. Note that `node_index` is a sparse matrix.

```python
X[3] <= 0.8
gini = 0.665
samples = 112
value = [37, 34, 41]

X[2] <= 4.95
gini = 0.496
samples = 75
value = [0, 34, 41]

node_indicator = clf.decision_path(X_test)
leaf_id = clf.apply(X_test)

sample_id = 0
# obtain ids of the nodes 'sample_id' goes through, i.e., row 'sample_id'
node_index = node_indicator.indices[node_indicator.indptr[sample_id]:
                        node_indicator.indptr[sample_id + 1]]

print('Rules used to predict sample \(id\):

    node_id in node_index:
        # continue to the next node if it is a leaf node
        if leaf_id[sample_id] == node_id:
```

(continues on next page)
# check if value of the split feature for sample 0 is below threshold
if (X_test[sample_id, feature[node_id]] <= threshold[node_id]):
    threshold_sign = "<="
else:
    threshold_sign = ">

print("decision node {node} : (X_test[{sample}, {feature}] = {value}) "
      "{inequality} {threshold}).".format(
          node=node_id,
          sample=sample_id,
          feature=feature[node_id],
          value=X_test[sample_id, feature[node_id]],
          inequality=threshold_sign,
          threshold=threshold[node_id])

Out:

Rules used to predict sample 0:

decision node 0 : (X_test[0, 3] = 2.4) > 0.800000011920929)
decision node 2 : (X_test[0, 2] = 5.1) > 4.950000047683716)

For a group of samples, we can determine the common nodes the samples go through.

sample_ids = [0, 1]
# boolean array indicating the nodes both samples go through
common_nodes = (node_indicator.toarray()[sample_ids].sum(axis=0) ==
    len(sample_ids))
# obtain node ids using position in array
common_node_id = np.arange(n_nodes)[common_nodes]

print("The following samples {samples} share the node(s) {nodes} in the "
      "tree.".format(samples=sample_ids, nodes=common_node_id))
print("This is {prop}% of all nodes.".format(
    prop=100 * len(common_node_id) / n_nodes))

Out:

The following samples [0, 1] share the node(s) [0 2] in the tree.
This is 40.0% of all nodes.

6.11.3 Incremental PCA

Incremental principal component analysis (IPCA) is typically used as a replacement for principal component analysis (PCA) when the dataset to be decomposed is too large to fit in memory. IPCA builds a low-rank approximation for the input data using an amount of memory which is independent of the number of input data samples. It is still dependent on the input data features, but changing the batch size allows for control of memory usage.

This example serves as a visual check that IPCA is able to find a similar projection of the data to PCA (to a sign flip), while only processing a few samples at a time. This can be considered a “toy example”, as IPCA is intended for large datasets which do not fit in main memory, requiring incremental approaches.

6.11.4 Comparison of LDA and PCA 2D projection of Iris dataset

The Iris dataset represents 3 kind of Iris flowers (Setosa, Versicolour and Virginica) with 4 attributes: sepal length, sepal width, petal length and petal width.

Principal Component Analysis (PCA) applied to this data identifies the combination of attributes (principal components, or directions in the feature space) that account for the most variance in the data. Here we plot the different samples on the 2 first principal components.

Linear Discriminant Analysis (LDA) tries to identify attributes that account for the most variance between classes. In particular, LDA, in contrast to PCA, is a supervised method, using known class labels.

6.11.5 Factor Analysis (with rotation) to visualize patterns

Investigating the Iris dataset, we see that sepal length, petal length and petal width are highly correlated. Sepal width is less redundant. Matrix decomposition techniques can uncover these latent patterns. Applying rotations to the resulting components does not inherently improve the predictive value of the derived latent space, but can help visualise their structure; here, for example, the varimax rotation, which is found by maximizing the squared variances of the weights, finds a structure where the second component only loads positively on sepal width.

| 6.11.6 Blind source separation using FastICA |

An example of estimating sources from noisy data.

Independent component analysis (ICA) is used to estimate sources given noisy measurements. Imagine 3 instruments playing simultaneously and 3 microphones recording the mixed signals. ICA is used to recover the sources i.e. what is played by each instrument. Importantly, PCA fails at recovering our instruments since the related signals reflect non-Gaussian processes.
import numpy as np
import matplotlib.pyplot as plt
from scipy import signal
from sklearn.decomposition import FastICA, PCA

# #############################################################################
# Generate sample data

### 6.11.8 FastICA on 2D point clouds

This example illustrates visually in the feature space a comparison by results using two different component analysis techniques.

*Independent component analysis (ICA) vs Principal component analysis (PCA).*

Representing ICA in the feature space gives the view of ‘geometric ICA’: ICA is an algorithm that finds directions in the feature space corresponding to projections with high non-Gaussianity. These directions need not be orthogonal in the original feature space, but they are orthogonal in the whitened feature space, in which all directions correspond to the same variance.

PCA, on the other hand, finds orthogonal directions in the raw feature space that correspond to directions accounting for maximum variance.

Here we simulate independent sources using a highly non-Gaussian process, 2 student T with a low number of degrees of freedom (top left figure). We mix them to create observations (top right figure). In this raw observation space, directions identified by PCA are represented by orange vectors. We represent the signal in the PCA space, after whitening by the variance corresponding to the PCA vectors (lower left). Running ICA corresponds to finding a rotation in this space to identify the directions of largest non-Gaussianity (lower right).
import numpy as np
import matplotlib.pyplot as plt
from sklearn.decomposition import PCA, FastICA

# #############################################################################
# Generate sample data

6.11.10 Model selection with Probabilistic PCA and Factor Analysis (FA)

Probabilistic PCA and Factor Analysis are probabilistic models. The consequence is that the likelihood of new data can be used for model selection and covariance estimation. Here we compare PCA and FA with cross-validation on low rank data corrupted with homoscedastic noise (noise variance is the same for each feature) or heteroscedastic noise (noise variance is the different for each feature). In a second step we compare the model likelihood to the likelihoods obtained from shrinkage covariance estimators.

One can observe that with homoscedastic noise both FA and PCA succeed in recovering the size of the low rank subspace. The likelihood with PCA is higher than FA in this case. However PCA fails and overestimates the rank when heteroscedastic noise is present. Under appropriate circumstances the low rank models are more likely than shrinkage models.

The automatic estimation from Automatic Choice of Dimensionality for PCA. NIPS 2000: 598-604 by Thomas P. Minka is also compared.

6.11.11 Sparse coding with a precomputed dictionary

Transform a signal as a sparse combination of Ricker wavelets. This example visually compares different sparse coding methods using the `SparseCoder` estimator. The Ricker (also known as Mexican hat or the second derivative of a Gaussian) is not a particularly good kernel to represent piecewise constant signals like this one. It can therefore be seen how much adding different widths of atoms matters and it therefore motivates learning the dictionary to best fit your type of signals.

The richer dictionary on the right is not larger in size, heavier subsampling is performed in order to stay on the same order of magnitude.
```python
import numpy as np
import matplotlib.pyplot as plt
from sklearn.decomposition import SparseCoder
from sklearn.utils.fixes import np_version, parse_version

def ricker_function(resolution, center, width):
    """Discrete sub-sampled Ricker (Mexican hat) wavelet""
    x = np.linspace(0, resolution - 1, resolution)
    x = ((2 / (np.sqrt(3 * width) * np.pi ** .25))
         * (1 - (x - center) ** 2 / width ** 2)
         * np.exp(-(x - center) ** 2 / (2 * width ** 2)))
    return x

def ricker_matrix(width, resolution, n_components):
    """Dictionary of Ricker (Mexican hat) wavelets""
    centers = np.linspace(0, resolution - 1, n_components)
    D = np.empty((n_components, resolution))
    for i, center in enumerate(centers):
        D[i] = ricker_function(resolution, center, width)
    D /= np.sqrt(np.sum(D ** 2, axis=1))[:, np.newaxis]
    return D

resolution = 1024
subsampling = 3  # subsampling factor
width = 100
n_components = resolution // subsampling

# Compute a wavelet dictionary

6.11.12 Image denoising using dictionary learning

An example comparing the effect of reconstructing noisy fragments of a raccoon face image using firstly online Dictionary Learning and various transform methods.

The dictionary is fitted on the distorted left half of the image, and subsequently used to reconstruct the right half. Note that even better performance could be achieved by fitting to an undistorted (i.e. noiseless) image, but here we start from the assumption that it is not available.

A common practice for evaluating the results of image denoising is by looking at the difference between the reconstruction and the original image. If the reconstruction is perfect this will look like Gaussian noise.

It can be seen from the plots that the results of Orthogonal Matching Pursuit (OMP) with two non-zero coefficients is a bit less biased than when keeping only one (the edges look less prominent). It is in addition closer from the ground truth in Frobenius norm.

The result of Least Angle Regression is much more strongly biased: the difference is reminiscent of the local intensity value of the original image.

Thresholding is clearly not useful for denoising, but it is here to show that it can produce a suggestive output with very high speed, and thus be useful for other tasks such as object classification, where performance is not necessarily related to visualisation.

Dictionary learned from face patches
Train time 2.7s on 22692 patches
Distorted image

Orthogonal Matching Pursuit

6.12 Ensemble methods

Examples concerning the `sklearn.ensemble` module.

6.12.1 Pixel importances with a parallel forest of trees

This example shows the use of forests of trees to evaluate the impurity-based importance of the pixels in an image classification task (faces). The hotter the pixel, the more important.

The code below also illustrates how the construction and the computation of the predictions can be parallelized within multiple jobs.
from sklearn.datasets import fetch_olivetti_faces

X, y = data.data, data.target

# Number of cores to use to perform parallel fitting of the forest model
n_jobs = 1

# Load the faces dataset
data = fetch_olivetti_faces()
X, y = data.data, data.target

print(__doc__)

from time import time
import matplotlib.pyplot as plt

from sklearn.datasets import fetch_olivetti_faces
from sklearn.ensemble import ExtraTreesClassifier

print(__doc__)

from time import time
import matplotlib.pyplot as plt

from sklearn.datasets import fetch_olivetti_faces
from sklearn.ensemble import ExtraTreesClassifier

# Number of cores to use to perform parallel fitting of the forest model
n_jobs = 1

# Load the faces dataset
data = fetch_olivetti_faces()
X, y = data.data, data.target
mask = y < 5  # Limit to 5 classes
X = X[mask]
y = y[mask]

# Build a forest and compute the pixel importances
print("Fitting ExtraTreesClassifier on faces data with \$d\ cores..." % n_jobs)
t0 = time()
forest = ExtraTreesClassifier(n_estimators=1000,
                             max_features=128,
                             n_jobs=n_jobs,
                             random_state=0)
forest.fit(X, y)
print("done in \$0.3fs" % (time() - t0))
importances = forest.feature_importances_
importances = importances.reshape(data.images[0].shape)

# Plot pixel importances
plt.matshow(importances, cmap=plt.cm.hot)
plt.title("Pixel importances with forests of trees")
plt.show()

Total running time of the script: ( 0 minutes 1.205 seconds)

6.12.2 Decision Tree Regression with AdaBoost

A decision tree is boosted using the AdaBoost.R2\(^1\) algorithm on a 1D sinusoidal dataset with a small amount of Gaussian noise. 299 boosts (300 decision trees) is compared with a single decision tree regressor. As the number of boosts is increased the regressor can fit more detail.

import numpy as np
import matplotlib.pyplot as plt
from sklearn.tree import DecisionTreeRegressor
from sklearn.ensemble import AdaBoostRegressor

# Create the dataset
rng = np.random.RandomState(1)
X = np.linspace(0, 6, 100)[..., np.newaxis]
y = np.sin(X).ravel() + np.sin(6 * X).ravel() + rng.normal(0, 0.1, X.shape[0])

# Fit regression model
regr_1 = DecisionTreeRegressor(max_depth=4)

regr_2 = AdaBoostRegressor(DecisionTreeRegressor(max_depth=4),
    n_estimators=300, random_state=rng)

regr_1.fit(X, y)
regr_2.fit(X, y)

## 6.12.3 Plot individual and voting regression predictions

A voting regressor is an ensemble meta-estimator that fits several base regressors, each on the whole dataset. Then it averages the individual predictions to form a final prediction. We will use three different regressors to predict the data: `GradientBoostingRegressor`, `RandomForestRegressor`, and `LinearRegression`). Then the above 3 regressors will be used for the `VotingRegressor`.

Finally, we will plot the predictions made by all models for comparison.

We will work with the diabetes dataset which consists of 10 features collected from a cohort of diabetes patients. The target is a quantitative measure of disease progression one year after baseline.

```python
print(__doc__)

import matplotlib.pyplot as plt
from sklearn.datasets import load_diabetes
from sklearn.ensemble import GradientBoostingRegressor
from sklearn.ensemble import RandomForestRegressor
from sklearn.linear_model import LinearRegression
from sklearn.ensemble import VotingRegressor
```

### Training classifiers

First, we will load the diabetes dataset and initiate a gradient boosting regressor, a random forest regressor and a linear regression. Next, we will use the 3 regressors to build the voting regressor:

```python
X, y = load_diabetes(return_X_y=True)

# Train classifiers
reg1 = GradientBoostingRegressor(random_state=1)
reg2 = RandomForestRegressor(random_state=1)
reg3 = LinearRegression()
reg1.fit(X, y)
reg2.fit(X, y)
```

(continues on next page)
Making predictions

Now we will use each of the regressors to make the 20 first predictions.

```python
xt = X[:20]

pred1 = reg1.predict(xt)
pred2 = reg2.predict(xt)
pred3 = reg3.predict(xt)
pred4 = ereg.predict(xt)
```

Plot the results

Finally, we will visualize the 20 predictions. The red stars show the average prediction made by `VotingRegressor`.

```python
plt.figure()
plt.plot(pred1, 'gd', label='GradientBoostingRegressor')
plt.plot(pred2, 'b^', label='RandomForestRegressor')
plt.plot(pred3, 'ys', label='LinearRegression')
plt.plot(pred4, 'r*', ms=10, label='VotingRegressor')

plt.tick_params(axis='x', which='both', bottom=False, top=False, labelbottom=False)
plt.ylabel('predicted')
plt.xlabel('training samples')
plt.legend(loc="best")
plt.title('Regressor predictions and their average')
plt.show()
```
6.12.4 Feature importances with forests of trees

This examples shows the use of forests of trees to evaluate the importance of features on an artificial classification task. The red bars are the impurity-based feature importances of the forest, along with their inter-trees variability.

As expected, the plot suggests that 3 features are informative, while the remaining are not.

**Warning:** Impurity-based feature importances can be misleading for high cardinality features (many unique values). See `sklearn.inspection.permutation_importance` as an alternative.

6.12.5 Monotonic Constraints

This example illustrates the effect of monotonic constraints on a gradient boosting estimator.

We build an artificial dataset where the target value is in general positively correlated with the first feature (with some random and non-random variations), and in general negatively correlated with the second feature.

By imposing a positive (increasing) or negative (decreasing) constraint on the features during the learning process, the estimator is able to properly follow the general trend instead of being subject to the variations.

This example was inspired by the XGBoost documentation.
from sklearn.experimental import enable_hist_gradient_boosting  # noqa
from sklearn.ensemble import HistGradientBoostingRegressor
from sklearn.inspection import plot_partial_dependence
import numpy as np
import matplotlib.pyplot as plt

print(__doc__)

rng = np.random.RandomState(0)

n_samples = 5000
f_0 = rng.rand(n_samples)  # positive correlation with y
f_1 = rng.rand(n_samples)  # negative correlation with y
X = np.c_[f_0, f_1]
noise = rng.normal(loc=0.0, scale=0.01, size=n_samples)
y = (5 * f_0 + np.sin(10 * np.pi * f_0) -
    5 * f_1 - np.cos(10 * np.pi * f_1) +
    noise)

fig, ax = plt.subplots()

# Without any constraint

    disp.axes_[0, f_idx].set_ylim(-6, 6)

plt.legend()
plt.suptitle("Monotonic constraints illustration")
plt.show()

Total running time of the script: ( 0 minutes 0.670 seconds)

6.12.6 IsolationForest example

An example using IsolationForest for anomaly detection.

The IsolationForest ‘isolates’ observations by randomly selecting a feature and then randomly selecting a split value between the maximum and minimum values of the selected feature.

Since recursive partitioning can be represented by a tree structure, the number of splittings required to isolate a sample is equivalent to the path length from the root node to the terminating node.

This path length, averaged over a forest of such random trees, is a measure of normality and our decision function.

Random partitioning produces noticeable shorter paths for anomalies. Hence, when a forest of random trees collectively produce shorter path lengths for particular samples, they are highly likely to be anomalies.
import numpy as np
import matplotlib.pyplot as plt
from sklearn.ensemble import IsolationForest

rng = np.random.RandomState(42)

# Generate train data
X = 0.3 * rng.randn(100, 2)
X_train = np.r_[X + 2, X - 2]

# Generate some regular novel observations
X = 0.3 * rng.randn(20, 2)
X_test = np.r_[X + 2, X - 2]

# Generate some abnormal novel observations
X_outliers = rng.uniform(low=-4, high=4, size=(20, 2))

# fit the model
clf = IsolationForest(max_samples=100, random_state=rng)
clf.fit(X_train)
y_pred_train = clf.predict(X_train)
y_pred_test = clf.predict(X_test)
y_pred_outliers = clf.predict(X_outliers)

# plot the line, the samples, and the nearest vectors to the plane

(continues on next page)
xx, yy = np.meshgrid(np.linspace(-5, 5, 50), np.linspace(-5, 5, 50))
Z = clf.decision_function(np.c_[xx.ravel(), yy.ravel()])
Z = Z.reshape(xx.shape)
plt.title("IsolationForest")
plt.contourf(xx, yy, Z, cmap=plt.cm.Blues_r)

b1 = plt.scatter(X_train[:, 0], X_train[:, 1], c='white', s=20, edgecolor='k')
b2 = plt.scatter(X_test[:, 0], X_test[:, 1], c='green', s=20, edgecolor='k')
c = plt.scatter(X_outliers[:, 0], X_outliers[:, 1], c='red', s=20, edgecolor='k')
plt.axis('tight')
plt.xlim((-5, 5))
plt.ylim((-5, 5))
plt.legend([b1, b2, c], ["training observations", "new regular observations", "new abnormal observations"], loc="upper left")
plt.show()

Total running time of the script: (0 minutes 0.395 seconds)

6.12.7 Plot the decision boundaries of a VotingClassifier

Plot the decision boundaries of a VotingClassifier for two features of the Iris dataset.

Plot the class probabilities of the first sample in a toy dataset predicted by three different classifiers and averaged by the VotingClassifier.

First, three exemplary classifiers are initialized (DecisionTreeClassifier, KNeighborsClassifier, and SVC) and used to initialize a soft-voting VotingClassifier with weights [2, 1, 2], which means that the predicted probabilities of the DecisionTreeClassifier and SVC each count 2 times as much as the weights of the KNeighborsClassifier classifier when the averaged probability is calculated.
from sklearn import datasets
from sklearn.tree import DecisionTreeClassifier
from sklearn.neighbors import KNeighborsClassifier
from sklearn.svm import SVC
from sklearn.ensemble import VotingClassifier

# Loading some example data
iris = datasets.load_iris()
X = iris.data[:, [0, 2]]
y = iris.target

# Training classifiers
clf1 = DecisionTreeClassifier(max_depth=4)
clf2 = KNeighborsClassifier(n_neighbors=7)
clf3 = SVC(gamma=.1, kernel='rbf', probability=True)
eclf = VotingClassifier(estimators=[('dt', clf1), ('knn', clf2),
(continues on next page)
('svc', clf3)],
    voting='soft', weights=[2, 1, 2])
clf1.fit(X, y)
clf2.fit(X, y)
clf3.fit(X, y)
eclf.fit(X, y)

# Plotting decision regions
x_min, x_max = X[:, 0].min() - 1, X[:, 0].max() + 1
y_min, y_max = X[:, 1].min() - 1, X[:, 1].max() + 1
xx, yy = np.meshgrid(np.arange(x_min, x_max, 0.1),
                     np.arange(y_min, y_max, 0.1))

f, axarr = plt.subplots(2, 2, sharex='col', sharey='row', figsize=(10, 8))
for idx, clf, tt in zip(product([0, 1], [0, 1]),
                       [clf1, clf2, clf3, eclf],
                       ['Decision Tree (depth=4)', 'KNN (k=7)',
                        'Kernel SVM', 'Soft Voting']):
    Z = clf.predict(np.c_[xx.ravel(), yy.ravel()])
    Z = Z.reshape(xx.shape)
    axarr[idx[0], idx[1]].contourf(xx, yy, Z, alpha=0.4)
    axarr[idx[0], idx[1]].scatter(X[:, 0], X[:, 1], c=y,
                                   s=20, edgecolor='k')
    axarr[idx[0], idx[1]].set_title(tt)
plt.show()

Total running time of the script: (0 minutes 0.422 seconds)

6.12.8 Comparing random forests and the multi-output meta estimator

An example to compare multi-output regression with random forest and the multioutput.MultiOutputRegressor meta-estimator.

This example illustrates the use of the multioutput.MultiOutputRegressor meta-estimator to perform multi-output regression. A random forest regressor is used, which supports multi-output regression natively, so the results can be compared.

The random forest regressor will only ever predict values within the range of observations or closer to zero for each of the targets. As a result the predictions are biased towards the centre of the circle.

Using a single underlying feature the model learns both the x and y coordinate as output.
```python
import numpy as np
import matplotlib.pyplot as plt
from sklearn.ensemble import RandomForestRegressor
from sklearn.model_selection import train_test_split
from sklearn.multioutput import MultiOutputRegressor

# Create a random dataset
rng = np.random.RandomState(1)
X = np.sort(200 * rng.rand(600, 1) - 100, axis=0)
y = np.array([np.pi * np.sin(X).ravel(), np.pi * np.cos(X).ravel()]).T
y += (0.5 - rng.rand(*y.shape))
X_train, X_test, y_train, y_test = train_test_split(X, y, train_size=400, test_size=200, random_state=4)
max_depth = 30
regr_multirf = MultiOutputRegressor(RandomForestRegressor(n_estimators=100,
max_depth=max_depth,
(continues on next page)```
regr_multirf.fit(X_train, y_train)

regr_rf = RandomForestRegressor(n_estimators=100, max_depth=max_depth,
                               random_state=2)
regr_rf.fit(X_train, y_train)

# Predict on new data
y_multirf = regr_multirf.predict(X_test)
y_rf = regr_rf.predict(X_test)

# Plot the results
plt.figure()
s = 50
a = 0.4
plt.scatter(y_test[:, 0], y_test[:, 1], edgecolor='k',
            c="navy", s=s, marker="s", alpha=a, label="Data")
plt.scatter(y_multirf[:, 0], y_multirf[:, 1], edgecolor='k',
            c="cornflowerblue", s=s, alpha=a,
            label="Multi RF score=\%.2f" % regr_multirf.score(X_test, y_test))
plt.scatter(y_rf[:, 0], y_rf[:, 1], edgecolor='k',
            c="c", s=s, marker="^", alpha=a,
            label="RF score=\%.2f" % regr_rf.score(X_test, y_test))
plt.xlim([-6, 6])
plt.ylim([-6, 6])
plt.xlabel("target 1")
plt.ylabel("target 2")
plt.title("Comparing random forests and the multi-output meta estimator")
plt.legend()
plt.show()

6.12.9 Prediction Intervals for Gradient Boosting Regression

This example shows how quantile regression can be used to create prediction intervals.
import numpy as np
import matplotlib.pyplot as plt

from sklearn.ensemble import GradientBoostingRegressor
np.random.seed(1)

def f(x):
    """The function to predict."""
    return x * np.sin(x)

# First the noiseless case
X = np.atleast_2d(np.random.uniform(0, 10.0, size=100)).T
X = X.astype(np.float32)

# Observations
y = f(X).ravel()

dy = 1.5 + 1.0 * np.random.random(y.shape)
n = np.random.normal(0, dy)
y += noise
y = y.astype(np.float32)

#----------------------------------------------------------------------

# The example is taken from
# https://github.com/scikit-learn/scikit-learn/blob/master
# /sklearn/ensemble/_gradient_boosting.py
Mesh the input space for evaluations of the real function, the prediction and its MSE

```python
xx = np.at least_2d(np.linspace(0, 10, 1000)).T
xx = xx.astype(np.float32)
alpha = 0.95

clf = GradientBoostingRegressor(loss='quantile', alpha=alpha,
                                 n_estimators=250, max_depth=3,
                                 learning_rate=.1, min_samples_leaf=9,
                                 min_samples_split=9)

clf.fit(X, y)

# Make the prediction on the meshed x-axis
y_upper = clf.predict(xx)

clf.set_params(alpha=1.0 - alpha)
clf.fit(X, y)

# Make the prediction on the meshed x-axis
y_lower = clf.predict(xx)

clf.set_params(loss='ls')
clf.fit(X, y)

# Make the prediction on the meshed x-axis
y_pred = clf.predict(xx)

# Plot the function, the prediction and the 95% confidence interval based on the MSE
fig = plt.figure()
plt.plot(xx, f(xx), 'g:', label=r'$f(x) = x\cdot\sin(x)$')
plt.plot(X, y, 'b.', markersize=10, label=u'Observations')
plt.plot(xx, y_pred, 'r-', label=u'Prediction')
plt.plot(xx, y_upper, 'k-')
plt.plot(xx, y_lower, 'k-')
plt.fill(np.concatenate([xx, xx[::-1]]),
         np.concatenate([y_upper, y_lower[::-1]]),
         alpha=.5, fc='b', ec='None', label='95% prediction interval')
plt.xlabel('$x$')
plt.ylabel('$f(x)$')
plt.ylim(-10, 20)
plt.legend(loc='upper left')
plt.show()
```

**Total running time of the script:** (0 minutes 0.784 seconds)
6.12.10 Gradient Boosting regularization

Illustration of the effect of different regularization strategies for Gradient Boosting. The example is taken from Hastie et al 2009.¹

The loss function used is binomial deviance. Regularization via shrinkage (learning_rate < 1.0) improves performance considerably. In combination with shrinkage, stochastic gradient boosting (subsample < 1.0) can produce more accurate models by reducing the variance via bagging. Subsampling without shrinkage usually does poorly. Another strategy to reduce the variance is by subsampling the features analogous to the random splits in Random Forests (via the max_features parameter).

6.12.12 Gradient Boosting regression

This example demonstrates Gradient Boosting to produce a predictive model from an ensemble of weak predictive models. Gradient boosting can be used for regression and classification problems. Here, we will train a model to tackle a diabetes regression task. We will obtain the results from `GradientBoostingRegressor` with least squares loss and 500 regression trees of depth 4.

Note: For larger datasets (n_samples >= 10000), please refer to `HistGradientBoostingRegressor`.

```python
print(__doc__)

# Author: Peter Prettenhofer <peter.prettenhofer@gmail.com>
# Maria Telenczuk <https://github.com/maikia>
# Katrina Ni <https://github.com/nilichen>
#
# License: BSD 3 clause

import matplotlib.pyplot as plt
import numpy as np
from sklearn import datasets, ensemble
from sklearn.inspection import permutation_importance
from sklearn.metrics import mean_squared_error
from sklearn.model_selection import train_test_split

# Load the data

First we need to load the data.

diabetes = datasets.load_diabetes()
X, y = diabetes.data, diabetes.target

# Data preprocessing

Next, we will split our dataset to use 90% for training and leave the rest for testing. We will also set the regression model parameters. You can play with these parameters to see how the results change.

```
n_estimators : the number of boosting stages that will be performed. Later, we will plot deviance against boosting iterations.
max_depth : limits the number of nodes in the tree. The best value depends on the interaction of the input variables.
min_samples_split : the minimum number of samples required to split an internal node.
learning_rate : how much the contribution of each tree will shrink.
loss : loss function to optimize. The least squares function is used in this case however, there are many other options (see `GradientBoostingRegressor`).
```

```python
X_train, X_test, y_train, y_test = train_test_split(
    X, y, test_size=0.1, random_state=13)

params = {'n_estimators': 500,
          'max_depth': 4,
          'min_samples_split': 5,
          'learning_rate': 0.01,
          'loss': 'ls'}
```
Fit regression model

Now we will initiate the gradient boosting regressors and fit it with our training data. Let’s also look and the mean squared error on the test data.

```python
reg = ensemble.GradientBoostingRegressor(**params)
reg.fit(X_train, y_train)

mse = mean_squared_error(y_test, reg.predict(X_test))
print("The mean squared error (MSE) on test set: {:.4f}"
      .format(mse))
```

Out:

```
The mean squared error (MSE) on test set: 3017.9419
```

Plot training deviance

Finally, we will visualize the results. To do that we will first compute the test set deviance and then plot it against boosting iterations.

```python
test_score = np.zeros((params['n_estimators'],), dtype=np.float64)
for i, y_pred in enumerate(reg.staged_predict(X_test)):
    test_score[i] = reg.loss_(y_test, y_pred)

fig = plt.figure(figsize=(6, 6))
plt.subplot(1, 1, 1)
plt.title('Deviance')
plt.plot(np.arange(params['n_estimators']) + 1, reg.train_score_, 'b-',
         label='Training Set Deviance')
plt.plot(np.arange(params['n_estimators']) + 1, test_score, 'r-',
         label='Test Set Deviance')
plt.legend(loc='upper right')
plt.xlabel('Boosting Iterations')
plt.ylabel('Deviance')
fig.tight_layout()
plt.show()
```
Plot feature importance

Careful, impurity-based feature importances can be misleading for high cardinality features (many unique values). As an alternative, the permutation importances of `reg` can be computed on a held out test set. See *Permutation feature importance* for more details.

For this example, the impurity-based and permutation methods identify the same 2 strongly predictive features but not in the same order. The third most predictive feature, “bp”, is also the same for the 2 methods. The remaining features are less predictive and the error bars of the permutation plot show that they overlap with 0.

```python
feature_importance = reg.feature_importances_
sorted_idx = np.argsort(feature_importance)
pos = np.arange(sorted_idx.shape[0]) + .5
fig = plt.figure(figsize=(12, 6))
plt.subplot(1, 2, 1)
plt.barh(pos, feature_importance[sorted_idx], align='center')
```
Total running time of the script: ( 0 minutes 1.811 seconds)

6.12.13 OOB Errors for Random Forests

The RandomForestClassifier is trained using bootstrap aggregation, where each new tree is fit from a bootstrap sample of the training observations $z_i = (x_i, y_i)$. The out-of-bag (OOB) error is the average error for each $z_i$ calculated using predictions from the trees that do not contain $z_i$ in their respective bootstrap sample. This allows the RandomForestClassifier to be fit and validated whilst being trained\(^1\).

The example below demonstrates how the OOB error can be measured at the addition of each new tree during training. The resulting plot allows a practitioner to approximate a suitable value of n_estimators at which the error stabilizes.

import matplotlib.pyplot as plt
from collections import OrderedDict
from sklearn.datasets import make_classification
from sklearn.ensemble import RandomForestClassifier

6.12.14 Two-class AdaBoost

This example fits an AdaBoosted decision stump on a non-linearly separable classification dataset composed of two “Gaussian quantiles” clusters (see `sklearn.datasets.make_gaussian_quantiles`) and plots the decision boundary and decision scores. The distributions of decision scores are shown separately for samples of class A and B. The predicted class label for each sample is determined by the sign of the decision score. Samples with decision scores greater than zero are classified as B, and are otherwise classified as A. The magnitude of a decision score determines the degree of likeness with the predicted class label. Additionally, a new dataset could be constructed containing a desired purity of class B, for example, by only selecting samples with a decision score above some value.

6.12.15 Hashing feature transformation using Totally Random Trees

RandomTreesEmbedding provides a way to map data to a very high-dimensional, sparse representation, which might be beneficial for classification. The mapping is completely unsupervised and very efficient.

This example visualizes the partitions given by several trees and shows how the transformation can also be used for non-linear dimensionality reduction or non-linear classification.

Points that are neighboring often share the same leaf of a tree and therefore share large parts of their hashed representation. This allows to separate two concentric circles simply based on the principal components of the transformed data with truncated SVD.

In high-dimensional spaces, linear classifiers often achieve excellent accuracy. For sparse binary data, BernoulliNB is particularly well-suited. The bottom row compares the decision boundary obtained by BernoulliNB in the transformed space with an ExtraTreesClassifier forests learned on the original data.

6.12.16 Multi-class AdaBoosted Decision Trees

This example reproduces Figure 1 of Zhu et al¹ and shows how boosting can improve prediction accuracy on a multi-class problem. The classification dataset is constructed by taking a ten-dimensional standard normal distribution and defining three classes separated by nested concentric ten-dimensional spheres such that roughly equal numbers of samples are in each class (quantiles of the $\chi^2$ distribution).

The performance of the SAMME and SAMME.R¹ algorithms are compared. SAMME.R uses the probability estimates to update the additive model, while SAMME uses the classifications only. As the example illustrates, the SAMME.R algorithm typically converges faster than SAMME, achieving a lower test error with fewer boosting iterations. The error of each algorithm on the test set after each boosting iteration is shown on the left, the classification error on the test set of each tree is shown in the middle, and the boost weight of each tree is shown on the right. All trees have a weight of one in the SAMME.R algorithm and therefore are not shown.

6.12.17 Discrete versus Real AdaBoost

This example is based on Figure 10.2 from Hastie et al 2009¹ and illustrates the difference in performance between the discrete SAMME² boosting algorithm and real SAMME.R boosting algorithm. Both algorithms are evaluated on a binary classification task where the target Y is a non-linear function of 10 input features.

Discrete SAMME AdaBoost adapts based on errors in predicted class labels whereas real SAMME.R uses the predicted class probabilities.

6.12.18 Early stopping of Gradient Boosting

Gradient boosting is an ensembling technique where several weak learners (regression trees) are combined to yield a powerful single model, in an iterative fashion.

Early stopping support in Gradient Boosting enables us to find the least number of iterations which is sufficient to build a model that generalizes well to unseen data.

The concept of early stopping is simple. We specify a validation_fraction which denotes the fraction of the whole dataset that will be kept aside from training to assess the validation loss of the model. The gradient boosting model is trained using the training set and evaluated using the validation set. When each additional stage of regression tree is added, the validation set is used to score the model. This is continued until the scores of the model in the last n_iter_no_change stages do not improve by at least tol. After that the model is considered to have converged and further addition of stages is “stopped early”.

The number of stages of the final model is available at the attribute n_estimators_.

This example illustrates how the early stopping can be used in the GradientBoostingClassifier model to achieve almost the same accuracy as compared to a model built without early stopping using many fewer estimators. This can significantly reduce training time, memory usage and prediction latency.

6.12.19 Feature transformations with ensembles of trees

Transform your features into a higher dimensional, sparse space. Then train a linear model on these features.

First fit an ensemble of trees (totally random trees, a random forest, or gradient boosted trees) on the training set. Then each leaf of each tree in the ensemble is assigned a fixed arbitrary feature index in a new feature space. These leaf indices are then encoded in a one-hot fashion.

Each sample goes through the decisions of each tree of the ensemble and ends up in one leaf per tree. The sample is encoded by setting feature values for these leaves to 1 and the other feature values to 0.

The resulting transformer has then learned a supervised, sparse, high-dimensional categorical embedding of the data.

6.12.20 Gradient Boosting Out-of-Bag estimates

Out-of-bag (OOB) estimates can be a useful heuristic to estimate the “optimal” number of boosting iterations. OOB estimates are almost identical to cross-validation estimates but they can be computed on-the-fly without the need for repeated model fitting. OOB estimates are only available for Stochastic Gradient Boosting (i.e. subsample < 1.0), the estimates are derived from the improvement in loss based on the examples not included in the bootstrap sample (the so-called out-of-bag examples). The OOB estimator is a pessimistic estimator of the true test loss, but remains a fairly good approximation for a small number of trees.

The figure shows the cumulative sum of the negative OOB improvements as a function of the boosting iteration. As you can see, it tracks the test loss for the first hundred iterations but then diverges in a pessimistic way. The figure also shows the performance of 3-fold cross validation which usually gives a better estimate of the test loss but is computationally more demanding.

6.12.21 Single estimator versus bagging: bias-variance decomposition

This example illustrates and compares the bias-variance decomposition of the expected mean squared error of a single estimator against a bagging ensemble.

In regression, the expected mean squared error of an estimator can be decomposed in terms of bias, variance and noise. On average over datasets of the regression problem, the bias term measures the average amount by which the predictions of the estimator differ from the predictions of the best possible estimator for the problem (i.e., the Bayes model). The variance term measures the variability of the predictions of the estimator when fit over different instances of the problem. Finally, the noise measures the irreducible part of the error which is due to the variability in the data.

The upper left figure illustrates the predictions (in dark red) of a single decision tree trained over a random dataset of a toy 1d regression problem. It also illustrates the predictions (in light red) of other single decision trees trained over other (and different) randomly drawn instances of the problem. Intuitively, the variance term...
here corresponds to the width of the beam of predictions (in light red) of the individual estimators. The larger the variance, the more sensitive are the predictions for $x$ to small changes in the training set. The bias term corresponds to the difference between the average prediction of the estimator (in cyan) and the best possible model (in dark blue). On this problem, we can thus observe that the bias is quite low (both the cyan and the blue curves are close to each other) while the variance is large (the red beam is rather wide).

The lower left figure plots the pointwise decomposition of the expected mean squared error of a single decision tree. It confirms that the bias term (in blue) is low while the variance is large (in green). It also illustrates the noise part of the error which, as expected, appears to be constant and around 0.01.

The right figures correspond to the same plots but using instead a bagging ensemble of decision trees. In both figures, we can observe that the bias term is larger than in the previous case. In the upper right figure, the difference between the average prediction (in cyan) and the best possible model is larger (e.g., notice the offset around $x=2$). In the lower right figure, the bias curve is also slightly higher than in the lower left figure. In terms of variance however, the beam of predictions is narrower, which suggests that the variance is lower. Indeed, as the lower right figure confirms, the variance term (in green) is lower than for single decision trees. Overall, the bias-variance decomposition is therefore no longer the same. The tradeoff is better for bagging: averaging several decision trees fit on bootstrap copies of the dataset slightly increases the bias term but allows for a larger reduction of the variance, which results in a lower overall mean squared error (compare the red curves int the lower figures). The script output also confirms this intuition. The total error of the bagging ensemble is lower than the total error of a single decision tree, and this difference indeed mainly stems from a reduced variance.

For further details on bias-variance decomposition, see section 7.3 of the Elements of Statistical Learning.

6.12.22 Plot the decision surfaces of ensembles of trees on the iris dataset

Plot the decision surfaces of forests of randomized trees trained on pairs of features of the iris dataset.

This plot compares the decision surfaces learned by a decision tree classifier (first column), by a random forest classifier (second column), by an extra-trees classifier (third column) and by an AdaBoost classifier (fourth column).

In the first row, the classifiers are built using the sepal width and the sepal length features only, on the second row using the petal length and sepal length only, and on the third row using the petal width and the petal length only.

In descending order of quality, when trained (outside of this example) on all 4 features using 30 estimators and scored using 10 fold cross validation, we see:

<table>
<thead>
<tr>
<th>Model</th>
<th>Score</th>
</tr>
</thead>
<tbody>
<tr>
<td>ExtraTreesClassifier()</td>
<td>0.95</td>
</tr>
<tr>
<td>RandomForestClassifier()</td>
<td>0.94</td>
</tr>
<tr>
<td>AdaBoost(DecisionTree(max_depth=3))</td>
<td>0.94</td>
</tr>
<tr>
<td>DecisionTree(max_depth=None)</td>
<td>0.94</td>
</tr>
</tbody>
</table>

Increasing max_depth for AdaBoost lowers the standard deviation of the scores (but the average score does not improve).

See the console’s output for further details about each model.

In this example you might try to:

1) vary the max_depth for the DecisionTreeClassifier and AdaBoostClassifier, perhaps try max_depth=3 for the DecisionTreeClassifier or max_depth=None for AdaBoostClassifier

2) vary n_estimators

It is worth noting that RandomForests and ExtraTrees can be fitted in parallel on many cores as each tree is built independently of the others. AdaBoost’s samples are built sequentially and so do not use multiple cores.
Classifiers on feature subsets of the Iris dataset

Out:

DecisionTree with features [0, 1] has a score of 0.9266666666666666
RandomForest with 30 estimators with features [0, 1] has a score of 0.9266666666666666

6.12.23 Combine predictors using stacking

Stacking refers to a method to blend estimators. In this strategy, some estimators are individually fitted on some training data while a final estimator is trained using the stacked predictions of these base estimators.

In this example, we illustrate the use case in which different regressors are stacked together and a final linear penalized regressor is used to output the prediction. We compare the performance of each individual regressor with the stacking strategy. Stacking slightly improves the overall performance.

Download the dataset

We will use Ames Housing dataset which was first compiled by Dean De Cock and became better known after it was used in Kaggle challenge. It is a set of 1460 residential homes in Ames, Iowa, each described by 80 features. We will use it to predict the final logarithmic price of the houses. In this example we will use only 20 most interesting features chosen using GradientBoostingRegressor() and limit number of entries (here we won’t go into the details on how to select the most interesting features).

The Ames housing dataset is not shipped with scikit-learn and therefore we will fetch it from OpenML.

```
import numpy as np
from sklearn.datasets import fetch_openml
from sklearn.utils import shuffle
def load_ames_housing():
    df = fetch_openml(name="house_prices", as_frame=True)
    X = df.data
    y = df.target

X, y = load_ames_housing()
```

6.12. Ensemble methods
Make pipeline to preprocess the data

Before we can use Ames dataset we still need to do some preprocessing. First, the dataset has many missing values. To impute them, we will exchange categorical missing values with the new category ‘missing’ while the numerical missing values with the ‘mean’ of the column. We will also encode the categories with either `sklearn.preprocessing.OneHotEncoder` or `sklearn.preprocessing.OrdinalEncoder` depending for which type of model we will use them (linear or non-linear model).

To facilitate this preprocessing we will make two pipelines. You can skip this section if your data is ready to use and does not need preprocessing.

```python
from sklearn.compose import make_column_transformer
from sklearn.impute import SimpleImputer
from sklearn.pipeline import make_pipeline
from sklearn.preprocessing import OneHotEncoder
from sklearn.preprocessing import OrdinalEncoder
from sklearn.preprocessing import StandardScaler

cat_cols = X.columns[X.dtypes == 'O']
num_cols = X.columns[X.dtypes == 'float64']

categories = [
    X[column].unique() for column in X[cat_cols]]

for cat in categories:
    cat[cat == None] = 'missing'  # noqa

cat_proc_nlin = make_pipeline(
    SimpleImputer(missing_values=None, strategy='constant',
                  fill_value='missing'),
    OrdinalEncoder(categories=categories)
)

num_proc_nlin = make_pipeline(SimpleImputer(strategy='mean'))

cat_proc_lin = make_pipeline(
    SimpleImputer(missing_values=None,
                  strategy='constant',
                  fill_value='missing'),
    OneHotEncoder(categories=categories)
)

num_proc_lin = make_pipeline(
    SimpleImputer(strategy='mean'),
    StandardScaler()  
)

# transformation to use for non-linear estimators
processor_nlin = make_column_transformer(
    (cat_proc_nlin, cat_cols),
    (num_proc_nlin, num_cols),
    remainder='passthrough')

# transformation to use for linear estimators
processor_lin = make_column_transformer(
    (cat_proc_lin, cat_cols),
    (num_proc_lin, num_cols),
    remainder='passthrough')
```
**Stack of predictors on a single data set**

It is sometimes tedious to find the model which will best perform on a given dataset. Stacking provide an alternative by combining the outputs of several learners, without the need to choose a model specifically. The performance of stacking is usually close to the best model and sometimes it can outperform the prediction performance of each individual model.

Here, we combine 3 learners (linear and non-linear) and use a ridge regressor to combine their outputs together.

Note: although we will make new pipelines with the processors which we wrote in the previous section for the 3 learners, the final estimator RidgeCV() does not need preprocessing of the data as it will be fed with the already preprocessed output from the 3 learners.

```python
from sklearn.experimental import enable_hist_gradient_boosting
from sklearn.ensemble import HistGradientBoostingRegressor
from sklearn.ensemble import RandomForestRegressor
from sklearn.ensemble import StackingRegressor
from sklearn.linear_model import LassoCV
from sklearn.linear_model import RidgeCV

lasso_pipeline = make_pipeline(processor_lin, LassoCV())
rf_pipeline = make_pipeline(processor_nlin, RandomForestRegressor(random_state=42))
gradient_pipeline = make_pipeline(processor_nlin, HistGradientBoostingRegressor(random_state=0))
estimators = [('Random Forest', rf_pipeline), ('Lasso', lasso_pipeline), ('Gradient Boosting', gradient_pipeline)]
stacking_regressor = StackingRegressor(estimators=estimators, final_estimator=RidgeCV())
```

**Measure and plot the results**

Now we can use Ames Housing dataset to make the predictions. We check the performance of each individual predictor as well as of the stack of the regressors.

The function `plot_regression_results` is used to plot the predicted and true targets.

```python
import time
import matplotlib.pyplot as plt
from sklearn.model_selection import cross_validate, cross_val_predict

def plot_regression_results(ax, y_true, y_pred, title, scores, elapsed_time):
    """Scatter plot of the predicted vs true targets.""
    ax.plot([y_true.min(), y_true.max()], [y_true.min(), y_true.max()], '--r', linewidth=2)
    ax.scatter(y_true, y_pred, alpha=0.2)
```

(continues on next page)
...continued from previous page...

```python
ax.spines['top'].set_visible(False)
ax.spines['right'].set_visible(False)
ax.get_xaxis().tick_bottom()
ax.get_yaxis().tick_left()
ax.spines['left'].set_position(('outward', 10))
ax.spines['bottom'].set_position(('outward', 10))
ax.set_xlim([y_true.min(), y_true.max()])
ax.set_ylim([y_true.min(), y_true.max()])
ax.set_xlabel('Measured')
ax.set_ylabel('Predicted')
extra = plt.Rectangle((0, 0), 0, 0, fc="w", fill=False,
edgecolor='none', linewidth=0)
ax.legend([extra], [scores], loc='upper left')
title = title + '
Evaluation in {:.2f} seconds'.format(elapsed_time)
ax.set_title(title)
```

def plot_regression_results(ax, y, y_pred, name, title):
    r\$R^2=(:.2f) \pm (.2f)$ = $\n$ + r\$MAE=(:.2f) \pm (.2f)$
    .format(np.mean(score['test_r2']),
    np.std(score['test_r2']),
    -np.mean(score['test_neg_mean_absolute_error']),
    np.std(score['test_neg_mean_absolute_error'])))
elapsed_time)

fig, axs = plt.subplots(2, 2, figsize=(9, 7))
axs = np.ravel(axs)
for ax, (name, est) in zip(axs, estimators + [('Stacking Regressor',
    stacking_regressor)]):
    start_time = time.time()
    score = cross_validate(est, X, y,
        scoring=['r2', 'neg_mean_absolute_error'],
        n_jobs=-1, verbose=0)
    elapsed_time = time.time() - start_time
    y_pred = cross_val_predict(est, X, y, n_jobs=-1, verbose=0)
    plot_regression_results(
      ax, y, y_pred,
      name,
      (r\$R^2=(:.2f) \pm (.2f)$ + 
        r\$MAE=(:.2f) \pm (.2f)$')
    .format(np.mean(score['test_r2']),
    np.std(score['test_r2']),
    -np.mean(score['test_neg_mean_absolute_error']),
    np.std(score['test_neg_mean_absolute_error'])))
elapsed_time)

plt.suptitle('Single predictors versus stacked predictors')
plt.tight_layout()
plt.subplots_adjust(top=0.9)
plt.show()
The stacked regressor will combine the strengths of the different regressors. However, we also see that training the stacked regressor is much more computationally expensive.

**Total running time of the script:** (0 minutes 9.517 seconds)

### 6.13 Examples based on real world datasets

Applications to real world problems with some medium sized datasets or interactive user interface.

#### 6.13.1 Outlier detection on a real data set

This example illustrates the need for robust covariance estimation on a real data set. It is useful both for outlier detection and for a better understanding of the data structure.

We selected two sets of two variables from the Boston housing data set as an illustration of what kind of analysis can be done with several outlier detection tools. For the purpose of visualization, we are working with two-dimensional examples, but one should be aware that things are not so trivial in high-dimension, as it will be pointed out.

In both examples below, the main result is that the empirical covariance estimate, as a non-robust one, is highly influenced by the heterogeneous structure of the observations. Although the robust covariance estimate is able to focus on the main mode of the data distribution, it sticks to the assumption that the data should be Gaussian distributed, yielding some biased estimation of the data structure, but yet accurate to some extent. The One-Class SVM does not
assume any parametric form of the data distribution and can therefore model the complex shape of the data much better.

**First example**

The first example illustrates how the Minimum Covariance Determinant robust estimator can help concentrate on a relevant cluster when outlying points exist. Here the empirical covariance estimation is skewed by points outside of the main cluster. Of course, some screening tools would have pointed out the presence of two clusters (Support Vector Machines, Gaussian Mixture Models, univariate outlier detection, ...). But had it been a high-dimensional example, none of these could be applied that easily.

```python
print(__doc__)

# Author: Virgile Fritsch <virgile.fritsch@inria.fr>

import numpy as np
from sklearn.covariance import EllipticEnvelope
from sklearn.svm import OneClassSVM
import matplotlib.pyplot as plt
import matplotlib.font_manager
from sklearn.datasets import load_wine

# Define "classifiers" to be used
classifiers = {
    "Empirical Covariance": EllipticEnvelope(support_fraction=1., contamination=0.25),
    "Robust Covariance (Minimum Covariance Determinant)": EllipticEnvelope(contamination=0.25),
    "OCSVM": OneClassSVM(nu=0.25, gamma=0.35)
}
colors = ["m", "g", "b"]
legend1 = {}
legend2 = {}

# Get data
X1 = load_wine(['data'][:, [1, 2]])  # two clusters

# Learn a frontier for outlier detection with several classifiers
xx1, yy1 = np.meshgrid(np.linspace(0, 6, 500), np.linspace(1, 4.5, 500))
for i, (clf_name, clf) in enumerate(classifiers.items()):
    plt.figure(i)
    clf.fit(X1)
    Z1 = clf.decision_function(np.c_[xx1.ravel(), yy1.ravel()])
    Z1 = Z1.reshape(xx1.shape)
    legend1[clf_name] = plt.contour(xx1, yy1, Z1, levels=[0], linewidths=2, colors=colors[i])

legend1_values_list = list(legend1.values())
legend1_keys_list = list(legend1.keys())

# Plot the results (= shape of the data points cloud)
plt.figure()  # two clusters
plt.title("Outlier detection on a real data set (wine recognition)"")
plt.scatter(X1[:, 0], X1[:, 1], color='black')
bbox_args = dict(boxstyle="round", fc="0.8")
arrow_args = dict(arrowstyle="->")
```

(continues on next page)
plt.annotate("outlying points", xy=(4, 2),
    xycoords="data", textcoords="data",
    xytext=(3, 1.25), bbox=bbox_args, arrowprops=arrow_args)
plt.xlim((xx1.min(), xx1.max()))
plt.ylim((yy1.min(), yy1.max()))
plt.legend((legend1_values_list[0].collections[0],
    legend1_values_list[1].collections[0],
    legend1_values_list[2].collections[0]),
    (legend1_keys_list[0], legend1_keys_list[1], legend1_keys_list[2]),
    loc="upper center",
    prop=matplotlib.font_manager.FontProperties(size=11))
plt.ylabel("ash")
plt.xlabel("malic_acid")

plt.show()
Second example

The second example shows the ability of the Minimum Covariance Determinant robust estimator of covariance to concentrate on the main mode of the data distribution: the location seems to be well estimated, although the covariance is hard to estimate due to the banana-shaped distribution. Anyway, we can get rid of some outlying observations. The One-Class SVM is able to capture the real data structure, but the difficulty is to adjust its kernel bandwidth parameter so as to obtain a good compromise between the shape of the data scatter matrix and the risk of over-fitting the data.

```python
# Get data
X2 = load_wine()['data'][[:, [6, 9]]] # "banana"-shaped

# Learn a frontier for outlier detection with several classifiers
xx2, yy2 = np.meshgrid(np.linspace(-1, 5.5, 500), np.linspace(-2.5, 19, 500))
for i, (clf_name, clf) in enumerate(classifiers.items()):
    plt.figure(2)
    clf.fit(X2)
    Z2 = clf.decision_function(np.c_[xx2.ravel(), yy2.ravel()])
    Z2 = Z2.reshape(xx2.shape)
    legend2[clf_name] = plt.contour(
        xx2, yy2, Z2, levels=[0], linewidths=2, colors=colors[i])

legend2_values_list = list(legend2.values())
legend2_keys_list = list(legend2.keys())

# Plot the results (= shape of the data points cloud)
plt.figure(2) # "banana" shape
plt.title("Outlier detection on a real data set (wine recognition)")
plt.scatter(X2[:, [0], X2[:, [1], color='black']
plt.xlim((xx2.min(), xx2.max()))
plt.ylim((yy2.min(), yy2.max()))
plt.legend((legend2_values_list[0].collections[0],
            legend2_values_list[1].collections[0],
            legend2_values_list[2].collections[0]),
            (legend2_keys_list[0], legend2_keys_list[1], legend2_keys_list[2]),
            loc="upper center",
            prop=matplotlib.font_manager.FontProperties(size=11))
plt.ylabel("color_intensity")
plt.xlabel("flavanoids")
plt.show()
```
6.13.2 Compressive sensing: tomography reconstruction with L1 prior (Lasso)

This example shows the reconstruction of an image from a set of parallel projections, acquired along different angles. Such a dataset is acquired in computed tomography (CT).

Without any prior information on the sample, the number of projections required to reconstruct the image is of the order of the linear size $l$ of the image (in pixels). For simplicity we consider here a sparse image, where only pixels on the boundary of objects have a non-zero value. Such data could correspond for example to a cellular material. Note however that most images are sparse in a different basis, such as the Haar wavelets. Only $l/7$ projections are acquired, therefore it is necessary to use prior information available on the sample (its sparsity): this is an example of compressive sensing.

The tomography projection operation is a linear transformation. In addition to the data-fidelity term corresponding to a linear regression, we penalize the L1 norm of the image to account for its sparsity. The resulting optimization problem is called the Lasso. We use the class Lasso, that uses the coordinate descent algorithm. Importantly, this implementation is more computationally efficient on a sparse matrix, than the projection operator used here.

The reconstruction with L1 penalization gives a result with zero error (all pixels are successfully labeled with 0 or 1), even if noise was added to the projections. In comparison, an L2 penalization (Ridge) produces a large number of labeling errors for the pixels. Important artifacts are observed on the reconstructed image, contrary to the L1 penalization. Note in particular the circular artifact separating the pixels in the corners, that have contributed to fewer projections than the central disk.

6.13.3 Topic extraction with Non-negative Matrix Factorization and Latent Dirichlet Allocation

This is an example of applying NMF and LatentDirichletAllocation on a corpus of documents and extract additive models of the topic structure of the corpus. The output is a plot of topics, each represented as bar plot using top few words based on weights.

Non-negative Matrix Factorization is applied with two different objective functions: the Frobenius norm, and the generalized Kullback-Leibler divergence. The latter is equivalent to Probabilistic Latent Semantic Indexing.

The default parameters (n_samples / n_features / n_components) should make the example runnable in a couple of tens of seconds. You can try to increase the dimensions of the problem, but be aware that the time complexity is polynomial in NMF. In LDA, the time complexity is proportional to (n_samples * iterations).

6.13.5 Model Complexity Influence

Demonstrate how model complexity influences both prediction accuracy and computational performance.

We will be using two datasets:

- *Diabetes dataset* for regression. This dataset consists of 10 measurements taken from diabetes patients. The task is to predict disease progression;
- *The 20 newsgroups text dataset* for classification. This dataset consists of newsgroup posts. The task is to predict on which topic (out of 20 topics) the post is written about.

We will model the complexity influence on three different estimators:

- *SGDClassifier* (for classification data) which implements stochastic gradient descent learning;
- *NuSVR* (for regression data) which implements Nu support vector regression;
- *GradientBoostingRegressor* (for regression data) which builds an additive model in a forward stage-wise fashion.

We make the model complexity vary through the choice of relevant model parameters in each of our selected models. Next, we will measure the influence on both computational performance (latency) and predictive power (MSE or Hamming Loss).

```python
print(__doc__)

# Authors: Eustache Diemert <eustache@diemert.fr>
# Maria Telenczuk <https://github.com/maikia>
# Guillaume Lemaitre <g.lemaitre58@gmail.com>
# License: BSD 3 clause

import time
import numpy as np
import matplotlib.pyplot as plt
from sklearn import datasets
from sklearn.utils import shuffle
from sklearn.metrics import mean_squared_error
from sklearn.svm import NuSVR
from sklearn.ensemble import GradientBoostingRegressor
from sklearn.linear_model import SGDClassifier
from sklearn.metrics import hamming_loss

# Initialize random generator
np.random.seed(0)

Load the data

First we load both datasets.

**Note:** We are using *fetch_20newsgroups_vectorized* to download 20 newsgroups dataset. It returns ready-to-use features.

**Note:** X of the 20 newsgroups dataset is a sparse matrix while X of diabetes dataset is a numpy array.
def generate_data(case):
    """Generate regression/classification data."""
    if case == 'regression':
        X, y = datasets.load_diabetes(return_X_y=True)
    elif case == 'classification':
        X, y = datasets.fetch_20newsgroups_vectorized(subset='all',
                                                    return_X_y=True)
    X, y = shuffle(X, y)
    offset = int(X.shape[0] * 0.8)
    X_train, y_train = X[:offset], y[:offset]
    X_test, y_test = X[offset:], y[offset:]
    data = {'X_train': X_train, 'X_test': X_test, 'y_train': y_train,
            'y_test': y_test}
    return data

regression_data = generate_data('regression')
classification_data = generate_data('classification')

Benchmark influence

Next, we can calculate the influence of the parameters on the given estimator. In each round, we will set the estimator with the new value of changing_param and we will be collecting the prediction times, prediction performance and complexities to see how those changes affect the estimator. We will calculate the complexity using complexity_computer passed as a parameter.

def benchmark_influence(conf):
    """Benchmark influence of `changing_param` on both MSE and latency. """
    prediction_times = []
    prediction_powers = []
    complexities = []
    for param_value in conf['changing_param_values']:
        conf['tuned_params'] = conf['changing_param'] = param_value
        estimator = conf['estimator'](**conf['tuned_params'])
        print("Benchmarking \$s\ " % estimator)
        estimator.fit(conf['data']['X_train'], conf['y_train'])
        conf['postfit_hook'](estimator)
        complexity = conf['complexity_computer'](estimator)
        complexities.append(complexity)
        start_time = time.time()
        for _ in range(conf['n_samples']):
            y_pred = estimator.predict(conf['data']['X_test'])
            elapsed_time = (time.time() - start_time) / float(conf['n_samples'])
            prediction_times.append(elapsed_time)
            pred_score = conf['prediction_performance_computer'](
                            conf['data']['y_test'], y_pred)
            prediction_powers.append(pred_score)
        print("Complexity: \$d \ | \$s: %.4f \ | Pred. Time: %s\n" % (complexity,
                                                                 conf['prediction_performance_label'],
                                                                 pred_score,
                                                                 elapsed_time))
    return prediction_powers, prediction_times, complexities

1027  6.13. Examples based on real world datasets
Choose parameters

We choose the parameters for each of our estimators by making a dictionary with all the necessary values. `changing_param` is the name of the parameter which will vary in each estimator. Complexity will be defined by the `complexity_label` and calculated using `complexity_computer`. Also note that depending on the estimator type we are passing different data.

```python
def _count_nonzero_coefficients(estimator):
    a = estimator.coef_.toarray()
    return np.count_nonzero(a)
```

```python
configurations = [
    {'estimator': SGDClassifier,
     'tuned_params': {'penalty': 'elasticnet', 'alpha': 0.001, 'loss':
                     'modified_huber', 'fit_intercept': True, 'tol': 1e-3},
     'changing_param': 'l1_ratio',
     'changing_param_values': [0.25, 0.5, 0.75, 0.9],
     'complexity_label': 'non_zero coefficients',
     'complexity_computer': _count_nonzero_coefficients,
     'prediction_performance_computer': hamming_loss,
     'prediction_performance_label': 'Hamming Loss (Misclassification Ratio)',
     'postfit_hook': lambda x: x.sparsify(),
     'data': classification_data,
     'n_samples': 30},
    {'estimator': NuSVR,
     'tuned_params': {'C': 1e3, 'gamma': 2 ** -15},
     'changing_param': 'nu',
     'changing_param_values': [0.1, 0.25, 0.5, 0.75, 0.9],
     'complexity_label': 'n_support_vectors',
     'complexity_computer': lambda x: len(x.support_vectors_),
     'data': regression_data,
     'postfit_hook': lambda x: x,
     'prediction_performance_computer': mean_squared_error,
     'prediction_performance_label': 'MSE',
     'n_samples': 30},
    {'estimator': GradientBoostingRegressor,
     'tuned_params': {'loss': 'ls'},
     'changing_param': 'n_estimators',
     'changing_param_values': [10, 50, 100, 200, 500],
     'complexity_label': 'n_trees',
     'complexity_computer': lambda x: x.n_estimators,
     'data': regression_data,
     'postfit_hook': lambda x: x,
     'prediction_performance_computer': mean_squared_error,
     'prediction_performance_label': 'MSE',
     'n_samples': 30},
]
```
Run the code and plot the results

We defined all the functions required to run our benchmark. Now, we will loop over the different configurations that we defined previously. Subsequently, we can analyze the plots obtained from the benchmark: Relaxing the $L_1$ penalty in the SGD classifier reduces the prediction error but leads to an increase in the training time. We can draw a similar analysis regarding the training time which increases with the number of support vectors with a Nu-SVR. However, we observed that there is an optimal number of support vectors which reduces the prediction error. Indeed, too few support vectors lead to an under-fitted model while too many support vectors lead to an over-fitted model. The exact same conclusion can be drawn for the gradient-boosting model. The only difference with the Nu-SVR is that having too many trees in the ensemble is not as detrimental.

```python
def plot_influence(conf, mse_values, prediction_times, complexities):
    
    """
    Plot influence of model complexity on both accuracy and latency.
    """

    fig = plt.figure()
    fig.subplots_adjust(right=0.75)

    # first axes (prediction error)
    ax1 = fig.add_subplot(111)
    line1 = ax1.plot(complexities, mse_values, c='tab:blue', ls='--')[0]
    ax1.set_xlabel('Model Complexity (%s)' % conf['complexity_label'])
    y1_label = conf['prediction_performance_label']
    ax1.set_ylabel(y1_label)
    ax1.spines['left'].set_color(line1.get_color())
    ax1.yaxis.label.set_color(line1.get_color())
    ax1.tick_params(axis='y', colors=line1.get_color())

    # second axes (latency)
    ax2 = fig.add_subplot(111, sharex=ax1, frameon=False)
    line2 = ax2.plot(complexities, prediction_times, c='tab:orange', ls='-')[0]
    ax2.yaxis.tick_right()
    ax2.yaxis.set_label_position("right")
    y2_label = "Time (s)"
    ax2.set_ylabel(y2_label)
    ax2.spines['right'].set_color(line2.get_color())
    ax2.yaxis.label.set_color(line2.get_color())
    ax2.tick_params(axis='y', colors=line2.get_color())

    plt.legend((line1, line2), ("prediction error", "latency"),
               loc='upper right')

    plt.title("Influence of varying '%s' on %s" % (conf['changing_param'],
                                                   conf['estimator'].__name__))

Conclusion

As a conclusion, we can deduce the following insights:

- a model which is more complex (or expressive) will require a larger training time;
- a more complex model does not guarantee to reduce the prediction error.

These aspects are related to model generalization and avoiding model under-fitting or over-fitting.

Total running time of the script: (0 minutes 17.187 seconds)

6.13.6 Visualizing the stock market structure

This example employs several unsupervised learning techniques to extract the stock market structure from variations in historical quotes.

The quantity that we use is the daily variation in quote price: quotes that are linked tend to cofluctuate during a day.

Learning a graph structure

We use sparse inverse covariance estimation to find which quotes are correlated conditionally on the others. Specifically, sparse inverse covariance gives us a graph, that is a list of connection. For each symbol, the symbols that it is connected too are those useful to explain its fluctuations.
Clustering

We use clustering to group together quotes that behave similarly. Here, amongst the various clustering techniques available in the scikit-learn, we use Affinity Propagation as it does not enforce equal-size clusters, and it can choose automatically the number of clusters from the data.

Note that this gives us a different indication than the graph, as the graph reflects conditional relations between variables, while the clustering reflects marginal properties: variables clustered together can be considered as having a similar impact at the level of the full stock market.

Embedding in 2D space

For visualization purposes, we need to lay out the different symbols on a 2D canvas. For this we use Manifold learning techniques to retrieve 2D embedding.

Visualization

The output of the 3 models are combined in a 2D graph where nodes represents the stocks and edges the:

- cluster labels are used to define the color of the nodes
- the sparse covariance model is used to display the strength of the edges
- the 2D embedding is used to position the nodes in the plan

This example has a fair amount of visualization-related code, as visualization is crucial here to display the graph. One of the challenge is to position the labels minimizing overlap. For this we use an heuristic based on the direction of the nearest neighbor along each axis.

### 6.13.7 Wikipedia principal eigenvector

A classical way to assert the relative importance of vertices in a graph is to compute the principal eigenvector of the adjacency matrix so as to assign to each vertex the values of the components of the first eigenvector as a centrality score:

https://en.wikipedia.org/wiki/Eigenvector_centrality

On the graph of webpages and links those values are called the PageRank scores by Google.

The goal of this example is to analyze the graph of links inside wikipedia articles to rank articles by relative importance according to this eigenvector centrality.

The traditional way to compute the principal eigenvector is to use the power iteration method:

https://en.wikipedia.org/wiki/Power_iteration

Here the computation is achieved thanks to Martinsson’s Randomized SVD algorithm implemented in scikit-learn.

The graph data is fetched from the DBpedia dumps. DBpedia is an extraction of the latent structured data of the Wikipedia content.

### 6.13.8 Species distribution modeling

Modeling species’ geographic distributions is an important problem in conservation biology. In this example we model the geographic distribution of two South American mammals given past observations and 14 environmental variables. Since we have only positive examples (there are no unsuccessful observations), we cast this problem as a density estimation problem and use the `OneClassSVM` as our modeling tool. The dataset is provided by Phillips et. al (2006). If available, the example uses `basemap` to plot the coast lines and national boundaries of South America.

The two species are:

- “Bradypus variegatus”, the Brown-throated Sloth.
- “Microryzomys minutus”, also known as the Forest Small Rice Rat, a rodent that lives in Peru, Colombia, Ecuador, Peru, and Venezuela.

**References**

Modeling distribution of species 'bradypus variegatus'
- fit OneClassSVM ... done.
- plot coastlines from coverage
- predict species distribution

6.13.10 Prediction Latency

This is an example showing the prediction latency of various scikit-learn estimators.

The goal is to measure the latency one can expect when doing predictions either in bulk or atomic (i.e. one by one) mode.

The plots represent the distribution of the prediction latency as a boxplot.
Out:

Benchmarking SGDRegressor(alpha=0.01, l1_ratio=0.25, penalty='elasticnet', tol=0.0001)
Benchmarking RandomForestRegressor()
Benchmarking SVR()
benchmarking with 100 features
benchmarking with 250 features

6.13.11 Out-of-core classification of text documents

This is an example showing how scikit-learn can be used for classification using an out-of-core approach: learning from data that doesn’t fit into main memory. We make use of an online classifier, i.e., one that supports the partial_fit method, that will be fed with batches of examples. To guarantee that the features space remains the same over time we leverage a HashingVectorizer that will project each example into the same feature space. This is especially useful in the case of text classification where new features (words) may appear in each batch.

```python

Plot results

The plot represents the learning curve of the classifier: the evolution of classification accuracy over the course of the mini-batches. Accuracy is measured on the first 1000 samples, held out as a validation set.

To limit the memory consumption, we queue examples up to a fixed amount before feeding them to the learner.

```python
def plot_accuracy(x, y, x_legend):
    """Plot accuracy as a function of x.""
    x = np.array(x)
    y = np.array(y)
    plt.title('Classification accuracy as a function of %s' % x_legend)
    plt.xlabel('x_label
    plt.ylabel('Accuracy')
    plt.grid(True)
    plt.plot(x, y)
```

```python
rcParams['legend.fontsize'] = 10

scikit-learn user guide, Release 0.24.dev0

6.14.2 Comparison of F-test and mutual information
This example illustrates the differences between univariate F-test statistics and mutual information.
We consider 3 features x_1, x_2, x_3 distributed uniformly over [0, 1], the target depends on them as follows:
y = x_1 + sin(6 * pi * x_2) + 0.1 * N(0, 1), that is the third features is completely irrelevant.
The code below plots the dependency of y against individual x_i and normalized values of univariate F-tests statistics
and mutual information.
As F-test captures only linear dependency, it rates x_1 as the most discriminative feature. On the other hand, mutual
information can capture any kind of dependency between variables and it rates x_2 as the most discriminative feature,
which probably agrees better with our intuitive perception for this example. Both methods correctly marks x_3 as
irrelevant.

print(__doc__)
import numpy as np
import matplotlib.pyplot as plt
from sklearn.feature_selection import f_regression, mutual_info_regression
np.random.seed(0)
X = np.random.rand(1000, 3)
y = X[:, 0] + np.sin(6 * np.pi * X[:, 1]) + 0.1 * np.random.randn(1000)
f_test, _ = f_regression(X, y)
f_test /= np.max(f_test)
mi = mutual_info_regression(X, y)
mi /= np.max(mi)
plt.figure(figsize=(15, 5))
for i in range(3):

## 6.14.4 Recursive feature elimination with cross-validation

A recursive feature elimination example with automatic tuning of the number of features selected with cross-validation.

Out:

```
Optimal number of features : 3
```
# Build a classification task using 3 informative features
X, y = make_classification(n_samples=1000, n_features=25, n_informative=3,
    n_redundant=2, n_repeated=0, n_classes=8,
    n_clusters_per_class=1, random_state=0)

# Create the RFE object and compute a cross-validated score.
svc = SVC(kernel="linear")
# The "accuracy" scoring is proportional to the number of correct
# classifications
min_features_to_select = 1  # Minimum number of features to consider
rfecv = RFECV(estimator=svc, step=1, cv=StratifiedKFold(2),
    scoring='accuracy',
    min_features_to_select=min_features_to_select)
rfecv.fit(X, y)
print("Optimal number of features : %d" % rfecv.n_features_)

# Plot number of features VS. cross-validation scores
plt.figure()
plt.xlabel("Number of features selected")
plt.ylabel("Cross validation score (nb of correct classifications)"

plt.plot(range(min_features_to_select,
    len(rfecv.grid_scores_) + min_features_to_select),
    rfecv.grid_scores_)
plt.show()

Total running time of the script: ( 0 minutes 2.273 seconds)

## 6.14.5 Model-based and sequential feature selection

This example illustrates and compares two approaches for feature selection: SelectFromModel which is based on feature importance, and SequentialFeatureSelection which relies on a greedy approach.

We use the Diabetes dataset, which consists of 10 features collected from 442 diabetes patients.

Authors: Manoj Kumar, Maria Telenczuk, Nicolas Hug.

License: BSD 3 clause
Loading the data

We first load the diabetes dataset which is available from within scikit-learn, and print its description:

```
from sklearn.datasets import load_diabetes
diabetes = load_diabetes()
X, y = diabetes.data, diabetes.target
print(diabetes.DESCR)
```

Out:

```
Diabetes dataset

Ten baseline variables, age, sex, body mass index, average blood pressure, and six blood serum measurements were obtained for each of n = 442 diabetes patients, as well as the response of interest, a quantitative measure of disease progression one year after baseline.

**Data Set Characteristics:**

- Number of Instances: 442
- Number of Attributes: First 10 columns are numeric predictive values
- Target: Column 11 is a quantitative measure of disease progression one year after baseline

**Attribute Information:**

- age  age in years
- sex
- bmi  body mass index
- bp  average blood pressure
- sl  tc, T-Cells (a type of white blood cells)
- s2  ld1, low-density lipoproteins
- s3  hdl, high-density lipoproteins
- s4  tch, thyroid stimulating hormone
- s5  ltg, lamotrigine
- s6  glu, blood sugar level

Note: Each of these 10 feature variables have been mean centered and scaled by the standard deviation times \( \sqrt{n_{\text{samples}}} \) (i.e. the sum of squares of each column totals 1).

Source URL:
https://www4.stat.ncsu.edu/~boos/var.select/diabetes.html

For more information see:
Feature importance from coefficients

To get an idea of the importance of the features, we are going to use the `LassoCV` estimator. The features with the highest absolute `coef_` value are considered the most important. We can observe the coefficients directly without needing to scale them (or scale the data) because from the description above, we know that the features were already standardized. For a more complete example on the interpretations of the coefficients of linear models, you may refer to Common pitfalls in interpretation of coefficients of linear models.

```python
import matplotlib.pyplot as plt
import numpy as np
from sklearn.linear_model import LassoCV

lasso = LassoCV().fit(X, y)
importance = np.abs(lasso.coef_)
feature_names = np.array(diabetes.feature_names)
plt.bar(height=importance, x=feature_names)
plt.title("Feature importances via coefficients")
plt.show()
```

![Feature importances via coefficients](image_url)
Selecting features based on importance

Now we want to select the two features which are the most important according to the coefficients. The `SelectFromModel` is meant just for that. `SelectFromModel` accepts a threshold parameter and will select the features whose importance (defined by the coefficients) are above this threshold.

Since we want to select only 2 features, we will set this threshold slightly above the coefficient of third most important feature.

```python
from sklearn.feature_selection import SelectFromModel
from time import time

threshold = np.sort(importance)[-3] + 0.01
tic = time()
sfm = SelectFromModel(lasso, threshold=threshold).fit(X, y)
toc = time()
print("Features selected by SelectFromModel: ",
      f"{feature_names[sfm.get_support()]}")
print(f"Done in {toc - tic:.3f}s")
```

Out:

```
Features selected by SelectFromModel: ['s1' 's5']
Done in 0.045s
```

Selecting features with Sequential Feature Selection

Another way of selecting features is to use `SequentialFeatureSelector` (SFS). SFS is a greedy procedure where, at each iteration, we choose the best new feature to add to our selected features based a cross-validation score. That is, we start with 0 features and choose the best single feature with the highest score. The procedure is repeated until we reach the desired number of selected features.

We can also go in the reverse direction (backward SFS), i.e. start with all the features and greedily choose features to remove one by one. We illustrate both approaches here.

```python
from sklearn.feature_selection import SequentialFeatureSelector

tic_fwd = time()
sfs_forward = SequentialFeatureSelector(lasso, n_features_to_select=2,
                                       direction='forward').fit(X, y)
toc_fwd = time()

 tic_bwd = time()
sfs_backward = SequentialFeatureSelector(lasso, n_features_to_select=2,
                                        direction='backward').fit(X, y)
toc_bwd = time()

print("Features selected by forward sequential selection: ",
      f"{feature_names[sfs_forward.get_support()]}")
print(f"Done in {toc_fwd - tic_fwd:.3f}s")
print("Features selected by backward sequential selection: ",
      f"{feature_names[sfs_backward.get_support()]}")
print(f"Done in {toc_bwd - tic_bwd:.3f}s")
```

Out:
Features selected by forward sequential selection: ['bmi' 's5']
Done in 3.415s
Features selected by backward sequential selection: ['bmi' 's5']
Done in 10.538s

Discussion

Interestingly, forward and backward selection have selected the same set of features. In general, this isn’t the case and the two methods would lead to different results.

We also note that the features selected by SFS differ from those selected by feature importance: SFS selects bmi instead of s1. This does sound reasonable though, since bmi corresponds to the third most important feature according to the coefficients. It is quite remarkable considering that SFS makes no use of the coefficients at all.

To finish with, we should note that SelectFromModel is significantly faster than SFS. Indeed, SelectFromModel only needs to fit a model once, while SFS needs to cross-validate many different models for each of the iterations. SFS however works with any model, while SelectFromModel requires the underlying estimator to expose a coef_ attribute or a feature_importances_ attribute. The forward SFS is faster than the backward SFS because it only needs to perform n_features_to_select = 2 iterations, while the backward SFS needs to perform n_features - n_features_to_select = 8 iterations.

Total running time of the script: (0 minutes 14.138 seconds)

6.14.6 Test with permutations the significance of a classification score

This example demonstrates the use of permutation_test_score to evaluate the significance of a cross-validated score using permutations.

```python
# Authors: Alexandre Gramfort <alexandre.gramfort@inria.fr>
# Lucy Liu
# License: BSD 3 clause
#
# Dataset
#
# We will use the :ref:`iris_dataset`, which consists of measurements taken
# from 3 types of irises.
from sklearn.datasets import load_iris
iris = load_iris()
X = iris.data
y = iris.target

We will also generate some random feature data (i.e., 2200 features), uncorrelated with the class labels in the iris dataset.

```python
import numpy as np
n_uncorrelated_features = 2200
rng = np.random.RandomState(seed=0)
# Use same number of samples as in iris and 2200 features
X_rand = rng.normal(size=(X.shape[0], n_uncorrelated_features))
```
**Permutation test score**

Next, we calculate the `permutation_test_score` using the original iris dataset, which strongly predict the labels and the randomly generated features and iris labels, which should have no dependency between features and labels. We use the `SVC` classifier and `Accuracy score` to evaluate the model at each round.

`permutation_test_score` generates a null distribution by calculating the accuracy of the classifier on 1000 different permutations of the dataset, where features remain the same but labels undergo different permutations. This is the distribution for the null hypothesis which states there is no dependency between the features and labels. An empirical p-value is then calculated as the percentage of permutations for which the score obtained is greater that the score obtained using the original data.

```python
from sklearn.svm import SVC
from sklearn.model_selection import StratifiedKFold
from sklearn.model_selection import permutation_test_score

clf = SVC(kernel='linear', random_state=7)
cv = StratifiedKFold(2, shuffle=True, random_state=0)

score_iris, perm_scores_iris, pvalue_iris = permutation_test_score(
    clff, X, y, scoring="accuracy", cv=cv, n_permutations=1000)

score_rand, perm_scores_rand, pvalue_rand = permutation_test_score(
    clff, X_rand, y, scoring="accuracy", cv=cv, n_permutations=1000)
```

**Original data**

Below we plot a histogram of the permutation scores (the null distribution). The red line indicates the score obtained by the classifier on the original data. The score is much better than those obtained by using permuted data and the p-value is thus very low. This indicates that there is a low likelihood that this good score would be obtained by chance alone. It provides evidence that the iris dataset contains real dependency between features and labels and the classifier was able to utilize this to obtain good results.

```python
import matplotlib.pyplot as plt

fig, ax = plt.subplots()

ax.hist(perm_scores_iris, bins=20, density=True)
ax.axvline(score_iris, ls='--', color='r')
score_label = (f"Score on original
    data: {score_iris:.2f}
    (p-value: {pvalue_iris:.3f})")
ax.text(0.7, 250, score_label, fontsize=12)
ax.set_xlabel("Accuracy score")
_ = ax.set_ylabel("Probability")
```
Random data

Below we plot the null distribution for the randomized data. The permutation scores are similar to those obtained using the original iris dataset because the permutation always destroys any feature label dependency present. The score obtained on the original randomized data in this case though, is very poor. This results in a large p-value, confirming that there was no feature label dependency in the original data.

```python
fig, ax = plt.subplots()
ax.hist(perm_scores_rand, bins=20, density=True)
ax.set_xlim(0.13)
anx.axvline(score_rand, ls='--', color='r')
score_label = (f"Score on original data: {score_rand:.2f}\n(p-value: {pvalue_rand:.3f})")
anx.text(0.14, 125, score_label, fontsize=12)
anx.set_xlabel("Accuracy score")
anx.set_ylabel("Probability")
plt.show()
```
Another possible reason for obtaining a high p-value is that the classifier was not able to use the structure in the data. In this case, the p-value would only be low for classifiers that are able to utilize the dependency present. In our case above, where the data is random, all classifiers would have a high p-value as there is no structure present in the data. Finally, note that this test has been shown to produce low p-values even if there is only weak structure in the data\(^1\).

### 6.14.7 Univariate Feature Selection

An example showing univariate feature selection.

Noisy (non informative) features are added to the iris data and univariate feature selection is applied. For each feature, we plot the p-values for the univariate feature selection and the corresponding weights of an SVM. We can see that univariate feature selection selects the informative features and that these have larger SVM weights.

In the total set of features, only the 4 first ones are significant. We can see that they have the highest score with univariate feature selection. The SVM assigns a large weight to one of these features, but also Selects many of the non-informative features. Applying univariate feature selection before the SVM increases the SVM weight attributed to the significant features, and will thus improve classification.

---

Out:

Classification accuracy without selecting features: 0.789
Classification accuracy after univariate feature selection: 0.868

```
import numpy as np
import matplotlib.pyplot as plt
from sklearn.datasets import load_iris
from sklearn.model_selection import train_test_split
from sklearn.preprocessing import MinMaxScaler
from sklearn.svm import LinearSVC
from sklearn.pipeline import make_pipeline
from sklearn.feature_selection import SelectKBest, f_classif

# Import some data to play with
```
The iris dataset

```python
X, y = load_iris(return_X_y=True)
```

Some noisy data not correlated

```python
E = np.random.RandomState(42).uniform(0, 0.1, size=(X.shape[0], 20))
```

Add the noisy data to the informative features

```python
X = np.hstack((X, E))
```

Split dataset to select feature and evaluate the classifier

```python
X_train, X_test, y_train, y_test = train_test_split(X, y, stratify=y, random_state=0)
```

```python
plt.figure(1)
plt.clf()
X_indices = np.arange(X.shape[-1])

# Univariate feature selection with F-test for feature scoring
# We use the default selection function to select the four most significant features
selector = SelectKBest(f_classif, k=4)
selector.fit(X_train, y_train)
scores = -np.log10(selector.pvalues_)
scores /= scores.max()
plt.bar(X_indices - .45, scores, width=.2,
       label=r'Univariate score ($-Log(p_{value})$)')

# Compare to the weights of an SVM
clf = make_pipeline(MinMaxScaler(), LinearSVC())
clf.fit(X_train, y_train)
print('Classification accuracy without selecting features: {:.3f}'.format(clf.score(X_test, y_test)))
svm_weights = np.abs(clf[-1].coef_).sum(axis=0)
svm_weights /= svm_weights.sum()
plt.bar(X_indices - .25, svm_weights, width=.2, label='SVM weight')

clf_selected = make_pipeline(SelectKBest(f_classif, k=4), MinMaxScaler(), LinearSVC())
clf_selected.fit(X_train, y_train)
print('Classification accuracy after univariate feature selection: {:.3f}'.format(clf_selected.score(X_test, y_test)))
svm_weights_selected = np.abs(clf_selected[-1].coef_).sum(axis=0)
svm_weights_selected /= svm_weights_selected.sum()
plt.bar(X_indices[selector.get_support()] - .05, svm_weights_selected, width=.2, label='SVM weights after selection')

plt.title("Comparing feature selection")
```
6.15 Gaussian Mixture Models

Examples concerning the `sklearn.mixture` module.

6.15.1 Density Estimation for a Gaussian mixture

Plot the density estimation of a mixture of two Gaussians. Data is generated from two Gaussians with different centers and covariance matrices.
```python
import numpy as np
import matplotlib.pyplot as plt
from matplotlib.colors import LogNorm
from sklearn import mixture

n_samples = 300

# generate random sample, two components
np.random.seed(0)

# generate spherical data centered on (20, 20)
shifted_gaussian = np.random.randn(n_samples, 2) + np.array([20, 20])

# generate zero centered stretched Gaussian data
C = np.array([[0., -0.7], [3.5, .7]])
stretched_gaussian = np.dot(np.random.randn(n_samples, 2), C)

# concatenate the two datasets into the final training set
X_train = np.vstack((shifted_gaussian, stretched_gaussian))

# fit a Gaussian Mixture Model with two components
clf = mixture.GaussianMixture(n_components=2, covariance_type='full')
clf.fit(X_train)

# display predicted scores by the model as a contour plot
x = np.linspace(-20., 30.)
y = np.linspace(-20., 40.)
X, Y = np.meshgrid(x, y)
XX = np.array([[X.ravel(), Y.ravel()]]).T
Z = -clf.score_samples(XX)
Z = Z.reshape(X.shape)
CS = plt.contour(X, Y, Z, norm=LogNorm(vmin=1.0, vmax=1000.0),
                 levels=np.logspace(0, 3, 10))
CB = plt.colorbar(CS, shrink=0.8, extend='both')
plt.scatter(X_train[:, 0], X_train[:, 1], .8)
plt.title('Negative log-likelihood predicted by a GMM')
plt.axis('tight')
plt.show()
```

Total running time of the script: (0 minutes 0.194 seconds)
6.15.2 Gaussian Mixture Model Ellipsoids

Plot the confidence ellipsoids of a mixture of two Gaussians obtained with Expectation Maximisation (GaussianMixture class) and Variational Inference (BayesianGaussianMixture class models with a Dirichlet process prior).

Both models have access to five components with which to fit the data. Note that the Expectation Maximisation model will necessarily use all five components while the Variational Inference model will effectively only use as many as are needed for a good fit. Here we can see that the Expectation Maximisation model splits some components arbitrarily, because it is trying to fit too many components, while the Dirichlet Process model adapts its number of states automatically.

This example doesn’t show it, as we’re in a low-dimensional space, but another advantage of the Dirichlet process model is that it can fit full covariance matrices effectively even when there are less examples per cluster than there are dimensions in the data, due to regularization properties of the inference algorithm.

```python
import itertools
import numpy as np
from scipy import linalg
import matplotlib.pyplot as plt
import matplotlib as mpl
from sklearn import mixture
```

(continues on next page)
```python
color_iter = itertools.cycle(['navy', 'c', 'cornflowerblue', 'gold', 'darkorange'])

def plot_results(X, Y_, means, covariances, index, title):
splot = plt.subplot(2, 1, 1 + index)
    for i, (mean, covar, color) in enumerate(zip(means, covariances, color_iter):
        v, w = linalg.eigh(covar)
        v = 2. * np.sqrt(2.) * np.sqrt(v)
        u = w[0] / linalg.norm(w[0])
        # as the DP will not use every component it has access to
        # unless it needs it, we shouldn't plot the redundant
        # components.
        if not np.any(Y_ == i):
            continue
        plt.scatter(X[Y_ == i, 0], X[Y_ == i, 1], .8, color=color)
        # Plot an ellipse to show the Gaussian component
        angle = np.arctan(u[1] / u[0])
        angle = 180. * angle / np.pi  # convert to degrees
        ell = mpl.patches.Ellipse(mean, v[0], v[1], 180. + angle, color=color)
        ell.set_clip_box(splot.bbox)
        ell.set_alpha(0.5)
        splot.add_artist(ell)
    plt.xlim(-9., 5.)
    plt.ylim(-3., 6.)
    plt.xticks(())
    plt.yticks(())
    plt.title(title)

# Number of samples per component
n_samples = 500

# Generate random sample, two components
np.random.seed(0)
C = np.array([[0., -0.1], [1.7, .4]])
X = np.r_[np.dot(np.random.randn(n_samples, 2), C),
         .7 * np.random.randn(n_samples, 2) + np.array([-6, 3])]

# Fit a Gaussian mixture with EM using five components
gmm = mixture.GaussianMixture(n_components=5, covariance_type='full').fit(X)
plot_results(X, gmm.predict(X), gmm.means_, gmm.covariances_, 0,
             'Gaussian Mixture')

# Fit a Dirichlet process Gaussian mixture using five components
dpgmm = mixture.BayesianGaussianMixture(n_components=5,
                                         covariance_type='full').fit(X)
plot_results(X, dpgmm.predict(X), dpgmm.means_, dpgmm.covariances_, 1,
             'Bayesian Gaussian Mixture with a Dirichlet process prior')

plt.show()
```

**Total running time of the script:** (0 minutes 0.204 seconds)
6.15.3 Gaussian Mixture Model Selection

This example shows that model selection can be performed with Gaussian Mixture Models using information-theoretic criteria (BIC). Model selection concerns both the covariance type and the number of components in the model. In that case, AIC also provides the right result (not shown to save time), but BIC is better suited if the problem is to identify the right model. Unlike Bayesian procedures, such inferences are prior-free.

In that case, the model with 2 components and full covariance (which corresponds to the true generative model) is selected.

```
import numpy as np
import itertools
from scipy import linalg
import matplotlib.pyplot as plt
import matplotlib as mpl
from sklearn import mixture
print(__doc__)

# Number of samples per component
n_samples = 500

# Generate random sample, two components
```
np.random.seed(0)
C = np.array([[0., -0.1], [1.7, .4]])
X = np.r_[np.dot(np.random.randn(n_samples, 2), C),
         .7 * np.random.randn(n_samples, 2) + np.array([-6, 3])]

### 6.15.4 GMM covariances

Demonstration of several covariances types for Gaussian mixture models.

See Gaussian mixture models for more information on the estimator.

Although GMM are often used for clustering, we can compare the obtained clusters with the actual classes from the dataset. We initialize the means of the Gaussians with the means of the classes from the training set to make this comparison valid.

We plot predicted labels on both training and held out test data using a variety of GMM covariance types on the iris dataset. We compare GMMs with spherical, diagonal, full, and tied covariance matrices in increasing order of performance. Although one would expect full covariance to perform best in general, it is prone to overfitting on small datasets and does not generalize well to held out test data.

On the plots, train data is shown as dots, while test data is shown as crosses. The iris dataset is four-dimensional. Only the first two dimensions are shown here, and thus some points are separated in other dimensions.

### 6.15.5 Gaussian Mixture Model Sine Curve

This example demonstrates the behavior of Gaussian mixture models fit on data that was not sampled from a mixture of Gaussian random variables. The dataset is formed by 100 points loosely spaced following a noisy sine curve. There is therefore no ground truth value for the number of Gaussian components.

The first model is a classical Gaussian Mixture Model with 10 components fit with the Expectation-Maximization algorithm.

The second model is a Bayesian Gaussian Mixture Model with a Dirichlet process prior fit with variational inference. The low value of the concentration prior makes the model favor a lower number of active components. This models “decides” to focus its modeling power on the big picture of the structure of the dataset: groups of points with alternating directions modeled by non-diagonal covariance matrices. Those alternating directions roughly capture the alternating nature of the original sine signal.

The third model is also a Bayesian Gaussian mixture model with a Dirichlet process prior but this time the value of the concentration prior is higher giving the model more liberty to model the fine-grained structure of the data. The result is a mixture with a larger number of active components that is similar to the first model where we arbitrarily decided to fix the number of components to 10.
Which model is the best is a matter of subjective judgment: do we want to favor models that only capture the big picture to summarize and explain most of the structure of the data while ignoring the details or do we prefer models that closely follow the high density regions of the signal?

The last two panels show how we can sample from the last two models. The resulting samples distributions do not look exactly like the original data distribution. The difference primarily stems from the approximation error we made by using a model that assumes that the data was generated by a finite number of Gaussian components instead of a continuous noisy sine curve.

6.15.6 Concentration Prior Type Analysis of Variation Bayesian Gaussian Mixture

This example plots the ellipsoids obtained from a toy dataset (mixture of three Gaussians) fitted by the BayesianGaussianMixture class models with a Dirichlet distribution prior (weight_concentration_prior_type='dirichlet_distribution') and a Dirichlet process prior (weight_concentration_prior_type='dirichlet_process'). On each figure, we plot the results for three different values of the weight concentration prior.

The BayesianGaussianMixture class can adapt its number of mixture components automatically. The parameter weight_concentration_prior has a direct link with the resulting number of components with non-zero weights. Specifying a low value for the concentration prior will make the model put most of the weight on few components set the remaining components weights very close to zero. High values of the concentration prior will allow a larger number of components to be active in the mixture.

The Dirichlet process prior allows to define an infinite number of components and automatically selects the correct number of components: it activates a component only if it is necessary.

On the contrary the classical finite mixture model with a Dirichlet distribution prior will favor more uniformly weighted components and therefore tends to divide natural clusters into unnecessary sub-components.

### 6.16 Gaussian Process for Machine Learning

Examples concerning the `sklearn.gaussian_process` module.

#### 6.16.1 Illustration of Gaussian process classification (GPC) on the XOR dataset

This example illustrates GPC on XOR data. Compared are a stationary, isotropic kernel (RBF) and a non-stationary kernel (DotProduct). On this particular dataset, the DotProduct kernel obtains considerably better results because the class-boundaries are linear and coincide with the coordinate axes. In general, stationary kernels often obtain better results.

6.16.2 Gaussian process classification (GPC) on iris dataset

This example illustrates the predicted probability of GPC for an isotropic and anisotropic RBF kernel on a two-dimensional version for the iris-dataset. The anisotropic RBF kernel obtains slightly higher log-marginal-likelihood by assigning different length-scales to the two feature dimensions.

```python
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt
from sklearn import datasets
from sklearn.gaussian_process import GaussianProcessClassifier
from sklearn.gaussian_process.kernels import RBF

# import some data to play with
iris = datasets.load_iris()
X = iris.data[:, :2]  # we only take the first two features.
y = np.array(iris.target, dtype=int)

h = .02  # step size in the mesh

kernel = 1.0 * RBF([1.0])
gpc_rbf_isotropic = GaussianProcessClassifier(kernel=kernel).fit(X, y)
kernel = 1.0 * RBF([1.0, 1.0])
gpc_rbf_anisotropic = GaussianProcessClassifier(kernel=kernel).fit(X, y)
```

Total running time of the script: ( 0 minutes 0.430 seconds)
Both kernel ridge regression (KRR) and Gaussian process regression (GPR) learn a target function by employing internally the “kernel trick”. KRR learns a linear function in the space induced by the respective kernel which corresponds to a non-linear function in the original space. The linear function in the kernel space is chosen based on the mean-squared error loss with ridge regularization. GPR uses the kernel to define the covariance of a prior distribution over the target functions and uses the observed training data to define a likelihood function. Based on Bayes theorem, a (Gaussian) posterior distribution over target functions is defined, whose mean is used for prediction.

A major difference is that GPR can choose the kernel’s hyperparameters based on gradient-ascent on the marginal likelihood function while KRR needs to perform a grid search on a cross-validated loss function (mean-squared error loss). A further difference is that GPR learns a generative, probabilistic model of the target function and can thus provide meaningful confidence intervals and posterior samples along with the predictions while KRR only provides predictions.

This example illustrates both methods on an artificial dataset, which consists of a sinusoidal target function and strong noise. The figure compares the learned model of KRR and GPR based on an ExpSineSquared kernel, which is suited for learning periodic functions. The kernel’s hyperparameters control the smoothness (l) and periodicity of the kernel.
Moreover, the noise level of the data is learned explicitly by GPR by an additional WhiteKernel component in the kernel and by the regularization parameter alpha of KRR.

The figure shows that both methods learn reasonable models of the target function. GPR correctly identifies the periodicity of the function to be roughly $2\pi$ (6.28), while KRR chooses the doubled periodicity $4\pi$. Besides that, GPR provides reasonable confidence bounds on the prediction which are not available for KRR. A major difference between the two methods is the time required for fitting and predicting: while fitting KRR is fast in principle, the grid-search for hyperparameter optimization scales exponentially with the number of hyperparameters ("curse of dimensionality"). The gradient-based optimization of the parameters in GPR does not suffer from this exponential scaling and is thus considerably faster on this example with 3-dimensional hyperparameter space. The time for predicting is similar; however, generating the variance of the predictive distribution of GPR takes considerable longer than just predicting the mean.

Out:

```

6.16.6 Probabilistic predictions with Gaussian process classification (GPC)

This example illustrates the predicted probability of GPC for an RBF kernel with different choices of the hyperparameters. The first figure shows the predicted probability of GPC with arbitrarily chosen hyperparameters and with the hyperparameters corresponding to the maximum log-marginal-likelihood (LML).

While the hyperparameters chosen by optimizing LML have a considerable larger LML, they perform slightly worse according to the log-loss on test data. The figure shows that this is because they exhibit a steep change of the class probabilities at the class boundaries (which is good) but have predicted probabilities close to 0.5 far away from the class boundaries (which is bad) This undesirable effect is caused by the Laplace approximation used internally by GPC.

The second figure shows the log-marginal-likelihood for different choices of the kernel’s hyperparameters, highlighting the two choices of the hyperparameters used in the first figure by black dots.

### 6.16.7 Gaussian process regression (GPR) with noise-level estimation

This example illustrates that GPR with a sum-kernel including a WhiteKernel can estimate the noise level of data. An illustration of the log-marginal-likelihood (LML) landscape shows that there exist two local maxima of LML. The first corresponds to a model with a high noise level and a large length scale, which explains all variations in the data by noise. The second one has a smaller noise level and shorter length scale, which explains most of the variation by the noise-free functional relationship. The second model has a higher likelihood; however, depending on the initial value for the hyperparameters, the gradient-based optimization might also converge to the high-noise solution. It is thus important to repeat the optimization several times for different initializations.
Initial: $1^{**}2 \times \text{RBF}(\text{length_scale}=100) + \text{WhiteKernel}(\text{noise_level}=1)$
Optimum: $0.00316^{**}2 \times \text{RBF}(\text{length_scale}=109) + \text{WhiteKernel}(\text{noise_level}=1)$
Log-Marginal-Likelihood: -23.87233736198489
Initial: 1**2 * RBF(length_scale=1) + WhiteKernel(noise_level=1e-05)
Optimum: 0.64**2 * RBF(length_scale=0.365) + WhiteKernel(noise_level=0).
Log-Marginal-Likelihood: -21.805090890162035

6.16.8 Gaussian Processes regression: basic introductory example

A simple one-dimensional regression example computed in two different ways:

1. A noise-free case
2. A noisy case with known noise-level per datapoint

In both cases, the kernel’s parameters are estimated using the maximum likelihood principle.

The figures illustrate the interpolating property of the Gaussian Process model as well as its probabilistic nature in the form of a pointwise 95% confidence interval.

Note that the parameter alpha is applied as a Tikhonov regularization of the assumed covariance between the training points.

6.16.9 Gaussian process regression (GPR) on Mauna Loa CO2 data.

This example is based on Section 5.4.3 of “Gaussian Processes for Machine Learning” [RW2006]. It illustrates an example of complex kernel engineering and hyperparameter optimization using gradient ascent on the log-marginal-likelihood. The data consists of the monthly average atmospheric CO2 concentrations (in parts per million by volume (ppmv)) collected at the Mauna Loa Observatory in Hawaii, between 1958 and 2001. The objective is to model the CO2 concentration as a function of the time t.

The kernel is composed of several terms that are responsible for explaining different properties of the signal:

- a long term, smooth rising trend is to be explained by an RBF kernel. The RBF kernel with a large length-scale enforces this component to be smooth; it is not enforced that the trend is rising which leaves this choice to the GP. The specific length-scale and the amplitude are free hyperparameters.

- a seasonal component, which is to be explained by the periodic ExpSineSquared kernel with a fixed periodicity of 1 year. The length-scale of this periodic component, controlling its smoothness, is a free parameter. In order to allow decaying away from exact periodicity, the product with an RBF kernel is taken. The length-scale of this RBF component controls the decay time and is a further free parameter.

- smaller, medium term irregularities are to be explained by a RationalQuadratic kernel component, whose length-scale and alpha parameter, which determines the diffuseness of the length-scales, are to be determined. According to [RW2006], these irregularities can better be explained by a RationalQuadratic than an RBF kernel component, probably because it can accommodate several length-scales.

- a “noise” term, consisting of an RBF kernel contribution, which shall explain the correlated noise components such as local weather phenomena, and a WhiteKernel contribution for the white noise. The relative amplitudes and the RBF's length scale are further free parameters.

Maximizing the log-marginal-likelihood after subtracting the target’s mean yields the following kernel with an LML of -83.214:

```
34.4**2 * RBF(length_scale=41.8)
+ 3.27**2 * RBF(length_scale=180) * ExpSineSquared(length_scale=1.44, periodicity=1)
+ 0.446**2 * RationalQuadratic(alpha=17.7, length_scale=0.957)
+ 0.197**2 * RBF(length_scale=0.138) + WhiteKernel(noise_level=0.0336)
```

Thus, most of the target signal (34.4ppm) is explained by a long-term rising trend (length-scale 41.8 years). The periodic component has an amplitude of 3.27ppm, a decay time of 180 years and a length-scale of 1.44. The long decay time indicates that we have a locally very close to periodic seasonal component. The correlated noise has an amplitude of 0.197ppm with a length scale of 0.138 years and a white-noise contribution of 0.0336ppm. Thus, the overall noise level is very small, indicating that the data can be very well explained by the model. The figure shows also that the model makes very confident predictions until around 2015.

6.16.10 Gaussian processes on discrete data structures

This example illustrates the use of Gaussian processes for regression and classification tasks on data that are not in fixed-length feature vector form. This is achieved through the use of kernel functions that operates directly on discrete structures such as variable-length sequences, trees, and graphs.

Specifically, here the input variables are some gene sequences stored as variable-length strings consisting of letters ‘A’, ‘T’, ‘C’, and ‘G’, while the output variables are floating point numbers and True/False labels in the regression and classification tasks, respectively.

A kernel between the gene sequences is defined using R-convolution\(^1\) by integrating a binary letter-wise kernel over all pairs of letters among a pair of strings.

This example will generate three figures.

In the first figure, we visualize the value of the kernel, i.e. the similarity of the sequences, using a colormap. Brighter color here indicates higher similarity.

In the second figure, we show some regression result on a dataset of 6 sequences. Here we use the 1st, 2nd, 4th, and 5th sequences as the training set to make predictions on the 3rd and 6th sequences.

In the third figure, we demonstrate a classification model by training on 6 sequences and make predictions on another 5 sequences. The ground truth here is simply whether there is at least one ‘A’ in the sequence. Here the model makes four correct classifications and fails on one.

### 6.17.2 Plot Ridge coefficients as a function of the regularization

Shows the effect of collinearity in the coefficients of an estimator.

**Ridge** Regression is the estimator used in this example. Each color represents a different feature of the coefficient vector, and this is displayed as a function of the regularization parameter.

This example also shows the usefulness of applying Ridge regression to highly ill-conditioned matrices. For such matrices, a slight change in the target variable can cause huge variances in the calculated weights. In such cases, it is useful to set a certain regularization (alpha) to reduce this variation (noise).

When alpha is very large, the regularization effect dominates the squared loss function and the coefficients tend to zero. At the end of the path, as alpha tends toward zero and the solution tends towards the ordinary least squares, coefficients exhibit big oscillations. In practise it is necessary to tune alpha in such a way that a balance is maintained between both.

### 6.17.4 SGD: convex loss functions

A plot that compares the various convex loss functions supported by `SGDClassifier`.
```python
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt

def modified_huber_loss(y_true, y_pred):
    z = y_pred * y_true
    loss = -4 * z
    loss[z >= -1] = (1 - z[z >= -1]) ** 2
    loss[z >= 1.] = 0
    return loss

xmin, xmax = -4, 4
xx = np.linspace(xmin, xmax, 100)
lw = 2
plt.plot([xmin, 0, 0, xmax], [1, 1, 0, 0], color='gold', lw=lw,
         label="Zero-one loss")
plt.plot(xx, np.where(xx < 1, 1 - xx, 0), color='teal', lw=lw,
         label="Hinge loss")
plt.plot(xx, -np.minimum(xx, 0), color='yellowgreen', lw=lw,
         label="Perceptron loss")
plt.plot(xx, np.log2(1 + np.exp(-xx)), color='cornflowerblue', lw=lw,
         label="Log loss")
```

(continues on next page)
6.17.5 Ordinary Least Squares and Ridge Regression Variance

Due to the few points in each dimension and the straight line that linear regression uses to follow these points as well as it can, noise on the observations will cause great variance as shown in the first plot. Every line’s slope can vary quite a bit for each prediction due to the noise induced in the observations.

Ridge regression is basically minimizing a penalised version of the least-squared function. The penalising shrinks the value of the regression coefficients. Despite the few data points in each dimension, the slope of the prediction is much more stable and the variance in the line itself is greatly reduced, in comparison to that of the standard linear regression.
import numpy as np
import matplotlib.pyplot as plt

from sklearn import linear_model

    clf.fit(X_train, y_train)
    ax.plot(X_test, clf.predict(X_test), linewidth=2, color='blue')
    ax.scatter(X_train, y_train, s=30, c='red', marker='+', zorder=10)

    ax.set_title(name)
6.17.6 Plot Ridge coefficients as a function of the L2 regularization

Ridge Regression is the estimator used in this example. Each color in the left plot represents one different dimension of the coefficient vector, and this is displayed as a function of the regularization parameter. The right plot shows how exact the solution is. This example illustrates how a well defined solution is found by Ridge regression and how regularization affects the coefficients and their values. The plot on the right shows how the difference of the coefficients from the estimator changes as a function of regularization.

In this example the dependent variable Y is set as a function of the input features: $y = X \ast w + c$. The coefficient vector $w$ is randomly sampled from a normal distribution, whereas the bias term $c$ is set to a constant.

As alpha tends toward zero the coefficients found by Ridge regression stabilize towards the randomly sampled vector $w$. For big alpha (strong regularisation) the coefficients are smaller (eventually converging at 0) leading to a simpler and biased solution. These dependencies can be observed on the left plot.

The right plot shows the mean squared error between the coefficients found by the model and the chosen vector $w$. Less regularised models retrieve the exact coefficients (error is equal to 0), stronger regularised models increase the error.

Please note that in this example the data is non-noisy, hence it is possible to extract the exact coefficients.
clf = Ridge()

X, y, w = make_regression(n_samples=10, n_features=10, coef=True,
                         random_state=1, bias=3.5)

6.17.8 Logistic function

Shown in the plot is how the logistic regression would, in this synthetic dataset, classify values as either 0 or 1, i.e. class one or two, using the logistic curve.
import numpy as np
import matplotlib.pyplot as plt
from sklearn import linear_model
from scipy.special import expit

# General a toy dataset: it's just a straight line with some Gaussian noise:
xmin, xmax = -5, 5
n_samples = 100
np.random.seed(0)
X = np.random.normal(size=n_samples)
y = (X > 0).astype(float)
X[X > 0] *= 4
X += .3 * np.random.normal(size=n_samples)
X = X[:, np.newaxis]

# Fit the classifier
clf = linear_model.LogisticRegression(C=1e5)
clf.fit(X, y)

# and plot the result
plt.figure(1, figsize=(4, 3))
plt.clf()
plt.scatter(X.ravel(), y, color='black', zorder=20)
X_test = np.linspace(-5, 10, 300)
loss = expit(X_test * clf.coef_ + clf.intercept_).ravel()
plt.plot(X_test, loss, color='red', linewidth=3)

ols = linear_model.LinearRegression()
ols.fit(X, y)
plt.plot(X_test, ols.coef_ * X_test + ols.intercept_, linewidth=1)
plt.axhline(.5, color='0.5')
plt.ylabel('y')
plt.xlabel('X')
plt.xticks(range(-5, 10))
plt.yticks([0, 0.5, 1])
plt.ylim(-.25, 1.25)
plt.xlim(-4, 10)
plt.legend(('Logistic Regression Model', 'Linear Regression Model'),
loc="lower right", fontsize='small')
plt.tight_layout()
plt.show()

**Total running time of the script:** ( 0 minutes 0.094 seconds)

### 6.17.9 Polynomial interpolation

This example demonstrates how to approximate a function with a polynomial of degree n_degree by using ridge regression. Concretely, from n_samples 1d points, it suffices to build the Vandermonde matrix, which is n_samples x n_degree+1 and has the following form:

\[
\begin{bmatrix}
1, x_1, x_1 ** 2, x_1 ** 3, \ldots, \\
1, x_2, x_2 ** 2, x_2 ** 3, \ldots
\end{bmatrix}, \ldots
\]

Intuitively, this matrix can be interpreted as a matrix of pseudo features (the points raised to some power). The matrix is akin to (but different from) the matrix induced by a polynomial kernel.

This example shows that you can do non-linear regression with a linear model, using a pipeline to add non-linear features. Kernel methods extend this idea and can induce very high (even infinite) dimensional feature spaces.
def f(x):
    """function to approximate by polynomial interpolation"""
    return x * np.sin(x)

# generate points used to plot
x_plot = np.linspace(0, 10, 100)

# generate points and keep a subset of them
x = np.linspace(0, 10, 100)
rng = np.random.RandomState(0)
rng.shuffle(x)
x = np.sort(x[:20])
y = f(x)

# create matrix versions of these arrays
X = x[:, np.newaxis]
X_plot = x_plot[:, np.newaxis]

colors = ['teal', 'yellowgreen', 'gold']
lw = 2
plt.plot(x_plot, f(x_plot), color='cornflowerblue', linewidth=lw,
        label="ground truth")
plt.scatter(x, y, color='navy', s=30, marker='o', label="training points")

for count, degree in enumerate([3, 4, 5]):
    model = make_pipeline(PolynomialFeatures(degree), Ridge())
    model.fit(X, y)
    y_plot = model.predict(X_plot)
    plt.plot(x_plot, y_plot, color=colors[count], linewidth=lw,
              label="degree %d" % degree)

plt.legend(loc='lower left')
plt.show()

6.17.10 Regularization path of L1- Logistic Regression

Train II-penalized logistic regression models on a binary classification problem derived from the Iris dataset. The models are ordered from strongest regularized to least regularized. The 4 coefficients of the models are collected and plotted as a “regularization path”: on the left-hand side of the figure (strong regularizers), all the coefficients are exactly 0. When regularization gets progressively looser, coefficients can get non-zero values one after the other. Here we choose the liblinear solver because it can efficiently optimize for the Logistic Regression loss with a non-smooth, sparsity inducing II penalty. Also note that we set a low value for the tolerance to make sure that the model has converged before collecting the coefficients. We also use warm_start=True which means that the coefficients of the models are reused to initialize the next model fit to speed-up the computation of the full-path.
Computing regularization path ...

## 6.17.12 SGD: Weighted samples

Plot decision function of a weighted dataset, where the size of points is proportional to its weight.
```python
import numpy as np
import matplotlib.pyplot as plt
from sklearn import linear_model

# we create 20 points
np.random.seed(0)
X = np.r_[np.random.randn(10, 2) + [1, 1], np.random.randn(10, 2)]
y = [1] * 10 + [-1] * 10
sample_weight = 100 * np.abs(np.random.randn(20))
# and assign a bigger weight to the last 10 samples
sample_weight[:10] *= 10

# plot the weighted data points
xx, yy = np.meshgrid(np.linspace(-4, 5, 500), np.linspace(-4, 5, 500))
plt.figure()
plt.scatter(X[:, 0], X[:, 1], c=y, s=sample_weight, alpha=0.9,
cmap=plt.cm.bone, edgecolor='black')

# fit the unweighted model
clf = linear_model.SGDClassifier(alpha=0.01, max_iter=100)
clf.fit(X, y)
Z = clf.decision_function(np.c_[xx.ravel(), yy.ravel()])
Z = Z.reshape(xx.shape)
```

6.17. Generalized Linear Models
### 6.17.13 Non-negative least squares

In this example, we fit a linear model with positive constraints on the regression coefficients and compare the estimated coefficients to a classic linear regression.

```python
print(__doc__)
import numpy as np
import matplotlib.pyplot as plt
from sklearn.metrics import r2_score

Generate some random data

```numpy.random.seed(42)
n_samples, n_features = 200, 50
X = np.random.randn(n_samples, n_features)
true_coef = 3 * np.random.randn(n_features)
# Threshold coefficients to render them non-negative
true_coef[true_coef < 0] = 0
y = np.dot(X, true_coef)
# Add some noise
y += 5 * np.random.normal(size=(n_samples, ))

Split the data in train set and test set

```from sklearn.model_selection import train_test_split
X_train, X_test, y_train, y_test = train_test_split(X, y, test_size=0.5)

Fit the Non-Negative least squares.

```from sklearn.linear_model import LinearRegression
reg_nnls = LinearRegression(positive=True)
y_pred_nnls = reg_nnls.fit(X_train, y_train).predict(X_test)
r2_score_nnls = r2_score(y_test, y_pred_nnls)
print("NNLS R2 score", r2_score_nnls)
```
Out:

NNLS R2 score 0.8225220806196525

Fit an OLS.

```python
reg_ols = LinearRegression()
y_pred_ols = reg_ols.fit(X_train, y_train).predict(X_test)
r2_score_ols = r2_score(y_test, y_pred_ols)
print("OLS R2 score", r2_score_ols)
```

Out:

OLS R2 score 0.7436926291700351

Comparing the regression coefficients between OLS and NNLS, we can observe they are highly correlated (the dashed line is the identity relation), but the non-negative constraint shrinks some to 0. The Non-Negative Least squares inherently yield sparse results.

```python
fig, ax = plt.subplots()
ax.plot(reg_ols.coef_, reg_nnls.coef_, linewidth=0, marker=".")
low_x, high_x = ax.get_xlim()
low_y, high_y = ax.get_ylim()
low = max(low_x, low_y)
high = min(high_x, high_y)
ax.plot([low, high], [low, high], ls="--", c=".3", alpha=.5)
ax.set_xlabel("OLS regression coefficients", fontweight="bold")
ax.set_ylabel("NNLS regression coefficients", fontweight="bold")
```
Out:

Total running time of the script: 0 minutes 0.070 seconds

6.17.14 Linear Regression Example

The example below uses only the first feature of the diabetes dataset, in order to illustrate the data points within the two-dimensional plot. The straight line can be seen in the plot, showing how linear regression attempts to draw a straight line that will best minimize the residual sum of squares between the observed responses in the dataset, and the responses predicted by the linear approximation.

The coefficients, residual sum of squares and the coefficient of determination are also calculated.
Out:

Coefficients:
[938.23786125]
Mean squared error: 2548.07
Coefficient of determination: 0.47

# Load the diabetes dataset

print(__doc__)

# Code source: Jaques Grobler
# License: BSD 3 clause

import matplotlib.pyplot as plt
import numpy as np
from sklearn import datasets, linear_model
from sklearn.metrics import mean_squared_error, r2_score

# Load the diabetes dataset
diabetes_X, diabetes_y = datasets.load_diabetes(return_X_y=True)

# Use only one feature
diabetes_X = diabetes_X[:, np.newaxis, 2]

# Split the data into training/testing sets
diabetes_X_train = diabetes_X[:-20]
diabetes_X_test = diabetes_X[-20:]

# Split the targets into training/testing sets
diabetes_y_train = diabetes_y[:-20]
diabetes_y_test = diabetes_y[-20:]

# Create linear regression object
regr = linear_model.LinearRegression()

# Train the model using the training sets
regr.fit(diabetes_X_train, diabetes_y_train)

# Make predictions using the testing set
diabetes_y_pred = regr.predict(diabetes_X_test)

# The coefficients
print('Coefficients:
', regr.coef_)
# The mean squared error
print('Mean squared error: %.2f
' % mean_squared_error(diabetes_y_test, diabetes_y_pred))
# The coefficient of determination: 1 is perfect prediction
print('Coefficient of determination: %.2f
' % r2_score(diabetes_y_test, diabetes_y_pred))

# Plot outputs
plt.scatter(diabetes_X_test, diabetes_y_test, color='black')
plt.plot(diabetes_X_test, diabetes_y_pred, color='blue', linewidth=3)
plt.xticks(()
plt.yticks()
plt.show()

6.17.15 Robust linear model estimation using RANSAC

In this example we see how to robustly fit a linear model to faulty data using the RANSAC algorithm.
Out:

Estimated coefficients (true, linear regression, RANSAC):
82.1903908407869 [54.17236387] [82.08533159]

```python
import numpy as np
from matplotlib import pyplot as plt
from sklearn import linear_model, datasets

n_samples = 1000
n_outliers = 50

X, y, coef = datasets.make_regression(n_samples=n_samples, n_features=1,
                                   n_informative=1, noise=10,
                                   coef=True, random_state=0)

# Add outlier data
```
np.random.seed(0)
X[:n_outliers] = 3 + 0.5 * np.random.normal(size=(n_outliers, 1))
y[:n_outliers] = -3 + 10 * np.random.normal(size=n_outliers)

# Fit line using all data
lr = linear_model.LinearRegression()
lr.fit(X, y)

# Robustly fit linear model with RANSAC algorithm
ransac = linear_model.RANSACRegressor()
ransac.fit(X, y)
inlier_mask = ransac.inlier_mask_
outlier_mask = np.logical_not(inlier_mask)

# Predict data of estimated models
line_X = np.arange(X.min(), X.max())[:, np.newaxis]
line_y = lr.predict(line_X)
